Cytotoxic responses are characterized by the actions of NK cells and CTLs, which are specialized for killing host cells infected by intracellular pathogens, stressed or damaged host cells, and tumor cells. NK cells can also be armed by IgG antibodies for ADCC, and both NK cells and CTLs produce IFN-γ, which activates macrophages. **Type 1** responses are characterized by the actions of group 1 ILCs (ILC1), T_H1 cells, opsonizing IgG antibody isotypes (for example, IgG1 and IgG2 in mice), and macrophages in response to intracellular pathogens, including intracellular bacteria, viruses, and parasites (see Fig. 11.5). **Type 2** responses are characterized by the actions of group 2 ILCs (ILC2), T_H2 cells, IgE, and the innate effector cells eosinophils, basophils, and tissue mast cells, which are armed for function by IgE bound to surface Fcε receptors. Type 2 responses are primarily induced by, and target, multicellular parasites, or helminths, although some parasitic protozoans also provoke type 2 immunity. **Type 3** responses are characterized by the actions of group 3 ILCs (ILC3), T_H17 cells, opsonizing IgG isotypes, and neutrophils in response to extracellular bacteria and fungi. It is the activation of NK cells and different subsets of ILCs that coordinates the local innate response at the site of pathogen entry prior to the development and recruitment of polarized CTL, T_H1, T_H2, or T_H17 antigen-specific responses induced by type 1 or type 2 conventional dendritic cells (cDC1 or cDC2 cells) in secondary lymphoid tissues. Unlike the effector CD4 T cells with which they share overlapping functional features, ILCs do not require antigenic priming and differentiation in order to acquire their effector functions. Instead, they seed barrier tissues prior to birth and, in mice, expand in number and acquire their full functionality prior to weaning and stably populate their tissue of residence throughout life. Thus, ILCs are able to respond rapidly to amplify the activities of other resident and recruited innate effector cells. However, with few exceptions, ILCs are largely nonmotile; they are bound geographically within barrier tissues and, unlike T cells, must often engage the innate effector cells whose functions they enhance at a distance via the secreted factors they produce. In the next section, we will consider in more detail the induction and actions of ILC subsets, as these responses precede and are integrated with adaptive T- and B-cell responses.

11-3 Subsets of ILCs are early responders of the immune response.

As discussed in Chapter 3, NK cells and ILC1 cells are characterized by their production of IFN-γ in response to IL-12 and IL-18 produced by pathogen-activated dendritic cells and macrophages. However, NK cells differ from ILC1 cells in their developmental origins and in their expression of cytotoxic granules containing perforin and granzymes, analogous to those expressed by CTLs (see Fig. 11.5). Moreover, unlike ILC1 cells, which are abundant in barrier tissues but rare in blood and spleen, NK cells circulate in blood and constitute a substantial fraction of mononuclear cells in the spleen. NK cells are therefore mobile, whereas ILC1 cells are largely stationary in the tissue sites they populate around birth.

The rapid induction of the cytolytic activity of NK cells through the recognition of surface molecules expressed on the target cells by a range of inhibitory and activating receptors (see Section 3-25) enables NK-cell killing of a range of pathogen-infected cells—in advance of the antigen-driven development and deployment of cytolytic CD8 T cells. When armed by IgG bound to their Fc receptors, NK cells can kill targets in an antigen-specific mode despite their lack of expression of antigenic receptors like those expressed by B and T cells. Finally, NK cells play a unique role in the killing of host cells that have lost

expression of MHC class I molecules because of down-regulation by certain viruses; this killing activity occurs via release of activation restraints on the NK cell by inhibitory receptors that recognize MHC class I (see Section 3-25).

In contrast to NK cells, ILC1 cells most closely mirror T_H1 cells. Like T_H1 cells, they lack the cytolytic granules that are characteristic of NK cells and CTLs and appear to participate in the clearance of intracellular pathogens primarily through their activation of infected macrophages by the release of IFN-γ. Thus, through production of IL-12 and IL-18, macrophages and dendritic cells can rapidly induce ILC1 production of IFN-γ, which acts back on macrophages to induce the heightened killing of intracellular pathogens in barrier tissues such as the gastrointestinal (GI) and respiratory tracts several days prior to the development and deployment of T_H1 cells.

ILC2 cells that reside in mucosal tissues are preferentially activated by the cytokines **thymic stromal lymphopoietin (TSLP)**—a STAT5-activating cytokine—and IL-33 and IL-25, all of which are produced in response to helminths. Activation of at least some ILC2 cells, including those in the respiratory tract, is also dependent on **leukotrienes**, which are short-lived, lipid signaling molecules derived from arachidonic acid (eicosanoids). Although details of the contributions of each of these inputs is not completely understood, activation of ILC2 cells appears to differ in different tissues. TSLP and IL-33 are produced by epithelial cells, stromal cells, and macrophages that sense molecular patterns common to helminths, such as chitin, a polysaccharide polymer of β-(1,4)-*N*-acetylglucosamine that is a widespread constituent of helminths and the exoskeletons of insects and of some fungi. IL-33 is an alarmin that is released by cell death, suggesting that an important inducer of the ILC2 response is tissue injury. The principal source of IL-25 is a specialized secretory epithelial cell found in mucosal tissues—the **tuft cell**—which is specialized for chemosensing of molecules produced by type 2 pathogens, including the metabolite **succinate**, as well as a range of tastants and odorants, via G protein–coupled succinate and taste receptors, respectively (see Fig. 11.3; detailed further in Chapter 12). Tuft cells can also produce TSLP and eicosanoids. Activated ILC2 cells rapidly produce large amounts of IL-13 and IL-5; IL-13 stimulates mucus production by goblet cells in the epithelium and mucosal smooth muscle contractions that facilitate worm expulsion—the so-called 'weep-and-sweep' response. IL-13 also stimulates increased differentiation of goblet cells and tuft cells, providing a feed-forward mechanism for amplifying type 2 responses (see Chapter 12). IL-5 stimulates the production and activation of eosinophils that can kill worms. Unlike T_H2 cells, with which they share many functional features, ILC2 cells appear to produce little or no IL-4 in mice, suggesting that expression of IL-4 may impart unique functions to T_H2 cells in inflamed tissues. However, eosinophils and basophils that are recruited by chemokines produced by ILC2 cells are activated to produce IL-4 in response to the IL-5 and IL-13 produced by ILC2 cells, possibly providing an indirect mechanism by which T_H2 differentiation is directed by ILC2 cells. Moreover, IL-13 produced by ILC2 cells appears to regulate the activation and migration to regional lymphoid tissues of dendritic cells that promote T_H2 differentiation, although it is unclear whether these dendritic cells can also produce IL-4.

ILC3 cells play a critical early role in defense against extracellular bacteria and fungi at barrier tissues. Similar to T_H17 cells, ILC3 cells are responsive to IL-23 and IL-1β; these cytokines elicit the production of IL-17 and IL-22, which promote early type 3 responses. IL-17 is a pro-inflammatory cytokine that acts on a variety of cells, including stromal cells, epithelial cells, and myeloid cells, to stimulate the production of other pro-inflammatory cytokines (for example, IL-6, IL-1β), hematopoietic growth factors (G-CSF and GM-CSF), and chemokines that recruit neutrophils and monocytes. IL-17 and IL-22 act on epithelial cells in mucosal tissues and skin to induce their production of antimicrobial peptides (AMPs), and IL-22 promotes enhanced barrier integrity.

As with other ILCs, the cytokines produced by ILC3 cells act indirectly via IL-6 and IL-1β in a positive feedback loop to enhance type 3 responses by increasing local production of IL-23 and IL-1β. Through induction of elevated IL-6, IL-1β, and IL-23, ILC3 cells might also promote the differentiation of T_H17 cells in mucosal lymphoid tissues, although this is unproven.

In a further parallel with effector CD4 T cells, an important feature of helper ILCs is that they activate other innate immune cells to kill or expel microbes, but they do not do so themselves. Instead, myelomonocytic cells, and even cells of barrier epithelia, are the agents of ILCs and effector CD4 T cells; they are recruited and/or activated through the pro-inflammatory cytokines and chemokines that these lymphoid cells produce in response to infection or tissue injury. As we will discuss later, because of their ability to focus effector cytokines on antigen-bearing target cells and to induce B-cell maturation and the production of class-switched antibodies, effector CD4 T cells provide an additional layer of licensing of innate effector cells that increases their lethality and ability to achieve microbial clearance.

Summary.

Integration of the innate and adaptive immune responses is required for effective protection of the host against pathogenic microorganisms. The responses of the innate immune system act early to restrain pathogens during the time required for the adaptive immune response to fully develop. Different types of pathogens cause the activation of different patterns of cytokine production by innate sensor cells. This, in turn, promotes the activation of different patterns of innate lymphoid cells (ILCs), which act locally to enhance barrier defense and recruit innate effector cells to sites of infection in advance of the arrival of antigen-specific CD4 and CD8 T cells whose functions they mirror. Coordination of the induction of different immune modules that are composed of related subsets of ILCs, innate effector cells, effector CD4 T cells, and class-switched antibodies underlies the different types of immunity directed against different types of pathogens.

Effector CD4 T cells augment the effector functions of innate immune cells.

In Chapter 9 we described how dendritic cells loaded with their antigen cargo migrate from the infected tissue to enter T-cell zones of secondary lymphoid tissues, where they initiate the adaptive immune response. We also discussed how CD8 T cells are primed to become cytotoxic effectors that are specialized for killing infected target cells that express MHC class I molecules, enabling them to eradicate intracellular infections in any nucleated cell. We also saw how transcription factor networks activated by specific cytokines direct the differentiation of naive CD4 T cells into distinct classes of effector CD4 T cells—T_H1, T_H2, and T_H17 (see Fig. 9.33). In Chapters 9 and 10 we discussed the specialized role of T_{FH} cells, which engage antigen-bearing B cells to control antibody class-switching and B-cell maturation in germinal centers in the context of type 1, type 2, and type 3 responses.

We now turn our attention to the specialized roles of subsets of these effector CD4 T cells after their differentiation in, and emigration from, secondary lymphoid tissues to orchestrate the functions of innate immune cells at sites of infection.

As discussed in Chapter 9 and in the preceding sections of this chapter, the pattern of cytokines produced by cells of the innate immune response during

the early course of infection is determined by how the pathogen influences the behavior of innate sensor cells that engage it. This has a major impact on how T cells differentiate during their initial contact with dendritic cells, thus determining the subsets of effector T cells that are generated. In turn, the recruitment of effector T cells to sites of infection sustains, amplifies, and enhances innate effector cell responses initiated by ILCs through effector mechanisms that require antigen-specific recognition, whether through cell–cell contact between CD4 or CD8 T cells and cell targets bearing their cognate antigens, or via pathogen-specific antibodies that T_{FH} cells help promote. In this part of the chapter, we will discuss how the differentiation of effector CD4 T cells alters their expression of surface receptors to program their egress from secondary lymphoid tissues and to sites of infection. We will then consider how T_H1, T_H2, and T_H17 cells interact with innate immune cells at sites of infection to bring about the clearance of the specific pathogens that elicit their development and recruitment. Finally, we will consider how the primary effector response is terminated as the pathogen is eliminated.

11-4 Effector T cells are guided to specific tissues and sites of infection by changes in their expression of adhesion molecules and chemokine receptors.

As discussed in Chapters 9 and 10, when naive T cells differentiate into effector T cells, changes occur in the expression of specific surface molecules that redirect their trafficking from T-cell zones into B-cell zones, in the case of T_{FH} cells, or from lymphoid to nonlymphoid tissues, in the case of other effector T cells. This includes changes in the expression of selectins and their ligands, integrins, and chemokine receptors. As we will see, some of these changes are generic; they are common to all CD4 and CD8 effector T cells. Others are tissue-specific, facilitating the recruitment of T cells back to the tissues in which they were primed. Yet others are T-cell subset-specific, particularly in the patterns of chemokine receptor expression, which direct T_{FH} cells to germinal centers, where they provide help to developing B cells, or direct T_H1, T_H2, and T_H17 cells to the same tissue sites as the myelomonocytic cells whose effector functions they will coordinate.

Activated naive CD4 T cells destined to become T_{FH} cells acquire expression of CXCR5 and lose expression of CCR7 and S1PR1 (see Section 9-15 and Section 10-3). Loss of CCR7 results in unresponsiveness to the T cell–zone chemokines CXCL21 and CXCL19, while sustained down-regulation of S1PR1 renders these cells insensitive to the S1P gradient that would otherwise guide their egress from the lymphoid tissue back to blood (see Section 9-5). The constitutive expression of CXCL13 by follicular dendritic cells establishes a gradient that acts via CXCR5 to attract developing T_{FH} cells from the T-cell zone, first to the border between the T-cell zone and a B-cell follicle where they can interact with B cells that present their cognate antigen and then into the B-cell follicle where they provide help to germinal center B cells. Unlike T_{FH} cells, other effector CD4 and CD8 T cells must leave the lymphoid tissue in which they have developed to interact with myeloid cells that present antigen at sites of infection in nonlymphoid tissues. As for T_{FH} cells, the exodus of these non-T_{FH} effector T cells from T-cell zones requires their loss of CCR7, but unlike T_{FH} cells, they reexpress S1PR1 as CD69 is down-regulated to direct them out of the lymphoid tissue and back into the blood (see Section 9-5).

Most non-T_{FH} effector cells also shed **L-selectin (CD62L)**, which mediates rolling on the high endothelial venules of secondary lymphoid tissues such as lymph nodes, in favor of **P-selectin glycoprotein ligand-1 (PSGL-1)**, a homodimeric sialoglycoprotein that is the major ligand for tethering and rolling on the P- and E-selectin expressed by endothelial cells activated by inflammatory cytokines (for example, TNF and IL-1) at sites of inflammation (Fig. 11.6). In

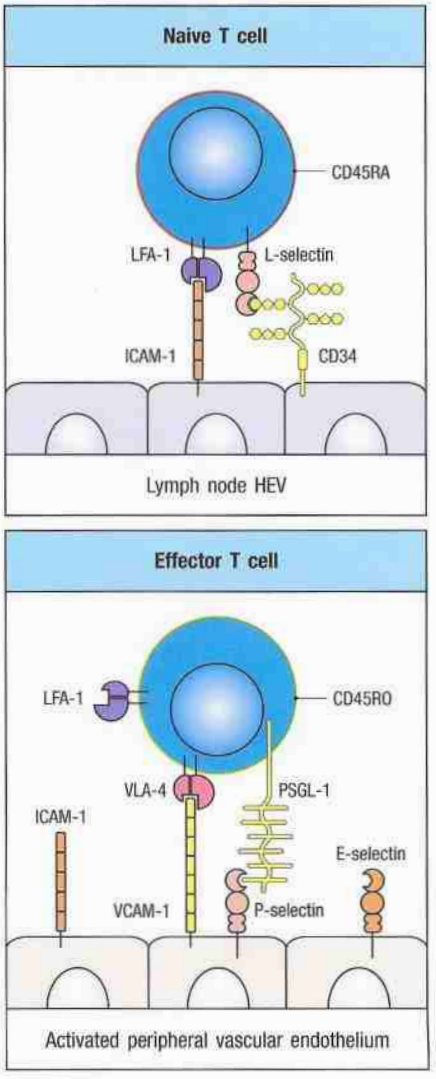

Fig. 11.6 Effector T cells change their surface molecules, allowing them to home to sites of infection. Naive T cells home to lymph nodes through the binding of L-selectin to sulfated carbohydrates displayed by various proteins, such as CD34 and GlyCAM-1 (not shown), on the high endothelial venule (HEV; upper panel). After encounter with antigen, many of the differentiated effector T cells lose expression of L-selectin, leave the lymph node about 4–5 days later, and now express the integrin VLA-4 and increased levels of LFA-1. These bind to VCAM-1 and ICAM-1, respectively, on peripheral vascular endothelium at sites of inflammation (lower panel). On differentiating into effector cells, T cells also alter their splicing of the mRNA encoding the cell-surface protein CD45, a receptor-type protein tyrosine phosphatase (PTP). The CD45RO isoform expressed by effector T cells lacks one or more exons that encode extracellular domains present in the CD45RA isoform expressed by naive T cells and appears to make effector T cells more sensitive to stimulation by specific antigen.

contrast to granulocytes and monocytes, which constitutively express glycosyltransferases necessary for biosynthesis of selectin ligands, T cells express these enzymes only after effector T-cell development. Effector differentiation induces expression of the glycosyltransferase **α-(1,3)-fucosyltransferase VII (FucT-VII)**, a key enzyme required for both P- and E-selectin ligand generation. Thus, although PSGL-1 is expressed by both naive and effector T cells, it is appropriately glycosylated for selectin binding only by effector T cells.

The expression of integrins that are important for the recruitment of effector T cells to inflamed tissues is also induced (see Fig. 11.6). Effector T cells retain expression of **LFA-1** ($\alpha_L\beta_2$), which is also expressed by naive T-cell precursors. However, they also synthesize the integrin $\alpha_4\beta_1$, or **VLA-4**, which binds to the adhesion molecule **VCAM-1**, a member of the immunoglobulin superfamily related to ICAM-1. When effector T cells are activated by chemokine signaling, VLA-4 is altered so that it can bind with high affinity to VCAM-1, similar to chemokine-induced binding of ICAM-1 by activated LFA-1 (see Section 3-18). Thus, chemokines activate VCAM-1 to bind VLA-4 on vascular endothelial cells near sites of inflammation, allowing extravasation of effector T cells. Although both VCAM-1 and ICAM-1 are expressed on activated endothelial-cell surfaces, there appears to be preferential utilization of the two adhesion pairs in some inflamed tissue vascular beds, with recruitment of effector T cells being more dependent on VLA-4 in some tissues, and more dependent on LFA-1 in others.

Expression of some adhesion molecules by effector T cells is programmed within the specific secondary lymphoid tissues in which they are primed such that they preferentially home back to the associated nonlymphoid tissues. Thus, the site of priming appears to imprint effector T cells with the ability to traffic to particular tissues. This is achieved by the expression of adhesion molecules that bind selectively to tissue-specific addressins. In this context, the adhesion molecules are often known as **homing receptors**. As an example, cDCs that prime T cells in the gut-associated lymphoid tissue (GALT) preferentially induce T-cell expression of the integrin $\alpha_4\beta_7$, which binds to the mucosal vascular addressin **MAdCAM-1** that is constitutively expressed by endothelial cells of high endothelial venules (HEVs) in GALT and in postcapillary venules within the gut mucosa (see Chapter 12). In this way, T cells primed in the GALT preferentially traffic to the gut.

T cells primed in the GALT also express specific chemokine receptors that bind chemokines produced constitutively—and specifically—by the gut epithelium. Thus, at homeostasis, CCR9 expressed on T cells primed in lymphoid tissues of the small intestine recruit those T cells back to the small intestine along a CCL25 gradient. In contrast, T cells primed in skin-draining lymph nodes preferentially home back to the skin. They are induced to express the adhesion molecule **cutaneous lymphocyte antigen (CLA)**, an isoform of PSGL-1 that differs in its pattern of glycosylation and binds to E-selectin on cutaneous vascular endothelium (Fig. 11.7). CLA-expressing T lymphocytes also express the chemokine receptors CCR4 and CCR10, which bind the chemokines CCL17 (TARC) and CCL27 (CTACK), respectively. These chemokines are constitutively produced by cells in the epidermis of the skin and line the endothelium of cutaneous blood vessels. Because these tissue-homing chemokines are produced at steady state, they are referred to as **homeostatic chemokines**. They are analogous to chemokines produced constitutively in lymphoid tissues at steady state, such as CCL19 and CCL21, which direct CCR7-bearing naive T cells along a gradient from the endothelium of HEVs to T-cell zones (Fig. 11.8). Homeostatic chemokines can be contrasted with **inflammatory chemokines**, which are elicited in the context of infection to recruit circulating immune cells to sites of inflammation.

In addition to the general and tissue-specific changes in trafficking molecules induced during effector T-cell differentiation, loss of CCR7 expression

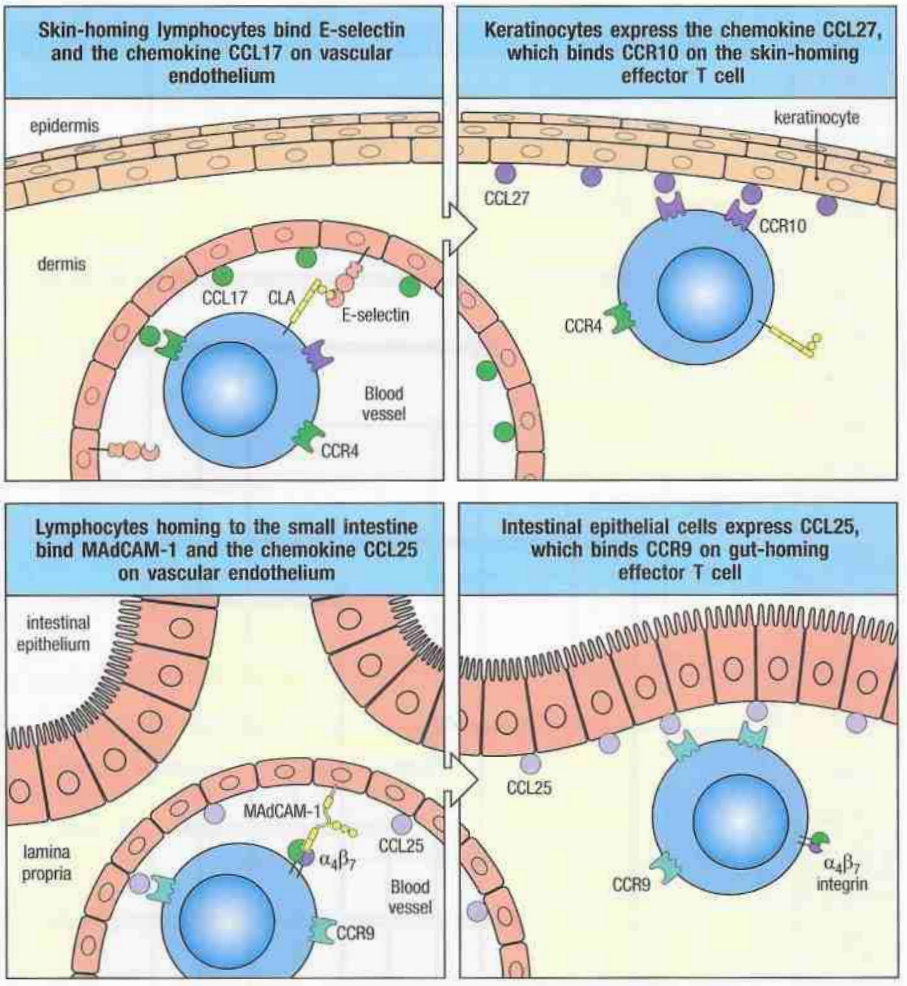

Fig. 11.7 Skin- and gut-homing T cells use particular combinations of integrins and chemokines to migrate specifically to their target tissues. Circulating lymphocytes primed in lymph nodes draining the skin bind to the endothelium lining a cutaneous blood vessel by interactions between cutaneous lymphocyte antigen (CLA) and constitutively expressed E-selectin on the endothelial cells (upper left panel). The adhesion is strengthened by an interaction between lymphocyte chemokine receptor CCR4 and the endothelial chemokine CCL17. Once through the endothelium, effector T lymphocytes are attracted to keratinocytes of the epidermis by the chemokine CCL27, which binds to the receptor CCR10 on lymphocytes (upper right panel). Similarly, $\alpha_4\beta_7$ expressed on circulating lymphocytes primed in gut-associated lymphoid tissue initially binds MAdCAM-1 (lower left panel), then uses CCR9 to move along a CCL25 chemokine gradient to traverse the endothelium and migrate to the intestinal epithelium (lower right panel).

is accompanied by subset-specific induction of other chemokine receptors. This results in distinct patterns of chemokine receptor expression by T_H1, T_H2, and T_H17 cells, which guides their differential recruitment to sites of inflammation contingent on the local patterns of inflammatory chemokines induced by innate immune responses to different types of pathogens (Fig. 11.9). For example, T_H1 cells express CCR5, which is also expressed on monocytes that mature into macrophages as they enter the inflammatory site. Thus, both T_H1 cells and the innate effector cells whose effector functions they enhance are recruited to the same tissue site by the same chemokines (see Fig. 11.8). As is the case for many other chemokine receptors, CCR5 has multiple ligands (CCL3, CCL4, CCL5, and CCL8), which may be induced by different cellular sources and by different pathogens targeted by type 1 immunity. Some of these are produced by activated macrophages themselves after their recruitment to the inflammatory site. This provides a feed-forward mechanism by which the emerging innate response is amplified and then contributes to the recruitment of T_H1 cells, which provide antigen-dependent 'help' to further activate the macrophages, as we discuss in Section 11-6. T_H1 cells also express CXCR3, which is shared by NK cells and cytotoxic CD8 T cells. In response to CXCR3 ligands—CXCL9, CXCL10, and CXCL11—these cells are recruited to the same inflammatory site to coordinate the cell-mediated killing of targets infected by intracellular pathogens, such as *Listeria monocytogenes*, which require the concerted actions of both T_H1 cells and cytotoxic effectors to clear the bacterium from macrophages and other cellular hosts.

T_H2 and T_H17 cells display different patterns of inflammatory chemokine receptors, some of which, like those expressed by T_H1 cells, are shared with

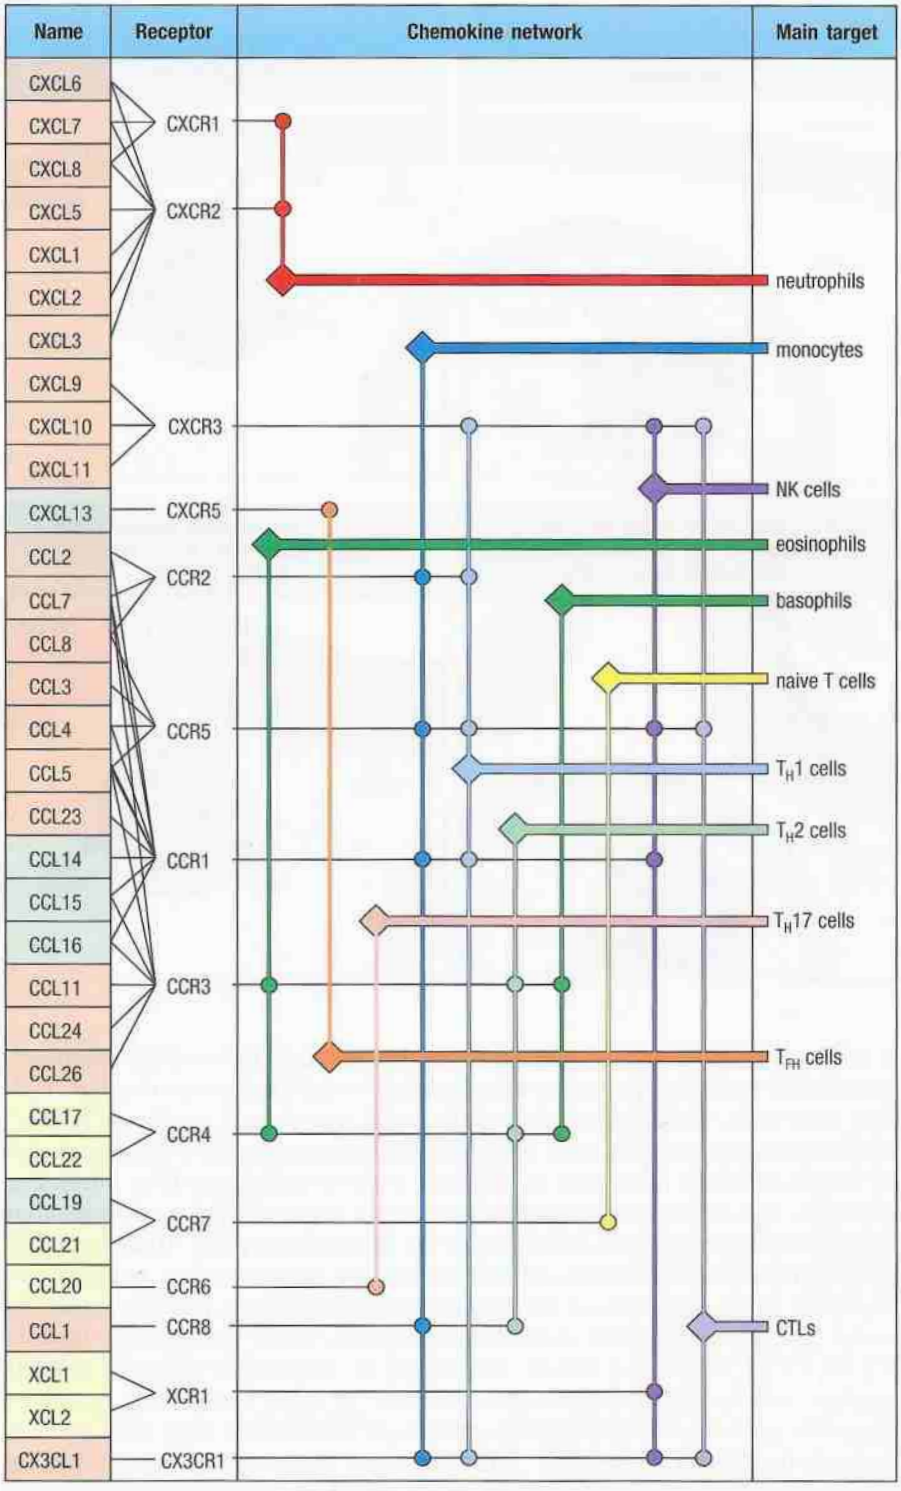

Fig. 11.8 Chemokine networks coordinate the interactions of innate and adaptive immune-cell populations. Chemokines are classified into four families on the basis of structural differences: CXCL, CCL, XCL, and CX3CL1. Chemokines (see the first column) can also be classified as pro-inflammatory (pink), homeostatic (green), and mixed function (yellow). Chemokines bind to a subfamily of seven-transmembrane G protein–coupled receptors, which are classified as CXCR, CCR, XCR, and CX3CR1 on the basis of the class of chemokines they bind. Many, but not all, of the chemokine–chemokine receptor networks that coordinate immune modules are represented here. The connection between receptors and cell types on which they are expressed is indicated by the 'circuit' representation of lines and connecting nodes. To connect chemokines and their receptors to target cells, follow a horizontal line and turn on a vertical one at each node; the rhomboids (diamond shapes) link vertical lines to the cell type. Note that most chemokine receptors can bind multiple chemokines.

the myelomonocytic cells with which they interact in inflamed tissues (see Figs. 11.8 and 11.9). The shared expression pattern of chemokine receptors by innate and adaptive effector cells represents an important mechanism for the spatiotemporal coordination and integration of immune effector modules in response to different types of pathogen (see Fig. 11.8). Thus, the local release of cytokines and chemokines at the site of infection has far-reaching consequences. In addition to recruiting granulocytes and monocytes, which constitutively express their specific complement of chemokine receptors while in circulation, changes induced in endothelial cells lining blood vessels also

enable newly generated effector T lymphocytes to enter infected tissues. Once in the tissue, recruited T cells may undergo further maturation and are activated to produce T helper cell subset-specific cytokines that further increase specific chemokine production by innate immune cells in an additional feed-forward mechanism that results in further effector T cell and innate effector cell trafficking into the tissue.

11-5 Pathogen-specific effector T cells are progressively enriched at sites of infection where they may undergo further maturation to acquire full effector function.

In the early stage of the adaptive immune response, only a minority of the effector T cells that enter infected tissues will be specific for pathogen. This is because activation of the endothelium of local blood vessels by inflammatory cytokines induces expression of selectins, integrin ligands, and chemokines that can recruit any circulating effector or memory T cell that expresses the appropriate trafficking receptors, irrespective of its antigenic specificity. This limits the potency of the antigen-specific response early. Moreover, at least for type 2 responses, T_H2 cells primed in secondary lymphoid organs require additional maturational signals in the inflamed tissue to which they are recruited to acquire full effector responses. As will be discussed in Section 11-10, the same cytokines that activate ILC2 cells—TSLP, IL-33, and IL-25—appear to be required for complete differentiation of T_H2 cells, at least in some target tissues, and this late-stage differentiation appears to be independent of signals from ILC2. Thus, sensing of module-specific innate cytokines may provide a mechanism to control the final activation of effector T cells, representing a further parallel with ILCs and a common local tissue checkpoint to regulate the effector response.

However, specificity and potency of the reaction is rapidly increased as the number and maturation state of pathogen-specific T cells increases and recognition of antigen within the inflamed tissue retains them there. Although the precise mechanisms controlling retention of antigen-activated effector T cells in the inflamed tissue are not entirely understood, it is thought that some of the same mechanisms that retain antigen-activated naive T cells within secondary lymphoid tissues during early effector T-cell development are at play. Thus, incoming T cells that are activated by antigen reexpress CD69, leading to down-regulation of S1PR1, and perhaps other members of the S1P receptor family, depriving them of the signal needed for tissue egress. Antigen-induced persistence of receptors for local chemokines may also contribute to retention of pathogen-specific T cells. Conversely, effector and memory T cells that enter tissues but do not recognize their cognate antigen are not retained there. While some may undergo apoptosis locally, most probably enter the afferent lymphatics and migrate to the draining lymph nodes and eventually return to the bloodstream. T cells in the afferent lymph that drains tissues therefore express markers of effector or memory T cells, characterized by expression of the CD45RO isoform of the cell-surface molecule CD45 and lack of L-selectin (see Fig. 11.6). Through the selective retention of pathogen-specific T cells and loss of nonspecific T cells, by the peak of an adaptive immune response, after several days of clonal expansion and differentiation, a large fraction of the T cells recruited to the inflamed tissue will be specific for the inciting pathogen and will be fully activated to eliminate it.

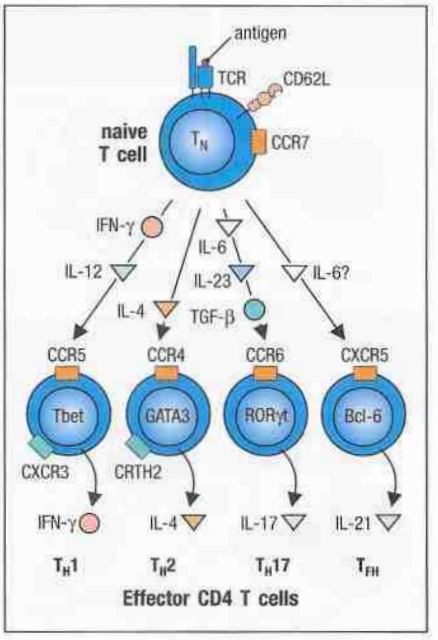

Fig. 11.9 The expression of adhesion and chemokine receptors is altered during effector T-cell differentiation. During a primary immune response, specific cytokines derived from the innate immune system (indicated along the four diverging arrows) and unique master transcription factors (Tbet, GATA3, RORγt, and Bcl-6) direct naive CD4 T cells to differentiate into T_H1, T_H2, T_H17, or T_{FH} effector cells. Effector T cells of each subset lose expression of L-selectin (CD62L) and CCR7 and express characteristic chemokine receptors.

11-6 T_H1 cells coordinate and amplify the host response to intracellular pathogens through classical activation of macrophages.

Type 1 responses (see Fig. 11.5) are important for the eradication of pathogens that have evolved mechanisms to survive and replicate within host cells, particularly those that do so within macrophages. T_H1 cells are the principal

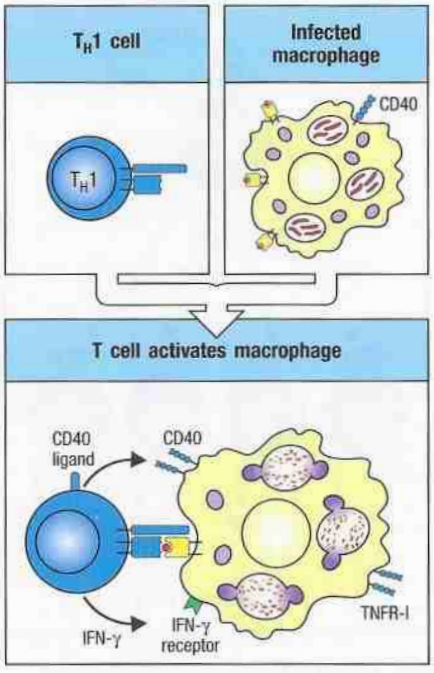

Fig. 11.10 T_H1 cells activate macrophages to become highly microbicidal. When an effector T_H1 cell specific for a bacterial peptide contacts an infected macrophage, the T cell is induced to secrete the macrophage-activating factor IFN-γ and to express CD40 ligand and other products that may activate the macrophage. Together these newly synthesized T_H1 proteins activate the macrophage for heightened intracellular killing and enhanced production of pro-inflammatory cytokines.

T-cell helpers for macrophages; they enhance the ability of macrophages to destroy intracellular pathogens taken up via phagocytosis. Thus, in the case of infections by intracellular bacteria such as mycobacteria and *Salmonella* or by protozoa such as *Leishmania* and *Toxoplasma*, all of which can survive within macrophages, T_H1 cells activate macrophages to heighten their microbicidal function. T_H1 cells can also participate in viral infections, whether to provide help to infected macrophages—or other MHC class II–expressing cells, such as the inflamed intestinal epithelium—to inhibit viral replication and destroy virus particles or to coordinate with cytotoxic CD8 T cells that recognize virus-infected cells and destroy them (see Chapter 9). T_{FH} cells that differentiate in the context of type 1 responses induce the production of subclasses of IgG antibodies (for example, IgG2a and IgG2c in mice; IgG2 and IgG3 in humans) that can opsonize intracellular pathogens that are released into the extracellular environment, neutralize virus particles in the blood and extracellular fluid, and arm NK cells for ADCC. Historically, overexuberant, tissue-damaging T cell–mediated immunity orchestrated by type 1 responses has been referred to as **delayed-type hypersensitivity**, to be distinguished from **immediate hypersensitivity**, such as allergic reactions and asthma, which are characterized by poorly controlled type 2 responses (see Section 11-10 and Chapters 14 and 15).

Single-cell pathogens of all types are ingested by macrophages and are often destroyed without the need for additional macrophage activation. However, in several clinically important infections, such as those caused by mycobacteria, pathogens ingested by macrophages are not killed and may even serve as hosts for chronic infection. Such microorganisms are able maintain themselves in the hostile environment of phagosomes—shielded from the effects of both antibodies and cytotoxic T cells—by inhibiting the fusion of phagosomes and lysosomes, preventing the acidification required to activate lysosomal proteases, or escaping the phagosome into the macrophage cytoplasm. Nevertheless, peptides derived from such microorganisms can be displayed by MHC class II molecules on the macrophage surface, where they are recognized by antigen-specific effector T_H1 cells. The T_H1 cell is stimulated to synthesize membrane-associated proteins and secrete cytokines that enhance the macrophage's antimicrobial defenses and enable it to either eliminate the pathogen or control its growth and spread (Fig. 11.10). This boost to antimicrobial mechanisms is often referred to as 'classical' macrophage activation, the result of which is the so-called **classically activated macrophage**, or **M1 macrophage** (Fig. 11.11). Although the range of macrophage subsets and activation states is still being defined, the M1 designation is useful in distinguishing the macrophage functions induced in the context of T_H1 responses from those induced by other types of immune responses, such as M2 macrophages induced in the context of T_H2 responses (see Section 11-10).

Macrophages require two main signals for classical activation. Both are delivered by T_H1 cells. One signal is the cytokine IFN-γ; the other is CD40L (see Fig. 11.10). Both signals are elicited by recognition of pathogenic peptide:MHC class II molecules on the macrophage surface by the T_H1 cell. Because CD40L and its receptor on the macrophage (CD40) are cell surface–associated molecules, and IFN-γ is thought to be delivered primarily across an immunological synapse that forms between the T cell and the macrophage, the T_H1 cell's effector actions are primarily focused on macrophages that harbor intracellular pathogens. T_H1 cells can also produce lymphotoxin and TNF-α, which, like CD40L, are TNF family cytokines that may contribute to M1-type macrophage activation. However, because inherited deficiency of *CD40L*, the most common cause of **X-linked hyper IgM syndrome**, results in defects in the killing of certain intracellular pathogens (for example, mycobacteria; see Section 13-8), it is likely that CD40L has a nonredundant role in macrophage activation.

Macrophages activated by T_H1 cells acquire potent antimicrobial effector activities, as illustrated in Fig. 11.11. This includes the induction of several key lysosomal enzymes that enhance the production of microbicidal reactive oxygen and nitrogen species after the fusion of phagosomes with lysosomes, as described in Section 3-2. In addition to inducing mechanisms for increased intracellular killing, T_H1 cells induce other changes in macrophages that enhance their recruitment of T-cell help. IFN-γ produced by T_H1 cells is a potent inducer of antigen processing and presentation; it stimulates increased synthesis of MHC class I and class II molecules and B7 molecules (CD80 and CD86) and is unique in up-regulating components of the MHC class II antigen-processing machinery (for example, invariant chain, HLA-DM; see Chapter 6), collectively making the macrophage more effective at presenting antigen to sustain T-cell help. IFN-γ also enhances expression of CD40 and TNF receptors on the M1 macrophage surface (see Figs. 11.10 and 11.11), resulting in heightened responsiveness to CD40L and TNF-α. In addition, M1 macrophages are activated by CD40L to secrete IL-12, which increases the amount of IFN-γ produced by ILC1 cells and T_H1 cells, thereby promoting a positive feedback loop that enhances macrophage activation.

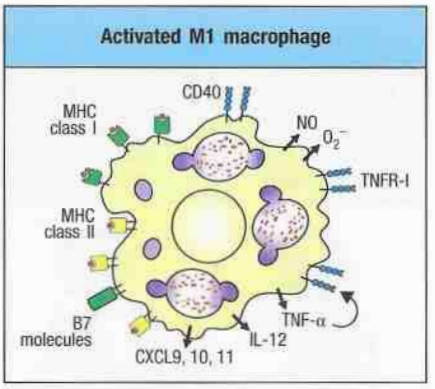

Fig. 11.11 Macrophages activated by T_H1 cells undergo changes that increase their antimicrobial effectiveness and amplify the immune response. Activated macrophages increase their expression of CD40 and of TNF receptors, and are also stimulated to secrete TNF-α. CD40 ligand (CD40L) and TNF-α synergize with IFN-γ secreted by T_H1 cells to induce classical, or M1, macrophage activation characterized by production of nitric oxide (NO) and superoxide (O_2^-). The macrophage also up-regulates its B7 molecules in response to binding CD40L and TNF-α and increases its expression of MHC class II molecules in response to IFN-γ, thus enabling a positive feed-forward loop that enhances activation of T_H1 cells.

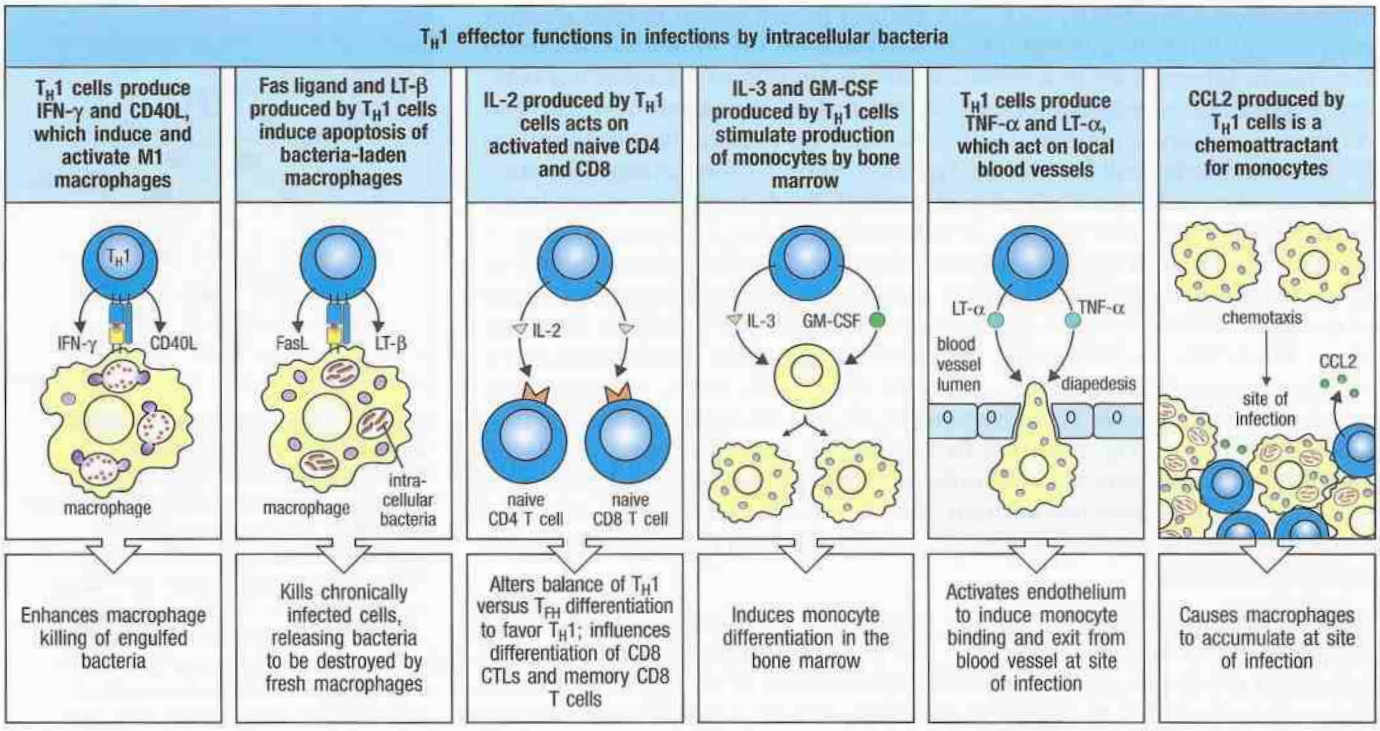
Another important function of T_H1 cells is the recruitment of additional phagocytic cells to sites of infection. T_H1 cells recruit monocytes—the precursors of macrophages—by multiple mechanisms (**Fig. 11.12**). Activated T_H1 cells make the hematopoietic growth factors IL-3 and GM-CSF, which stimulate the production of new monocytes in the bone marrow and result in increased monocytes in circulation. TNF-α and LT-α secreted by T_H1 cells at sites of infection up-regulate endothelial-cell expression of selectins and integrin ligands that enhance the local recruitment of monocytes. Chemokines such as CXCL2, which is produced by T_H1 cells at inflammatory sites, direct the migration of monocytes through the vascular endothelium and into the infected tissue, where they differentiate into macrophages (see Section 3-1). Moreover, the secretion of cytokines and chemokines by M1 macrophages to enhance the recruitment of monocytes to sites of infection—including TNF-α and IL-1β—is increased by the actions of T_H1 cells. Collectively, these T_H1-mediated effects provide a positive feedback loop that amplifies and sustains type 1 responses until the pathogen is controlled or eliminated.

Certain intracellular bacteria, including some mycobacteria and *Listeria monocytogenes*, have evolved mechanisms to escape from phagocytic vesicles and enter the cytoplasm, where they are no longer susceptible to the microbicidal actions of activated macrophages. However, their presence can be detected by cytotoxic CD8 T cells. The pathogens released when macrophages are killed by these CTLs can be killed in the extracellular environment by antibody-mediated mechanisms or phagocytosed by freshly recruited macrophages. In this circumstance, the provision of T_H1-mediated 'help' for the development of CTLs, such as the provision of IL-2, may play an important role in coordinating the T_H1 and CTL responses.

ANIMATION 11.2

11-7 Activation of macrophages by T_H1 cells must be tightly regulated to avoid tissue damage.

As discussed in Chapter 9, distinguishing features of effector T cells are their capacity for antigen-induced activation of effector functions with limited requirement for co-stimulation, and also their efficient delivery of effector molecules through polarized secretion or expression of cytokines and cell-surface molecules—often through formation of an immunological synapse with an antigen-bearing cell (see Section 9-18). After a T_H1 cell recognizes its cognate antigen expressed by a macrophage, the secretion of effector



T_H1 effector functions in infections by intracellular bacteria
T_H1 cells produce IFN-γ and CD40L, which induce and activate M1 macrophages

Alters balance of T_H1 versus T_{FH} differentiation to favor T_H1; influences differentiation of CD8 CTLs and memory CD8 T cells
Induces monocyte differentiation in the bone marrow
Activates endothelium to induce monocyte binding and exit from blood vessel at site of infection
Causes macrophages to accumulate at site of infection

Fig. 11.12 The immune response to intracellular bacteria is coordinated by activated T_H1 cells. The activation of T_H1 cells by infected macrophages results in the synthesis of cytokines that both induce M1 macrophage activation and coordinate the immune response to intracellular pathogens. IFN-γ, CD40 ligand, and TNF-α synergize in activating the macrophage, which allows it to kill engulfed pathogens. Chronically infected macrophages lose the ability to kill intracellular bacteria, and membrane-bound Fas ligand or LT-β produced by the T_H1 cell can kill these macrophages, releasing the engulfed bacteria, which are taken up and killed by fresh macrophages. In this way, IFN-γ and LT-β synergize in the removal of intracellular bacteria. IL-2 produced by T_H1 cells augments effector T-cell differentiation and CD8 memory-cell development. IL-3 and GM-CSF stimulate the production of new monocytes by acting on hematopoietic stem cells in the bone marrow. New macrophages are recruited to the site of infection by the actions of secreted TNF-α, LT-α, and other cytokines on vascular endothelium, which signal monocytes to leave the bloodstream and enter the tissues where they become macrophages. Chemokines with monocyte chemotactic activity (for example, CCL3) signal monocytes to migrate into sites of infection and accumulate there. Thus, the T_H1 cell coordinates a macrophage response that is highly effective in destroying intracellular infectious agents.

molecules can take several hours. Therefore, T_H1 cells must adhere to their target cells longer than cytotoxic CD8 T cells, which can deliver a death signal in minutes and then detach to interact with other targets. However, similar to cytotoxic T cells, the T_H1 cell orients its secretory machinery toward the site of contact with the macrophage and secretes newly synthesized cytokines there (see Fig. 9.41). CD40 ligand also seems to be delivered to the same contact site. So, although all macrophages have receptors for IFN-γ and may respond to this cytokine, the infected macrophage that presents antigen to the T_H1 cell is more likely to become activated than nearby uninfected macrophages.

In addition to more efficiently focusing activating signals on infected macrophages, the antigen-specific induction of macrophage activation may play an important role in limiting tissue injury. By targeting only infected macrophages through peptide:MHC recognition, T_H1 cells minimize 'collateral damage' to normal components of the inflamed tissue that might otherwise result from oxygen radicals, NO, and proteases that are toxic to host cells as well as to the pathogen that is targeted for destruction. Thus, antigen-specific macrophage activation by T_H1 cells is a means to deploy this powerful defensive mechanism to maximum effect while minimizing local tissue damage. In this regard, it is notable that although ILC1 cells are also producers of IFN-γ , they lack antigen receptors that can focus the cytokine

on infected macrophages for more efficient activation. It is not yet known whether ILC1 cells have other mechanisms with which to direct IFN-γ onto macrophages—analogous to the activating and inhibitory receptors deployed by NK cells—or whether they play a more limited role in macrophage activation, and whether the IFN-γ they produce downstream of activating signals is more important in indirectly modulating the local inflammatory response.

11-8 Chronic activation of macrophages by T_H1 cells mediates the formation of granulomas to contain intracellular pathogens that cannot be cleared.

Some intracellular pathogens, most notably *Mycobacterium tuberculosis*, are sufficiently resistant to the microbicidal effects of activated macrophages that they are incompletely eliminated by a type 1 response. This gives rise to chronic, low-level infection that requires an ongoing T_H1 response to prevent pathogen proliferation and spread. In this circumstance, chronic coordination between T_H1 cells and macrophages underlies the formation of the immunological reaction called the **granuloma**, in which microbes are held in check within a central area of macrophages surrounded by activated lymphocytes (Fig. 11.13). A characteristic feature of granulomas is the fusion of several macrophages to form **multinucleated giant cells**, which can be found at the border of the central focus of activated macrophages and the lymphocytes that surround them and which appear to have heightened antimicrobial activity. A granuloma serves to 'wall off' pathogens that resist destruction. In tuberculosis, the centers of large granulomas can become isolated and the cells there die, probably from a combination of lack of oxygen and the cytotoxic effects of activated macrophages. As the dead tissue in the center resembles cheese, this process is called 'caseous' necrosis. Thus, the chronic activation of T_H1 cells can cause significant pathology. The absence of the T_H1 response, however, leads to the more serious consequence of death from disseminated infection, which is seen frequently in individuals with AIDS and concomitant mycobacterial infection.

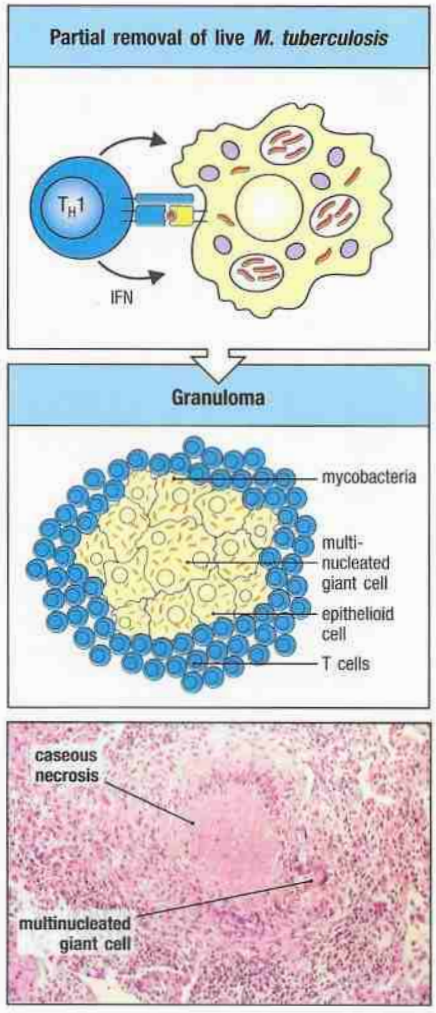

Fig. 11.13 Granulomas form when an intracellular pathogen or its constituents cannot be completely eliminated. When mycobacteria such as *M. tuberculosis* (red) resist the effects of macrophage activation, a characteristic localized inflammatory response called a granuloma develops. This consists of a central core of infected macrophages. The core may include multinucleated giant cells, which are fused macrophages, surrounded by large macrophages often called epithelioid cells, but in granulomas caused by mycobacteria the core usually becomes necrotic—referred to as caseous necrosis because of the cheese-like consistency of material that accumulates in the necrotic centers. Mycobacteria can persist in the cells of the granuloma. The central core is surrounded by T cells, many of which are CD4-positive. The exact mechanisms by which this balance is achieved, and how it breaks down, are not fully understood. An example of a caseating granuloma in the lung of an individual with tuberculosis is shown in the bottom panel.

11-9 Defects in type 1 immunity reveal its important role in the elimination of intracellular pathogens.

In mice whose gene for IFN-γ or CD40 ligand has been deleted by gene targeting, classical macrophage activation is impaired; consequently, the animals succumb to sublethal doses of *Mycobacterium, Salmonella,* and *Leishmania* species. Classical macrophage activation is also crucial in controlling vaccinia virus. However, although IFN-γ and CD40 ligand are probably the most important effector molecules synthesized by T_H1 cells, the immune response to pathogens that proliferate in macrophage vesicles is complex, and other cytokines secreted by T_H1 cells may also be crucial (see Fig. 11.12).

The depletion of CD4 T cells in people with HIV/AIDS causes ineffective T_H1 responses that can lead to the dissemination of microbes that are normally cleared by macrophages. This is the case with the opportunist fungal pathogen *Pneumocystis jirovecii* (see also Chapter 13). The lungs of healthy people are kept clear of *P. jirovecii* by phagocytosis and intracellular killing by alveolar macrophages. Pneumonia caused by *P. jirovecii* is, however, a frequent cause of death in people with AIDS. In the absence of CD4 T cells, phagocytosis of *P. jirovecii* and intracellular killing by lung macrophages are impaired, and the pathogen colonizes the surface of the lung epithelium and invades lung tissue. The requirement for CD4 T cells seems to be due, at least in part, to a

requirement for the macrophage-activating cytokines IFN-γ and TNF-α produced by T_H1 cells.

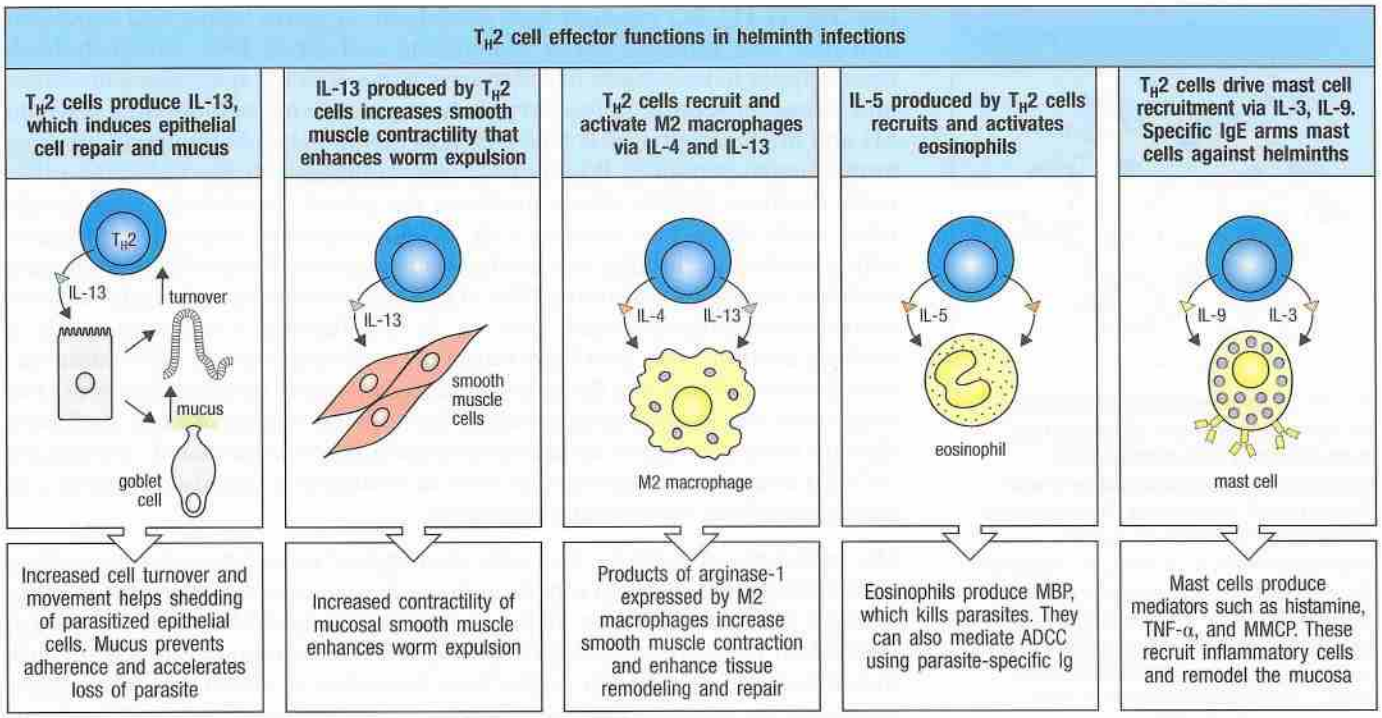
11-10 T_H2 cells coordinate type 2 responses to expel intestinal helminths and repair tissue injury.

Type 2 immunity is primarily elicited in response to helminth parasites: roundworms (nematodes) and two types of flatworms—tapeworms (cestodes) and flukes (trematodes). Unlike microbial pathogens, or 'micropathogens' (bacteria, viruses, fungi, and protozoa), which replicate rapidly and can overwhelm host defenses by sheer numbers, most helminths do not replicate in their mammalian host. Moreover, helminths are multicellular; they are metazoan 'macropathogens' that are far too large—ranging in size from approximately 1 mm to more than 1 meter—to be engulfed by host phagocytic cells. Host defense against helminthic pathogens therefore requires very different strategies.

In the developing world, the intestines of virtually all humans and domestic animals are colonized by helminth parasites. Many of these infections may be cleared rapidly by the generation of an effective type 2 response, although often the host response is only successful in reducing worm burden, not in completely clearing the parasite, resulting in chronic disease. In these circumstances, the parasite persists for long periods despite the host's attempts to expel it, and it causes disease by competing with the host for nutrients or by causing local tissue injury. As noted earlier (see Section 11-6), aberrant type 2 responses can cause chronic immediate hypersensitivity diseases, typified by allergic reactions or asthma.

Irrespective of the type of helminth involved or its site of host entry, the host adaptive response is orchestrated by T_H2 cells (**Fig. 11.14**; and see Fig. 9.33). The T_H2 response is induced by the actions of worm products on a variety of different innate cells: epithelial cells, including tuft cells; mast cells; cDC2 cells; and perhaps ILC2 cells. Type 2 conventional dendritic cells required for the presentation of helminth antigens to naive CD4 T cells appear to be activated by IL-13 produced by ILC2 cells and by innate cytokines, such as epithelium-derived TSLP, which repress the development of T_H1- and T_H17-inducing dendritic cells in favor of dendritic cells that promote T_H2 cell differentiation. The initial source of the IL-4 required for T_H2 cell differentiation appears to be context-specific and redundant. Thus, although several cell types have been proposed as the source, including iNKT cells, mast cells, and basophils, none of these has been proven to be essential.

The initial development of T_H2 cells in draining lymphoid tissues is followed by their exodus to sites of helminth invasion, where they may undergo further maturation driven by the same cytokines that activate ILC2 cells—TSLP, IL-33, and IL-25. Mature T_H2 cells activated in sites of infection produce many of the same cytokines as ILC2 cells to enhance both the recruitment and function of circulating type 2 innate effector cells (eosinophils and basophils) and the activation of tissue-resident innate effectors (mast cells). Like T_H1 and T_H17 cells, T_H2 cells express a distinct complement of chemokine receptors that is shared with the circulating innate effector cells with which they interact, thus selectively guiding the T_H2 cells to sites of ongoing type 2 responses (see Figs.11.8 and 11.9). Thus, CCR3 and CCR4 are expressed by T_H2 cells, eosinophils, and basophils. The chemokines recognized by these receptors (the CCR3-binding eotaxins CCL11, CCL24, and CCL26) are induced by the actions of IL-13 and IL-4 on multiple innate immune cells in tissue sites of helminth infection. Each of these cells also expresses CRTH2, the ligand for which—prostaglandin D2 (PGD2)—is produced in abundance by activated tissue mast cells, as



T_H2 cell effector functions in helminth infections

Increased cell turnover and movement helps shedding of parasitized epithelial cells. Mucus prevents adherence and accelerates loss of parasite
Increased contractility of mucosal smooth muscle enhances worm expulsion
Products of arginase-1 expressed by M2 macrophages increase smooth muscle contraction and enhance tissue remodeling and repair
Eosinophils produce MBP, which kills parasites. They can also mediate ADCC using parasite-specific Ig
Mast cells produce mediators such as histamine, TNF-α, and MMCP. These recruit inflammatory cells and remodel the mucosa

Fig. 11.14 Protective responses to intestinal helminths are mediated by T_H2 cells. Most intestinal helminths induce both protective and pathological immune responses by CD4 T cells. T_H2 responses tend to be protective, creating an unfriendly environment for the parasite and leading to its expulsion and the generation of protective immunity (see the text for details). M2 macrophage, alternatively activated macrophage; MBP, major basic protein; MMCP, mucosal mast cell protease.

well as by T_H2 cells themselves and possibly by tuft cells. Hence, each cell in the type 2 immune module (ILC2 cells, eosinophils, basophils, mast cells, and T_H2 cells) can further amplify the recruitment of circulating type 2 cells through this chemokine network.

Although the T_H2 effector response can coordinate the direct killing of some worms by enhancing innate effector-cell functions, a major focus of the anti-helminth response is expelling the worms and limiting the tissue damage they cause when they invade the host—functions that are mediated by type 2 cytokines. IL-13 directly enhances the production of mucus by goblet cells, activates smooth muscle cells in mucosal tissues for hypermotility, and increases the migration and turnover of epithelial cells in the mucosa (see Fig. 11.14, first panel). In the intestines, which are the most common site of worm infestation, each of these actions is a critical component of the host response, as it helps to eliminate parasites that have attached to the epithelium and decreases the surface area available for colonization.

The response to helminths generates IgE antibody, induced by IL-4–producing T_{FH} cells that develop in concert with T_H2 cells (see Fig. 11.14). IgE binds to Fcε receptors expressed by mast cells, eosinophils, and basophils, which arms them for antigen-specific recognition and activation. Type 2 adaptive responses also promote production of IgG1, which is recognized by macrophages and engages them in the type 2 response. IL-4 produced by T_H2 cells and IL-13 produced by both T_H2 cells and ILCs can induce differentiation of **alternatively activated macrophages** (also called **M2 macrophages**). Unlike classically activated M1 macrophages, which acquire new functions after interaction with T_H1 cells and are potent activators of inflammation

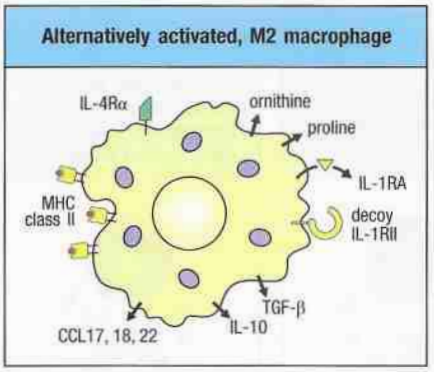

Fig. 11.15 Macrophages activated by T_H2 cells undergo changes that increase their effectiveness in eradicating helminths and promote tissue repair responses. Macrophages activated by T_H2 cells up-regulate expression of the IL-4 and IL-13 receptors (for example, IL-4Rα) and are induced to express arginase-1, which results in the secretion of ornithine and proline. Ornithine enhances smooth muscle contractility, which can enhance worm expulsion and may be directly cytotoxic to some helminth larvae. It also promotes tissue repair. Proline is a critical amino acid for collagen synthesis, which is important for tissue remodeling and repair. M2 macrophages can also repress local tissue inflammation through their production of IL-1 receptor antagonist (IL-1RA) and a decoy IL-1 receptor (IL-1RII), both of which act to inhibit IL-1 receptor signaling. M2 macrophages also produce the anti-inflammatory cytokine IL-10 as well as TGF-β, which has pleiotropic effects in wound healing.

(see Fig. 11.11), M2 macrophages participate in worm killing and expulsion and may also promote tissue remodeling and repair (**Fig. 11.15**). Indeed, there appear to be subsets of M2 macrophages that are specialized for either anti-helminth actions or tissue repair. In any case, a major difference between M1 and M2 macrophages is their different metabolism of arginine to produce antipathogen products. Whereas M1 macrophages express inducible nitric oxide synthase (iNOS), which produces the potent intracellular microbicide nitric oxide (NO) (see Section 3-2), M2 macrophages express **arginase-1**, which produces ornithine and proline from arginine. Along with other factors, ornithine increases the contractility of mucosal smooth muscle and promotes tissue remodeling and repair (see Fig. 11.15). Through a mechanism that is unclear, ornithine has also been found to be directly toxic to IgG-coated larvae of certain helminths. Because helminths that have invaded tissues are too large to be ingested by macrophages, the targeted release of toxic mediators directly onto the worm by antibody-dependent cell-mediated cytotoxicity (ADCC) enables macrophages, as well as eosinophils (discussed shortly), to attack these large extracellular pathogens.

Macrophages activated by T_H2 cells also appear to be important in walling off invading worms and in repairing tissue damage caused as worms migrate through host tissues. These 'tissue repair' functions of M2 macrophages are dependent on secreted factors important in tissue remodeling and include the stimulation of collagen production, formation of which requires proline generated by arginase-1 activity. Moreover, T_H2-activated macrophages can also induce the formation of granulomas that entrap worm larvae in tissues. In this regard, antigen-specific macrophage activation by T_H2 cells has non-redundant function in type 2 responses. Although ILC2 cells and innate effector cells may promote M2 macrophage activation via IL-13, they appear to be unable to sustain this response, at least in part because they are sessile and unable to engage and directly deliver cytokines to antigen-bearing macrophages through cell–cell contacts. Thus, in several models of worm infection, anti-helminth responses are considerably impaired in Rag-deficient or T cell–depleted mice, demonstrating that sustained and optimal alternative activation of macrophages requires T_H2 cells.

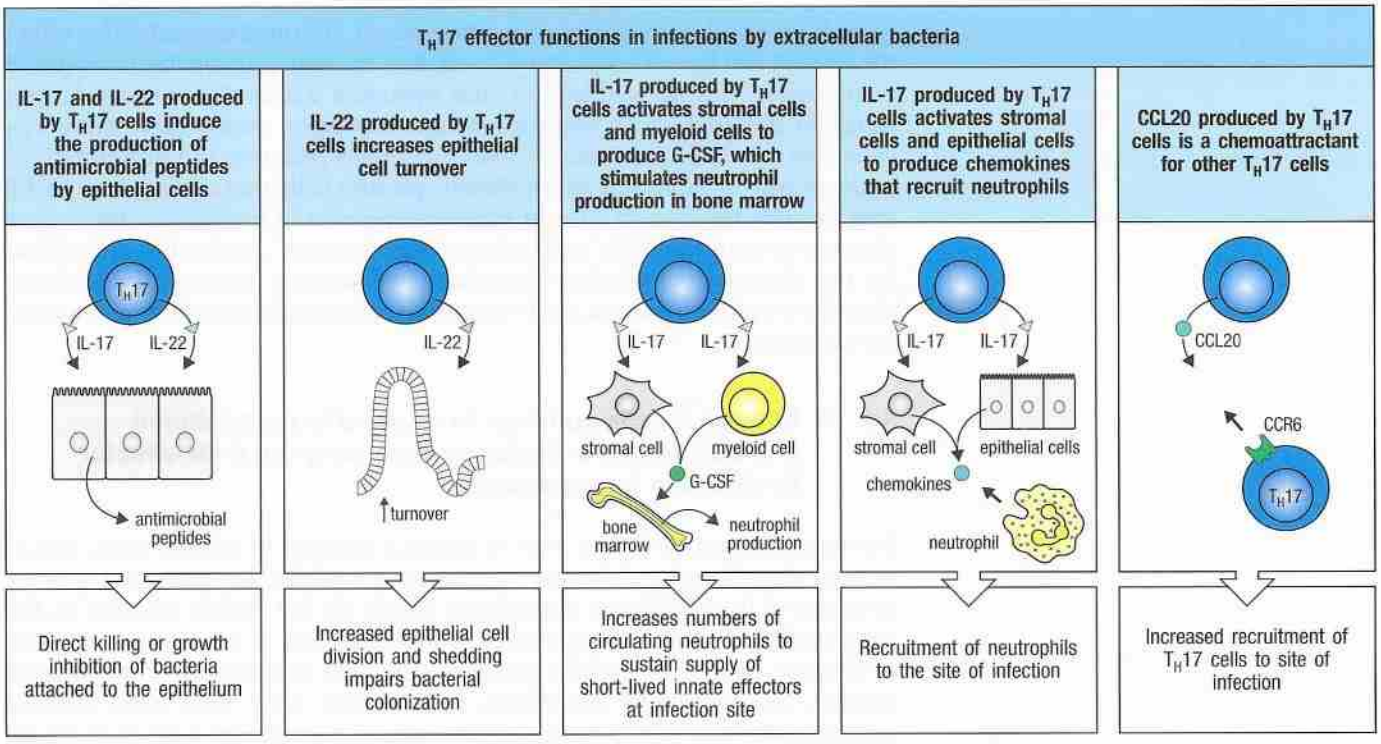
The IL-5 produced by T_H2 cells and ILC2 cells recruits and activates eosinophils (see Fig. 11.14), which have direct toxic effects on worms via the release of cytotoxic molecules stored in their secretory granules, such as major basic protein (MBP). In addition to Fcε receptors that arm them for degranulation via bound IgE, eosinophils bear Fc receptors for IgG and IgA and can mediate ADCC against IgG- and IgA-coated parasites (see Fig. 10.38). They also express the Fcα receptor (CD89) and degranulate in response to stimulation by secretory IgA.

IL-3 and IL-9 produced by T_H2 cells in the mucosae recruit, expand, and activate a specialized population of mast cells known as **mucosal mast cells** (see Fig. 11.14). The innate cytokines IL-25 and IL-33 also activate mucosal mast cells early in a response to helminths. Mucosal mast cells differ from their counterparts in other tissues by having only small numbers of IgE receptors and producing very little histamine. When activated by cytokines or by the binding of worm antigens to receptor-bound IgE, mucosal mast cells release large amounts of preformed inflammatory mediators that are stored in secretory granules: prostaglandins, leukotrienes, and several proteases, including the mucosal mast cell protease (MMCP-1), which can degrade the epithelial tight junctions to increase epithelial permeability and enable fluid flow into the mucosal lumen. Together, the mast cell–derived mediators increase vascular and epithelial permeability, increase intestinal motility, stimulate the production of mucus by goblet cells, and induce leukocyte recruitment, all of which contribute to the 'weep-and-sweep' response that helps to expel parasites from the host.

11-11 T_H17 cells coordinate type 3 responses to enhance the clearance of extracellular bacteria and fungi.

The subset of effector T cells generated in response to infection by extracellular bacteria and fungi is T_H17, so-named because of its unique production of IL-17 among CD4 T-cell subsets. At homeostasis, T_H17 cells are deployed almost exclusively in the intestinal mucosa, where they contribute to the mutualistic relationship between the host and the intestinal microbiota—which is composed of extracellular bacteria and some fungi. However, they are also critical for defense against pathogenic extracellular bacteria and fungi that invade at barrier sites as well as components of the normal microbiota that may enter the host when epithelial barrier function is compromised, whether as the result of trauma or pathogenic infection. In these settings, a principal function of T_H17 cells is the orchestration of type 3 responses, in which neutrophils are the principal innate effector cell.

As discussed in Chapter 9, the development of T_H17 cells is guided by the combined actions of TGF-β and the pro-inflammatory cytokines IL-6, IL-1, and IL-23 (see Fig. 9.34). In the intestines of mice, these cytokines are preferentially produced by cDC2 cells that recognize PAMPs produced by extracellular bacteria, such as flagellin, which is recognized by TLR-5, or PAMPs produced by fungi, such as β-glucan polymers of glucose expressed by yeast and fungi that are recognized by Dectin-1. As for T_H1 and T_H2 cells, the egress of T_H17 cells from secondary lymphoid tissues is associated with altered chemokine expression: primarily the induction of CCR6, the ligand for which (CCL20) is produced by activated epithelial cells in mucosal tissues and skin, and by T_H17 cells themselves and ILC3 cells (Fig. 11.16; and see Fig. 11.5). Also like T_H1 and T_H2 cells, T_H17 cells primed in secondary lymphoid tissues may require additional maturational signals within inflamed tissues to which they are recruited for full effector function (for example, IL-23).



T_H17 effector functions in infections by extracellular bacteria
IL-17 and IL-22 produced by T_H17 cells induce the production of antimicrobial peptides by epithelial cells

Fig. 11.16 The immune response to extracellular bacteria and some fungi is coordinated by activated T_H17 cells. T_H17 cells activated by antigen-bearing macrophages and dendritic cells in barrier tissues (for example, intestinal or respiratory mucosae, urogenital tract, and skin) produce cytokines that activate local epithelial and stromal cells to coordinate the immune response to extracellular bacteria and some types of fungi.

T_H17 cells are stimulated to release IL-17A and IL-17F when activated by antigen at sites of infection (see Fig. 11.16). A primary effect of these cytokines is the enhanced production and recruitment of neutrophils. The receptor for IL-17A and IL-17F is expressed widely on cells such as fibroblasts, epithelial cells, and keratinocytes. IL-17 induces these cells to secrete various cytokines, including IL-6, which may amplify and sustain the T_H17 response, and the hematopoietic factor granulocyte colony-stimulating factor (G-CSF), which increases the production of neutrophils by the bone marrow. IL-17 also stimulates production of the chemokines CXCL8 and CXCL2, the receptors for which (CXCR1 and CXCR2) are primarily expressed by neutrophils (see Fig. 11.8). Thus, one important action of IL-17 at sites of infection is to induce local cells to secrete cytokines and chemokines that attract neutrophils—a function shared with ILC3 cells.

T_H17 cells also produce IL-22, a member of the IL-10 family that acts cooperatively with IL-17 to induce the expression by epithelial cells of antimicrobial proteins (see Fig. 11.16). These include β-defensins and the C-type lectins, Reg3β and Reg3γ, all of which can directly kill bacteria (see Section 2-4). IL-22 and IL-17 can also induce epithelial cells to produce metal-binding proteins that are bacteriostatic and fungistatic. **Lipocalin-2** limits iron availability to bacterial pathogens; S100A8 and S100A9 are two antimicrobial peptides that heterodimerize to form the antimicrobial protein **calprotectin**, which sequesters zinc and manganese from microbes. Many of these antimicrobial agents are also produced by neutrophils recruited to the site of infection; calprotectin has been reported to compose up to a third of the cytosolic protein of neutrophils. IL-22 also stimulates the proliferation and shedding of epithelial cells as a mechanism to deprive bacteria and fungi of a 'foothold' for colonization at epithelial surfaces. While ILC3 cells in barrier tissues respond rapidly to pathogens to produce IL-22, pathogen-specific T_H17 cells have been shown to amplify and sustain the production of IL-22 at sites of infection.

As in type 1 and type 2 responses, integration of innate and adaptive effector cells in the type 3 response is mediated in large part by the production of pathogen-specific antibodies that opsonize extracellular bacteria and fungi for destruction by neutrophils, macrophages, and complement. T_{FH} cells that develop coordinately with T_H17 cells promote the production of high-affinity IgG and IgA antibodies by plasma cells that can express CCR6 and thereby localize to sites of type 3 responses in barrier tissues, where they can arm neutrophils and macrophages 'on-site.' Antibodies are critical for the clearance of primary infections by common extracellular bacteria that elicit type 3 responses, such as *Staphylococcus aureus* and *Streptococcus pneumoniae*.

11-12 Effector T cells continue to respond to maturational and maintenance signals as they carry out their effector functions in target tissues.

The commitment of CD4 T cells to distinct lineages of effector cells occurs in secondary lymphoid tissues, such as lymph nodes. However, the effector activities of these cells are not defined simply by the signals received in the lymphoid tissues. Increasing evidence indicates that at least some activities of effector CD4 T cells—and perhaps also their maintenance in inflamed tissues—are contingent on signals they receive once they enter sites of infection. In view of the potential for each of the effector subsets to cause immune-mediated disease, about which we will learn more in Chapters 14 and 15, this requirement likely reflects the need for tissue checkpoints that provide ongoing regulation of effector T-cell functions to minimize the risk of allergy or autoimmunity.

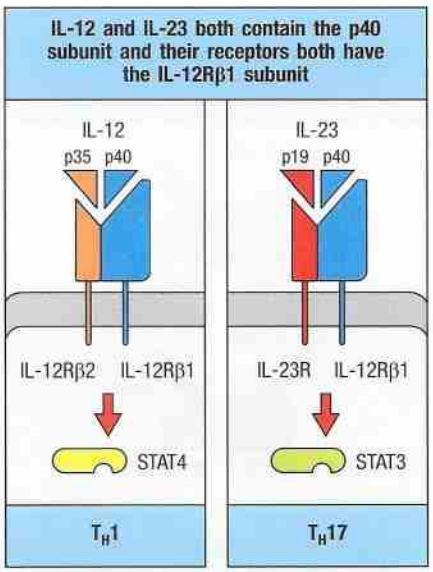

Fig. 11.17 The cytokines IL-12 and IL-23 have a component in common, as do their receptors. The heterodimeric cytokines IL-12 and IL-23 both contain the p40 subunit, and the receptors for IL-12 and IL-23 have in common the IL-12Rβ1 subunit, which binds the p40 subunit. IL-12 signaling primarily activates the transcriptional activator STAT4, which increases IFN-γ production. IL-23 primarily activates STAT3, but also activates STAT4 weakly (not shown). Both cytokines augment the activity and/or proliferation of the CD4 subsets that express receptors for them; T_H1 cells express IL-12R, and T_H17 cells express primarily IL-23R, but can also express low levels of IL-12R (not shown). Mice deficient in p40 lack expression of both of these cytokines and manifest immune defects as a result of deficiencies in both T_H1 and T_H17 activities.

As we have seen, commitment of naive T cells to become T_H1, T_H2, or T_H17 cells is triggered by antigenic priming in the context of different inductive cytokines: IFN-α/β or IFN-γ; IL-4; or TGF-β and IL-6, respectively. These initial conditions appear insufficient, however, to generate complete or fully effective responses. To complete effector differentiation, each T-cell subset also requires stimulation by another cytokine: IL-12 in the case of T_H1 cells; IL-23 in the case of T_H17 cells; and probably TSLP in the case of T_H2 cells. Note that each of these cytokines also plays a role in activation of the corresponding ILC subset. As will be discussed in Section 11-13, each of these STAT-activating cytokines can also act in concert with a pro-inflammatory NFκB-activating cytokine (for example, IL-18 for T_H1 cells or IL-1 for T_H17 cells) to induce some functions of their target effector T cell.

In the case of T_H1 and T_H17 cells, the cytokines IL-12 and IL-23 are closely related in structure; each is a heterodimer, and they have a subunit in common (Fig. 11.17). IL-12 is composed of one p40 (IL-12p40) and one p35 (IL-12p35) subunit, whereas IL-23 has the p40 (IL-12p40) subunit and a unique p19 (IL-23p19) subunit. T_H1 cells express the receptor for IL-12; T_H17 cells express the receptor for IL-23. As will be discussed later (Section 11-14), T_H17 cells can also express low levels of the receptor for IL-12, which has important implications for their terminal differentiation. As for the ligands, the receptors for IL-12 and IL-23 are also related. They have a common subunit, IL-12Rβ1, which is expressed by naive T cells and binds the shared IL-12p40 subunit of IL-12 and IL-23. Upon receipt of differentiating cytokine signals, developing T_H1 cells synthesize IL-12Rβ2, the inducible component of the mature IL-12 receptor heterodimer, which binds the IL-12p35 subunit of IL-12; T_H17 cells synthesize IL-23R, the inducible component of the mature IL-23 receptor, which binds IL-23p19.

IL-12 and IL-23 play important roles in the maturation and functional activities of T_H1 and T_H17 cells, respectively. Like many other cytokines, both act through the JAK-STAT intracellular signaling pathway (see Fig. 9.35). IL-23 signaling primarily activates the intracellular transcriptional activator STAT3, but it also activates STAT4. In contrast, IL-12 strongly activates STAT4, with minimal activation of STAT3. IL-23 does not initiate the commitment of naive CD4 T cells to become T_H17 cells, but it does stimulate their expansion and contributes to their maintenance and full effector activities. Many *in vivo* responses that depend on IL-17 are diminished in the absence of IL-23. For example, mice lacking the IL-23–specific subunit p19 show decreased production of IL-17A and IL-17F in the lung after infection by *Klebsiella pneumoniae*.

While IL-12 contributes to the early development of T_H1 cells, it also appears to contribute to the effector activity of committed T_H1 cells at sites of infection. Studies of two different pathogens have shown that the initial differentiation of T_H1 cells is not sufficient for protection and that continual signals may be required. Mice deficient in IL-12p40 can resist initial infection by *Toxoplasma gondii* as long as IL-12 is administered continually. If IL-12 is administered during the first 2 weeks of infection, p40-deficient mice survive the initial infection and establish a latent chronic infection characterized by cysts containing

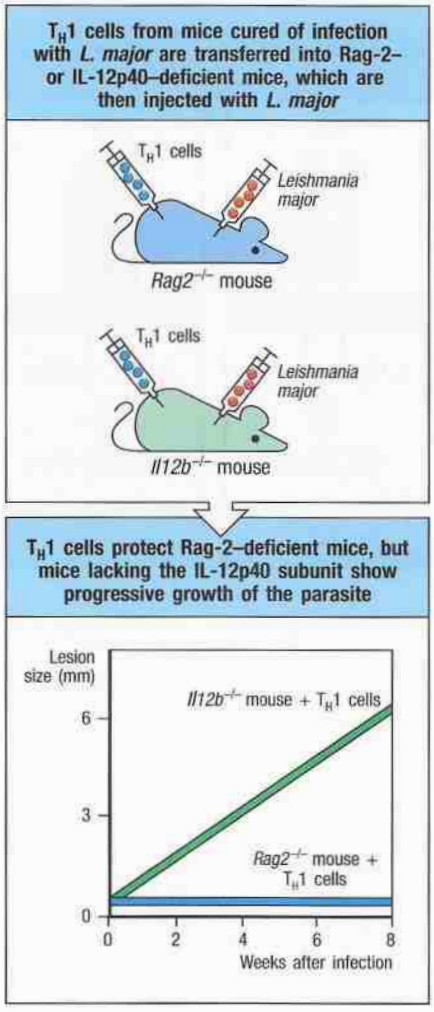

Fig. 11.18 Continual IL-12 is necessary for resistance to pathogens requiring T_H1 responses. Mice that have eliminated an infection with *Leishmania major* and have generated T_H1 cells specific to the pathogen were used as a source of T cells that were adoptively transferred either into Rag-2–deficient (*Rag2*$^{-/-}$) mice, which lack T cells and B cells and cannot control *L. major* infection but can produce IL-12, or into mice lacking IL-12p40 (*Il12b*$^{-/-}$), which cannot produce IL-12. On subsequent infection of the Rag-2–deficient mice, lesions did not enlarge because the transferred T_H1 cells conferred immunity. But despite the fact that the transferred cells were already differentiated T_H1 cells, they did not confer resistance to IL-12p40–deficient mice, which lacked a source of IL-12 to support T_H1 function.

the pathogen. When IL-12 administration is stopped, however, these mice gradually reactivate the latent cysts and the animals eventually die of toxoplasmic encephalitis. IFN-γ production by pathogen-specific T cells decreases in the absence of IL-12 but can be restored by IL-12 administration. Similarly, the adoptive transfer of differentiated T_H1 cells from mice cured of *Leishmania major* protects Rag-deficient mice infected by *L. major*, but it cannot protect IL-12p40–deficient mice (Fig. 11.18). Together, these experiments indicate that T_H1 cells continue to respond to signals after their initial priming and that continual IL-12 may be needed to sustain the effectiveness of differentiated T_H1 cells against at least some pathogens.

T_H2 cells also appear to receive cytokine signals that are important for their full effector function and/or maintenance in inflamed tissues. Although details of their specific roles remain to be defined, TSLP, IL-33, and IL-25 have all been implicated in the late maturation of T_H2 cells after their entry into sites of type 2 inflammation. It has also been shown that TSLP, the receptor for which is expressed by naive CD4 T cells, may promote the differentiation of a subset of T_H2 cells that express IL-15, IL-5, and IL-9 without IL-4, raising the possibility that under conditions of high production of TSLP, differentiation of T_H2 cells is favored at the expense of type 2 T_{FH} cells.

11-13 Effector T cells can be activated to release cytokines independently of antigen recognition.

A central paradigm in adaptive immunity is the requirement for antigen recognition by the cognate receptors of naive lymphocytes to induce their differentiation into mature effector cells. However, effector T cells also acquire the ability to be activated by pairs of cytokines, independently of antigen recognition by their T-cell receptor. The cytokine pairs that mediate this 'noncognate' function of differentiated effector cells appear to be the same as those that activate the ILC subset that parallels each T-cell subset (Fig. 11.19). And in each case, the pair of stimulating cytokines includes one cytokine that activates a receptor that signals via a STAT factor, and one that activates a receptor that signals via NFκB—typically a member of the IL-1 receptor family. Thus, for both T_H1 cells and ILC1 cells, stimulation by IL-12 (STAT4) plus IL-18 induces production of IFN-γ. Similarly, stimulation of T_H2 and ILC2 cells by TSLP (STAT5) plus IL-25 or IL-33 produces IL-5 and IL-13. T_H2 cells, like ILC2 cells, also express the CRTH2 receptor for prostaglandin D2 (PGD2), and can be induced to express their effector cytokines by coordinate activation with PGD2 plus IL-33. Finally, both T_H17 and ILC3 cells produce IL-17 and IL-22 when stimulated by IL-23 (STAT3) plus IL-1.

In this way, mature effector CD4 T cells can acquire innate-like functional properties that allow them to amplify different types of immune responses without the requirement for antigen recognition. Note that in the case of type 1

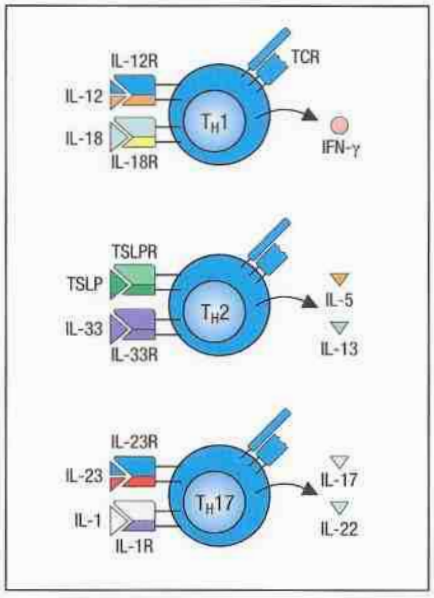

Fig. 11.19 Effector T cells can be activated to release cytokines independently of antigen recognition. Analogous to ILCs, effector T cells can be stimulated to produce effector cytokines independently of T-cell receptor signaling via the coordinate actions of pairs of cytokines.

and type 3 cells, the IL-1 family member involved (IL-18 and IL-1, respectively) is produced by inflammasome activation in myeloid cells. Conversely, IL-33, which activates type 2 responses, is inactivated by the inflammasome, indicating another basis for counterregulation between type 2 and type 1 or type 3 immune responses and suggesting that IL-33 favors tissue repair. Although the precise role of noncognate activation of effector T cells by cytokines is not clearly defined, it may provide a mechanism to augment effector T-cell function during active tissue inflammation in primary responses. It may also be a means by which tissue-resident memory T cells that remain in nonlymphoid tissues after clearance of pathogen in a primary response could be rapidly recruited in recall, or memory, responses in an antigen-independent manner (see Section 11-20), essentially serving innate-like functions similar to ILCs.

11-14 Effector CD4 T cells demonstrate plasticity and cooperativity that enable adaptation during antipathogen responses.

Thus far we have discussed subsets of effector CD4 T cells as though they are intrinsically stable, such that their functional phenotype is unchanging after their development. Similarly, we have discussed the different types of immunity as though they are unimodal; that is, only one type of response is recruited to clear a given pathogen. Although this is often the case, it is not always so. Just as the pathogens can modify their tactics to evade destruction, so too can the elicited effector T cells adapt in order to clear these pathogens. Adaptation can occur by flexibility in the programming of individual T cells, referred to as **T-cell plasticity**, wherein effector T cells can transition into different cytokine phenotypes contingent on changes in the local inflammatory environment. It can also occur as a result of cooperation between different subsets of T cells. Plasticity applies to cells of the same clonal origin and thus identical antigenic specificity, whereas cooperation applies to cells that develop from different clonal precursors and target different antigens, typically at different stages of an infection.

Although some degree of plasticity has been experimentally demonstrated for each of the major effector CD4 subsets, it appears to be most prevalent in type 3 responses. It is common for T_H17 cells to deviate, or be 'reprogrammed,' into T_H1-type cells—a process referred to as **transdifferentiation** (Fig. 11.20). Transdifferentiation was discovered using cytokine reporter mice, in which T_H17 cells that express IL-17F could be identified and isolated on the basis of their expression of a cell-associated reporter molecule controlled by the gene *Il17f*. When T_H17 cells isolated using the reporter were restimulated in the presence of the T_H1-polarizing cytokine IL-12, their progeny rapidly lost expression of IL-17 and acquired expression of IFN-γ. Moreover, repetitive restimulation of T_H17 cells with the T_H17 lineage cytokine IL-23 could lead to a subset of progeny that also acquired features of T_H1 cells. In both cases, transdifferentiation of T_H17 cells into T_H1 cells required expression of the T_H1-associated transcription factor Tbet and loss of the T_H17-associated transcription factor RORγt, both of which were contingent on activation of STAT4 by the IL-12 and IL-23 receptors. Thus, T_H17 cells deficient for either Tbet or STAT4 failed to transdifferentiate into T_H1 cells; that is, they lost their intrinsic 'T_H17-cell plasticity.' Recent studies have suggested that type 3 ILCs may similarly undergo an ILC3 to ILC1 transition, although this has been difficult to prove experimentally.

An example of the importance of effector T-cell plasticity and cooperativity between subsets is found in host protection against facultative intracellular bacterial pathogens, such as *Salmonella*, which, unlike obligate extracellular bacteria, have also evolved mechanisms to survive within macrophages that are not activated by IFN-γ. Early in infection, *Salmonella* can colonize the intestinal epithelium similarly to other enteric Gram-negative pathogens. During this period, a T_H17 response dominates, resulting in a robust IL-17– and

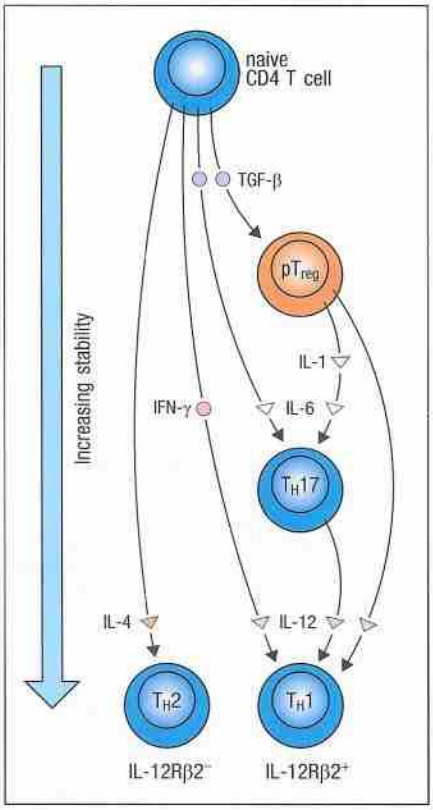

Fig. 11.20 Plasticity of CD4⁺ T-cell subsets. There is a hierarchy of stability of effector and regulatory CD4 T cells. Naive CD4⁺ T cells are multipotent, whereas T_H1 and T_H2 cells appear to be relatively stable, or at 'ground state'; that is, they are highly resistant to transitioning into other effector-cell phenotypes. Peripheral regulatory T (pT_{reg}) cells and T_H17 cells are less stable and can transition into other subsets, depending on prevailing cytokines. When acted on by IL-6 and IL-1, pT_{reg} cells can transition, or 'transdifferentiate,' into T_H17 cells, or when acted on by IL-12, they can become T_H1 cells. T_H17 cells acted on by IL-12 can transition into T_H1 cells. Notably, the transdifferentiation of pT_{reg} cells into T_H17 cells or of T_H17 cells into T_H1 cells appears to be unidirectional, or irreversible. Developing T_H2 cells (left) repress expression of the inducible component of the IL-12 receptor (IL-12Rβ) and are unresponsive to IL-12; pT_{reg}, T_H17, and T_H1 subsets (right) remain responsive to IL-12.

IL-22–induced influx of neutrophils that engulf extracellular bacteria and the release of antimicrobial proteins that restrain bacterial growth in the intestinal lumen. During this intestinal phase of infection, much of the T-cell response appears to be directed against antigenic epitopes within bacterial flagellins, which are potent activators of TLR-5. Activation of this innate sensor promotes IL-23 expression by cDC2 cells in the intestine, thereby inducing a type 3 immune response. Flagellin-specific T_H1 cells also emerge during the early intestinal phase of infection and may arise from T_H17 cell precursors as a result of plasticity. To escape destruction by macrophages activated for intracellular killing by these 'ex-T_H17' T_H1 cells, *Salmonella* simultaneously down-regulates the expression of flagellin and begins synthesizing new proteins, such as SseI and SseJ, that suppress intracellular killing within macrophages. This allows *Salmonella* to both evade detection by flagellin-specific T cells and use the host macrophage as a safe haven to shield it from extracellular killing—at least temporarily—as the infection spreads systemically.

During the systemic phase of the infection, the T-cell response shifts to become focused on those antigens that enable the intracellular lifestyle of the pathogen. Some of these newly expressed antigens appear to activate cytosolic sensors within cDC1 cells, which produce IL-12 to activate pathogen-specific T_H1 cells and a type 1 response. The pathogen can now be cleared by T_H1-induced macrophage activation directed against these newly expressed antigens. Because the antipathogen response now includes both type 3 and type 1 immunity to different sets of antigens that the bacterium requires for its extracellular and intracellular lifestyles, *Salmonella* is deprived of a niche for its survival and is cleared from the host.

11-15 Integration of cell- and antibody-mediated immunity is critical for protection against many types of pathogens.

The type of effector response required for host protection depends on the infectious strategy and lifestyle of the pathogen. Central to the integration of innate immunity and adaptive immunity in each immune module is the production of pathogen-specific, class-switched antibodies. Antibodies can function directly to neutralize pathogens and/or their toxins and can activate microbicidal actions of the complement pathway. They can also act indirectly by enhancing the uptake and destruction of pathogens by phagocytes in type 1 and type 3 responses or by arming innate immune effector cells to direct their degranulation in the context of type 2 responses (**Fig. 11.21**; and see Sections 10-22 through 10-25 and Sections 11-6 through 11-11). Although the signals that control the developmental fate of T_{FH} cells are yet to be fully characterized, there appears to be overlap with signals controlling the development of each subset of non-T_{FH} effector CD4 T cells. Accordingly, many of the same subset-specific cytokines produced by non-T_{FH} effector cells to modulate the antimicrobial actions of different innate effector cells are produced by T_{FH} cells to direct B-cell class switching to specific antibody isotypes that are targeted to the same innate effector cells. Thus, whereas IL-21 produced by most T_{FH} cells induces class switching to IgG1—a component of each of the helper immune response types (for example, types 1, 2, and 3)—IL-4 produced by T_{FH} cells in type 2 responses is required for IgE class switching, and IFN-γ produced by type 1 T_{FH} cells promotes IgG2 (mouse) or IgG3 (human) class switching while repressing IgE class switching. The coordinated differentiation of T_{FH} with non-T_{FH} effector T cells thus results in antibody isotypes that are appropriately matched to the types of innate effector cells that dominate each type of infection to enhance their functions.

As we learned in Chapter 10, the targeting of specific antibody isotypes to different innate effector cells is determined by the pattern of Fc receptors (FcRs) they express (see Fig. 11.21). In this way, different antibody isotypes

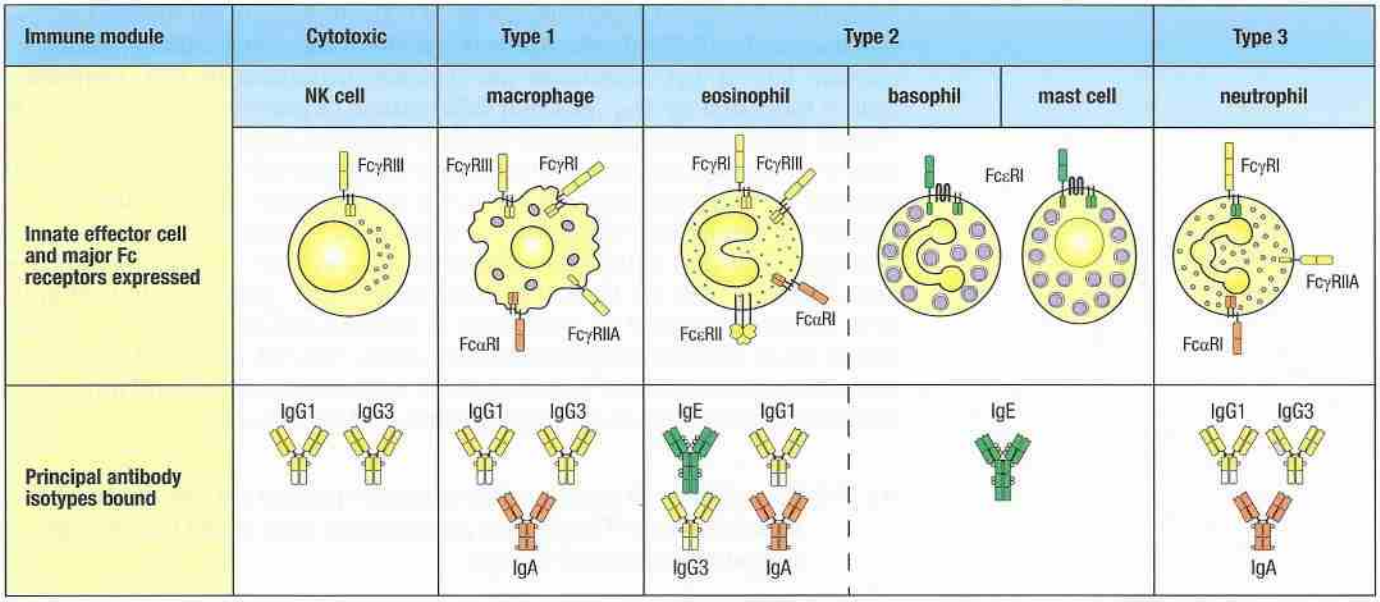

Fig. 11.21 The innate effector cells of each immune module are armed by different antibody isotypes on the basis of the pattern of Fc receptors they express. See text for details.

preferentially activate different innate effector cells. The affinity of the FcR for each immunoglobulin Fc region it recognizes dictates whether the receptor binds free antibody or requires prior binding of the antibody to multivalent antigen (see Section 10-21 for more detailed discussion). For most FcRs, the binding affinity for Fc regions is such that antibody is only bound in aggregate. For high-affinity FcRs, such as FcεRI, free antibody can be bound and becomes, in essence, an antigen-specific receptor that couples antigen recognition (via antibody) to Fc-receptor signaling. Irrespective of the mode of antibody isotype binding, FcR signaling requires cross-linking by multivalent antigen and, in the case of ITAM-coupled FcRs, activates the innate effector cell.

In the case of phagocytic innate effector cells, such as macrophages or neutrophils, opsonizing IgG isotypes produced in type 1or type 3 responses promote the phagocytosis and destruction of antibody-decorated pathogens by activating Fcγ receptors (for example, FcγRI or FcγRIIA). This enables phagocytic targeting of extracellular bacteria—or intracellular bacteria as they move from cell to cell, and may be particularly important for clearing small numbers of remaining bacteria toward the end of the antipathogen response. Opsonizing and complement-fixing antibodies are critical for clearance of many encapsulated extracellular bacteria, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*, which evade alternative pathway activation and uptake by phagocytes.

Binding of IgG1 to the same Fc receptors on eosinophils induces the targeted release of eosinophilic granules onto IgG1-decorated parasites rather than phagocytosis. IgE, which is bound with high affinity by FcεRI expressed on basophils and mast cells or by FcεRII on eosinophils, is uniquely induced by type 2 T_{FH} cells that produce IL-4 and recognizes free- or pathogen-associated antigens to stimulate granule and lipid mediator release from these innate effector cells. Similarly, IL-5 produced by type 2 T_{FH} cells induces IgA, which binds to FcαRI on eosinophils. Thus, the antibody isotypes induced in the context of a type 2 response are critical to amplification and focusing of the anti-parasite response by nonphagocytic innate effector cells.

Specific antibody isotypes are also important in defense against many of the intracellular pathogens that provoke a cytotoxic immune response,

particularly viruses. Despite the ability of CTLs to directly kill infected cells—and the inability of CD8 T cells to provide help for B cells—high-affinity, pathogen-specific IgG or IgA antibodies are typically generated in CTL responses. This is mediated by T_{FH} cells that differentiate in parallel with effector CD8 T cells. Although the generation of class-switched antibodies generally lags that of CTLs—and in some viral infections the initial infection may be cleared without an antibody response—the role of antibodies in viral clearance is critical for host defense against some viruses (for example, Ebola virus). IgG1 and IgG3 produced in the context of cytotoxic and type 1 responses also arm NK cells for ADCC via FcγRIII (CD16). In this way, pathogen-derived antigens that are expressed on the surface of infected cells can target the cells for killing by an antibody-dependent mechanism. NK cell–mediated ADCC has been shown to contribute to host defense against several viral and intracellular bacterial infections, including influenza and *Salmonella*.

11-16 Resolution of an infection is accompanied by the death of most effector T cells and persistence of a small number of long-lived memory T cells.

When a pathogen is eliminated by an immune response, so too are the pathogen-specific antigens that drive the clonal expansion and differentiation of effector T cells. In the absence of antigen, and as a consequence of its loss, most effector T cells undergo apoptotic cell death, removing themselves from the T-cell repertoire (see Fig. 9.23). In mice, greater than 90% of clonally expanded T cells die upon clearance of specific antigen. As we will discuss later, the cells that persist following this 'clonal contraction' are **memory T cells**. Although details of the mechanisms resulting in clonal contraction of effector T cells remain incompletely understood, it appears to be due, at least in part, to the loss of pro-survival signals that are produced by ongoing antigenic stimulation and/or cytokine signaling.

One signal that is contributed by T-cell receptor (TCR) stimulation is the production of IL-2, which is lost with the loss of antigen. Also, expression of the high-affinity component of the IL-2 receptor (IL-2Rα, or CD25) by TCR signaling is transient, such that ongoing antigen recognition is required for efficient IL-2 signaling. One consequence of IL-2 signaling is the expression of the anti-apoptotic survival factor Bcl-2, which prevents activation of the **intrinsic (or mitochondrial) pathway of apoptosis** that leads to assembly of the apoptosome (see Section 9-21 and Fig. 9.45). Thus, loss of IL-2 production and/or loss of CD25 result in down-regulation of Bcl-2 and heightened susceptibility to intrinsic apoptotic death. Moreover, most naive T cells lose expression of the specific component of the IL-7 receptor, **IL-7Rα (CD127)**, soon after activation. Like IL-2 signaling, IL-7 signaling activates STAT5, which promotes expression of Bcl-2. Thus, as IL-2 signaling is lost with the decline in antigen, effector T cells cannot be 'rescued' by IL-7 signaling and may undergo activation of the intrinsic pathway of apoptosis (see Fig. 9.45). However, other pathways must be important, as mice deficient for IL-2Rβ also undergo clonal expansion and contraction, and mice with enforced expression of IL-7Rα are not rescued from clonal contraction.

A second mechanism that can contribute to effector T-cell death is activated by signaling via members of the TNF receptor superfamily, such as Fas (CD95), which can activate the **extrinsic (or death receptor) pathway of apoptosis** (see Fig. 9.45). Coupling of Fas signaling to the apoptosis pathway is inhibited by the cellular caspase 8–like inhibitory protein (c-FLIP), which is induced by TCR signaling. As TCR signaling is lost, c-FLIP expression declines, and Fas signaling can now be coupled to the **death-inducing signaling complex (DISC)**, resulting in Fas ligand (FasL)-induced apoptosis. Loss-of-function mutations in *Fas* or *FasL* lead to the increased survival of lymphocytes and

is one cause of the disease **autoimmune lymphoproliferative syndrome, or ALPS** (see Section 9-21).

The relative contribution of the intrinsic and extrinsic apoptotic pathways to effector T-cell loss appears to depend on the infectious agent, but they appear to be complementary mechanisms, as mice with specific deficiencies targeting one of these two pathways have milder defects in T-cell clearance than mice with deficiencies of both. Irrespective of the apoptotic pathway induced, dying T cells are rapidly cleared by phagocytes that recognize the membrane lipid phosphatidylserine on their surface. This lipid is normally found only on the inner surface of the plasma membrane, but in apoptotic cells it rapidly redistributes to the outer surface, where it can be recognized by specific receptors on many cells. Thus, not only is the pathogen removed at the end of infection, but also most of the pathogen-specific effector T cells are also removed. Some of the pathogen-specific effector T cells survive, however, and provide the basis for memory T-cell responses, as will be discussed in the next part of the chapter.

Summary.

Effector CD4 T cells develop in response to, and subsequently amplify and sustain, innate immune responses that are induced by pathogens. Pathogen-derived antigens are transported to local lymphoid organs by migratory dendritic cells or freely in lymph to be taken up by lymphoid-resident DCs and are presented to antigen-specific naive T cells that continually recirculate through the lymphoid organs. T-cell priming and the differentiation of effector T cells occurs here, and the effector T cells either leave the lymphoid organ to provide cell-mediated immunity at sites of infection in the tissues or remain in the lymphoid organ to participate in humoral immunity by activating antigen-binding B cells. Distinct types of CD4 T cells develop in response to infection by different types of pathogens, and their development is influenced largely by the cytokines produced by innate sensor cells and ILCs that are activated early in the response.

Effector CD4 T cells serve to amplify and enhance early innate responses orchestrated by ILCs, while T_{FH} cells that develop in concert with each subset of effector T cells direct the production of high-affinity antibodies that arm innate effector cells for heightened pathogen elimination. T_H1 responses promote the development and activation of classical, M1 macrophages to protect against intracellular pathogens. T_H2 responses are directed against infections by parasites such as helminths and promote the development and activation of alternative, M2 macrophages and the recruitment of eosinophils and basophils to sites of infection. T_H17 cells are integral to the clearance of extracellular bacteria and fungi by orchestrating sustained neutrophil recruitment and production of antimicrobial peptides by epithelial cells of barrier tissues such as the intestines, lungs, and skin. CD8 T cells have an important role in protective immunity, especially in protecting the host against infection by viruses and intracellular infections by *Listeria* and other microbial pathogens that have special means for entering the host cell's cytoplasm. Primary CD8 T-cell responses to pathogens usually require CD4 T-cell help but can occur in response to some pathogens without such help. The patterns of antipathogenic response are not fixed, and effector T cells retain plasticity for adapting their response as pathogens alter their survival strategy in response to pressure from the immune system. Ideally, the adaptive immune response eliminates the infectious agent, at which time the expanded clonal populations of effector T cells contract, retaining only small populations of long-lived memory cells, which provide the host with a state of protective immunity against reinfection with the same pathogen.

Immunological memory.

In this part of the chapter, we will examine how long-lasting, protective immunity is maintained after an infection has been successfully eliminated. Immunological memory is a defining consequence of an adaptive immune response; it enables the immune system to respond more rapidly and effectively to pathogens that have been encountered previously and prevents them from causing disease. Memory responses, called secondary immune responses, **tertiary immune responses**, and so on, depending on the number of exposures to antigen, differ from primary responses in rapidity of onset, location, and magnitude. As we will see, immunological memory results from the persistence of antigen-experienced memory T cells that are retained long term at increased clonal precursor frequencies, have altered patterns of recirculation, and more rapidly express their effector functions upon re-challenge by antigen. Selective survival of T-cell clones with higher affinity for pathogen-associated antigens also increases the sensitivity of recall responses to low levels of antigen, and thus to lower pathogen numbers. Similar changes also occur in the B-cell compartment, resulting in increases in the quantity and affinity of pathogen-specific antibodies in a recall, or memory, response.

11-17 Immunological memory is long lived after infection or vaccination.

It has long been appreciated that individuals exposed to a given infectious agent become immune to that agent; they are protected from subsequent challenges by that specific infectious agent but not from challenges by other infectious agents to which they have not been exposed. The phenomenon was first recorded by the ancient Greeks and has been the basis for vaccination programs for more than 200 years. Most children in developed countries are now vaccinated against a number of viral infections (for example, measle, mumps, rubella, and varicella) and bacterial infections (for example, diphtheria and pertussis). Before vaccination was widespread, many were naturally exposed to these pathogens and developed acute, potentially dangerous illnesses. Whether through vaccination or infection, children exposed to these agents acquire long-term or, in some cases, lifelong protection from reinfection; this state of protection is a consequence of immunological memory.

Although immunological memory has been recognized for centuries, its mechanistic underpinnings have only begun to be elucidated recently. Within the past few decades it has become established that immune memory reflects the generation of a small, heterogeneous population of specialized **memory cells** formed during a primary adaptive immune response that can persist for extended periods in the absence of the antigen that originally induced them. Although some infectious agents are never cleared entirely, most are, yet the immune cells that were generated to protect against reinfection are long lived. The idea that immunological memory does not depend on repeated exposure to infection has been supported by observations of populations of people living on remote islands. In that setting, a virus such as measles can cause an epidemic, infecting all people living on the island at that time, after which the virus disappears for many years. On reintroduction from outside the island, the virus does not affect the original population but causes disease in those people born since the first epidemic.

The duration of immunological memory has been estimated in people who received vaccines early in life and have been examined for responses to the immunizing agent much later. Experimental studies in mice have also been used to estimate the duration of immune memory. Perhaps the most compelling data in humans have come from studies of those who received vaccinia, the

virus used to immunize against smallpox (Fig. 11.22). Because smallpox was eradicated by 1977, it is presumed that the responses of vaccinated individuals represent true immunological memory and are not due to restimulation from time to time by the smallpox virus. One study found strong vaccinia-specific CD4 and CD8 T-cell memory responses as long as 75 years after the original immunization, and from the strength of these responses it was estimated that the memory response had an approximate half-life—that is, the time required for a response to diminish to 50% of its original strength—of between 8 and 15 years. By contrast with T-cell memory, titers of antivirus antibody remained stable, almost without measurable decline. Similar to the geographical isolation studies, these findings indicate that immunological memory need not be maintained by repeated exposure to infectious virus, implying that memory is sustained by long-lived, antigen-specific lymphocytes that were induced by the original exposure and persist until a second encounter with the pathogen. As will be discussed later, the developmental origins of memory cells remain the subject of considerable debate, but, at least for memory T cells, it is clear that subsets with differing circulatory behaviors and differing potential for immediate effector functions upon re-challenge by antigen are a common feature.

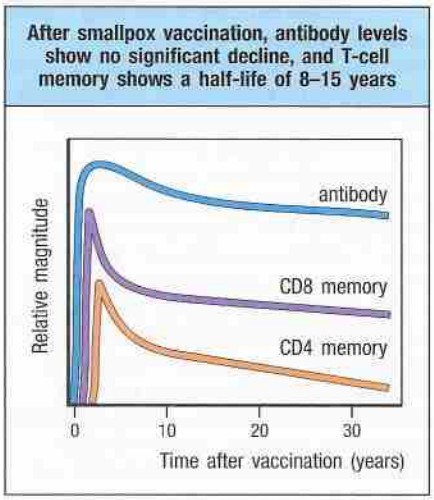

Fig. 11.22 Antiviral immunity after smallpox vaccination is long lived. Because smallpox has been eradicated, recall responses measured in people who were vaccinated for smallpox can be taken to represent true memory in the absence of reinfection. After smallpox vaccination, antibody levels show an early peak with a period of rapid decay, which is followed by long-term maintenance that shows minimal decay. CD4 and CD8 T-cell memory is long lived but gradually decays, with a longer half-life for CD8 T cells.

11-18 MHC tetramers and adoptive transfers of clonal T-cell populations have enabled the study of T-cell memory.

Immunological memory can be measured experimentally in various ways. Historically, analysis of T-cell memory relied on *in vivo* or *ex vivo* assays of T-cell function rather than a direct identification of antigen-specific memory T cells. Some assays of T-cell effector function, particularly those of CD4 T cells, such as providing help to B cells or macrophages, can take several days to perform. For this reason, such assays are not optimal for distinguishing memory T cells from preexisting effector cells, because memory cells may be reactivated during the time frame of the assay.

Two general approaches have been employed in recent years to better define the development and general features of antigen-specific memory T cells: adoptive transfers of limited numbers of naive, monoclonal CD4 or CD8 T cells derived from mice carrying specific T-cell receptor (TCR) transgenes of known peptide:MHC specificity that can be tracked during an antigenic challenge (see Appendix I, Section A-31); and the use of MHC tetramers (see Appendix I, Section A-24). In adoptive transfer studies, antibodies specific to the transgenic TCR or a congenic marker expressed by the transferred T cells, but not by the host T cells, allow the transferred cells to be tracked. MHC tetramers measure the frequency of all endogenous clones with a given peptide:MHC specificity but do not distinguish between different T-cell clones of the same specificity. Therefore, they identify a polyclonal population. MHC tetramers were generated for MHC class I molecules first, in the mid-late 1990s, but are now also available for some MHC class II molecules. Although adoptive transfers of TCR-transgenic T cells permits analysis of a single clonal population, this approach is limited to studies in mice, whereas the use of MHC tetramers allows the study of antigen-specific T cells in both mice and in humans.

Studies using both adoptive transfers of TCR-transgenic T cells and MHC tetramers have allowed a direct analysis of population dynamics during the formation and persistence of antigen-specific memory T cells and of their phenotypic and functional characteristics. In the example shown in Fig. 11.23, T-cell responses to infection by the intracellular bacteria *Listeria monocytogenes* in mice were analyzed with MHC class II tetramers specific to the toxin **listeriolysin O (LLO)**. In the naive T-cell repertoire of the mouse, there are approximately 100 LLO-specific CD4 T cells, which undergo ~1000-fold expansion into effector T cells during the **expansion phase** of about a week

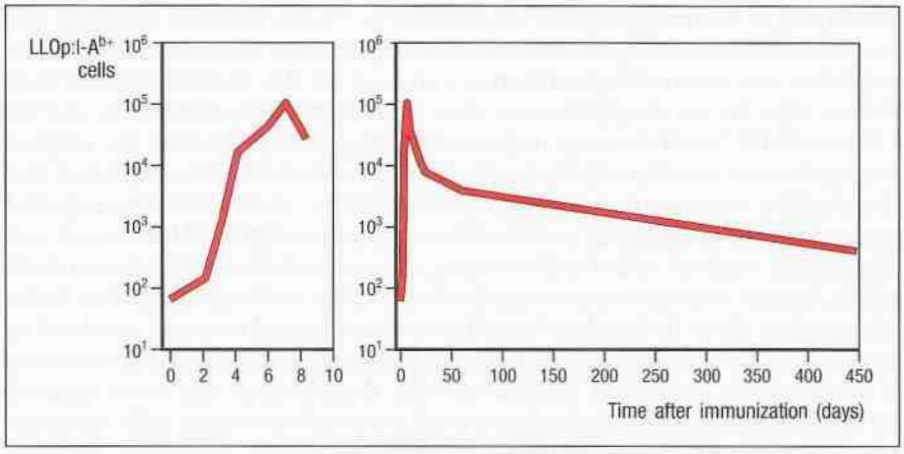

Fig. 11.23 Generation of memory T cells after an infection. After an infection, in this case with an attenuated strain of *Listeria monocytogenes*, the number of T cells specific for the listeriolysin (LLO) virulence factor increases dramatically and then falls back to give a sustained low level of memory T cells. T-cell responses are detected by binding of an MHC tetramer consisting of an LLO peptide bound by I-A^b. The left panel shows the primary response of CD4 T cells that are LLO-specific, and the right panel shows the contraction and memory phase. Approximately 100 T cells in the naive T-cell repertoire expand to about 100,000 effector cells by day 7 (~1000-fold expansion), and then contract to about 7000 memory cells by day 25 (~93% cell loss). These memory cells then slowly decay to ~500 cells by day 450. Data courtesy of Marc Jenkins.

after infection. When the infection is eliminated, a rapid **contraction phase** follows in which LLO-specific T cells are reduced by about 10- to 20-fold over the course of a few weeks. This is followed by a much longer **memory phase**, which results in a population of memory T cells with a half-life of about 60 days, resulting in a frequency about 10-fold higher than that in the naive repertoire after approximately one-half the life span of the mouse (450 days). Similar studies of CD8 T cells in mice infected by lymphocytic choriomeningitis virus (LCMV) show a similar pattern of T-cell expansion, contraction, and memory phases, albeit with greater amplitude of cell number increase at the peak of expansion and in the memory phase, as well as a longer memory-cell half-life.

Studies of humans immunized with the yellow fever virus (YFV) vaccine using peptide:MHC class I tetramers have established that, at least for CD8 T cells, the half-life of individual cells that underwent clonal expansion in response to the YFV vaccine was approximately 3 months, and the average half-life of cell division of these cells was over a year during the memory phase. Thus, memory CD8 T cells in humans demonstrate remarkably slow cell turnover, surviving for extended periods without a requirement for cell division. Accordingly, at any point in time the large majority of memory cells are in an intermitotic phase. In comparison, mouse memory CD8 T cells divide, on average, about 10 times more frequently than memory CD8 T cells in humans, although still quite infrequently.

11-19 The developmental origins of memory T cells parallel those of effector T cells.

Characterization of the numbers and functions of clonal T-cell populations enabled by adoptive transfer and the use of MHC tetramers has established that while there is substantial heterogeneity in the output of the clonal T-cell response, in comparison to their naive precursors the number of memory T cells that persist long-term after antigen clearance is approximately 10- to 100-fold higher. Moreover, at the population level, memory T cells are more sensitive to antigen, they proliferate more rapidly and robustly in response to the same antigen dose, and they more rapidly display heightened effector responses (for example, production of IFN-γ) compared to their naive precursors. Thus, the clonal progeny of naive T cells that become long-lived memory T cells persist at increased numbers and with increased functional capabilities. As we will see in the next section, memory T cells also have a greater range of surveillance capabilities compared to naive T cells; that is, they are not restricted to searching for antigen in secondary lymphoid tissues (see Section 11-20). Collectively, these properties provide a basis for more rapid and effective clonal T-cell responses in secondary and subsequent challenges by the same antigen.

The precise origins of the small fraction of cells that persist as memory T cells as the effector T-cell response subsides has been difficult to determine. Despite approaches that allow the tracking of clonal populations over the course of infection and after its resolution, the heterogeneous nature of the clonal response and the relative rarity of long-lived memory cells has made delineation of memory T-cell development challenging. However, two general models for memory T-cell development have gained favor (Fig. 11.24). In one model, often referred to as the **linear model of memory-cell development**, memory T cells arise from effector T cells as the primary immune response subsides. In a second model, often referred to as the **branching (or asymmetric division) model of memory-cell development**, an antigen-activated naive T cell gives rise to daughter cells that preferentially commit to either the effector- or memory-cell program.

Of course, as with many models of lineage development, these two models are not mutually exclusive, and the developmental origins of individual memory T cells may combine features of both. However, key experimental observations using adoptive transfer studies of CD4 or CD8 T cells in mice indicate that at least some memory T cells arise from effector T-cell precursors, supporting the linear model. In one study that tracked the fate of T_H1 cells and CTLs that expressed an IFN-γ reporter transgene in response to LCMV infection, memory T cells arose from both CD4 and CD8 effector T cells that expressed the IFN-γ

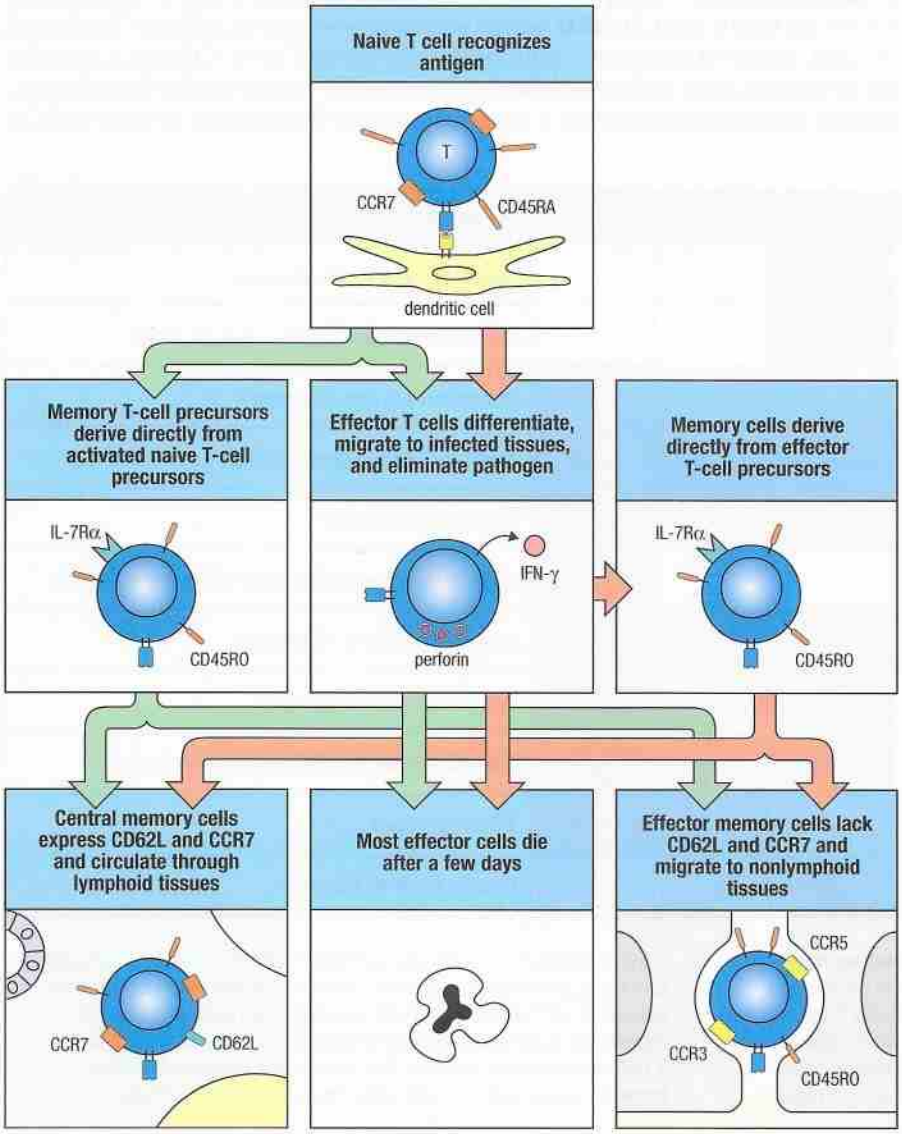

Fig. 11.24 Alternative models for the development of central memory T (T_{CM}) cell and effector memory T (T_{EM}) cell subsets. Memory T cells can arise from activated effector cells (linear model of memory-cell development; red arrows) or directly from activated naive T cells (asymmetric, or branching, model of memory-cell development; green arrows). In both models, most effector T cells generated in a primary response die after the primary response. Two types of memory T cells can arise from a primary T-cell response, irrespective of their origins: central memory T (T_{CM}) cells and effector memory T (T_{EM}) cells. Central memory cells (T_{CM}) express CD62L and CCR7 and recirculate in peripheral lymphoid tissues similarly to naive T cells. When they recognize antigen in lymphoid tissues, a recall response is initiated, and the cells rapidly undergo effector T-cell differentiation over the course of days. Effector memory cells (T_{EM}) lack CD62L and CCR7 and recirculate primarily in blood. They are rapidly recruited into inflamed tissues where they initiate effector T-cell responses after restimulation by cognate antigen. Note that these two models are not mutually exclusive. That is, in a given immune response, both pathways may contribute to the memory T-cell pool.

reporter, demonstrating that long-lived memory CD4 and CD8 T cells could arise from effector T cells. In a second study, it was found that epigenetic repression of genes universally expressed by naive but not effector CD8 T cells, including those encoding L-selectin (CD62L), CCR7, and the IL-7 receptor (CD127), was reversed in memory cells that also bore epigenetic imprinting of genes indicative of mature CTL differentiation—IFN-γ, perforin, and granzymes. This study concluded that memory T cells could arise by 'dedifferentiation' of effector T cells, thereby re-acquiring at least some characteristics of naive T cells. Although these studies did not refute the branching model of memory-cell development, they indicate that at least some memory T cells arise from effector T cells.

11-20 Memory T cells are heterogeneous and include central memory, effector memory, and tissue-resident subsets.

Changes in cell-surface proteins that occur on memory T cells are significant and have been used to characterize major subsets with different tissue recirculation and recall characteristics (Fig. 11.25). While some surface molecules are common to all memory T cells, others are subset-specific and identify memory T cells that share properties with naive or effector T cells. Three subsets of memory T cells have been identified. They include both CD4 and CD8 T cells: **central memory T (T_{CM})** cells; **effector memory T (T_{EM})** cells; and **tissue-resident memory T (T_{RM})** cells. Common markers for all antigen-experienced T cells are **CD44** and **CD45RO**, which are expressed both by effector T cells and by each subset of memory T cells, but not by naive T cells. CD44 is a receptor for hyaluronic acid and other ligands expressed by endothelial cells and extracellular matrix glycoproteins; it may facilitate the localization of these cells to

Protein/Function	Naive	Effector	T_{CM}	T_{EM}	T_{RM}	Comments
CD62L	+++	–	+++	–	–	Selectin for homing to lymph nodes

Fig. 11.25 Expression of many proteins alters when naive T cells become memory T cells. Proteins that are expressed differently in naive T cells, effector T cells, and memory T cell subsets (T_{CM}, T_{EM}, and T_{RM}) include adhesion molecules, which govern interactions with antigen-presenting cells and endothelial cells; chemokine receptors, which affect migration to lymphoid tissues and sites of inflammation; proteins and receptors that promote the survival of memory cells; and proteins that are involved in effector functions, such as granzyme B. Some changes also increase the sensitivity of the memory T cell to antigen stimulation. This list represents a general picture that applies to both CD4 and CD8 T cells in mice and humans, but some details that may differ between these sets of cells have been omitted for simplicity.

peripheral tissues, although its exact function is not known. Different isoforms of **CD45**, a cell-surface tyrosine phosphatase expressed on all hematopoietic cells, are also useful in distinguishing naive from effector and memory T cells. In humans, the CD45RO isoform identifies effector and memory cells and is produced by alternative splicing that removes three exons encoded in the CD45 extracellular domain, whereas the **CD45RA** isoform includes at least one of these exons and identifies naive T cells. The functional consequences of the alternatively spliced isoforms are unclear.

Surface markers that distinguish memory T-cell subsets are related to recirculation and tissue localization and reflect the different surveillance patterns of each of the three major subsets (Fig. 11.26). Each subset has distinct activation characteristics. T_{CM} cells are characterized by expression of L-selectin (CD62L) and CCR7, which are also expressed by naive T cells, and direct their recirculation through the T-cell zones of secondary lymphoid tissues (see Section 9-3). T_{CM} cells primarily migrate from the blood into the secondary lymphoid organs, then into the lymphatic system and back into the blood, a migratory pattern like that of naive T cells. However, T_{CM} cells differ from naive T cells in their heightened sensitivity to antigen recognition and rapid expression of CD40 ligand (CD40L) in recall responses, although they are slower to acquire other effector functions (for example, production of cytokines) compared with other memory subsets. T_{EM} cells lack expression of L-selectin (CD62L) and CCR7 but express high levels of β_1 and β_2 integrins, and so are specialized for rapidly entering inflamed tissues. They also express receptors for inflammatory chemokines and can rapidly mature into effector T cells that secrete large amounts of effector cytokines (for example, IFN-γ, IL-4, or IL-17) early after restimulation with antigen. At steady state, many T_{EM} cells appear to

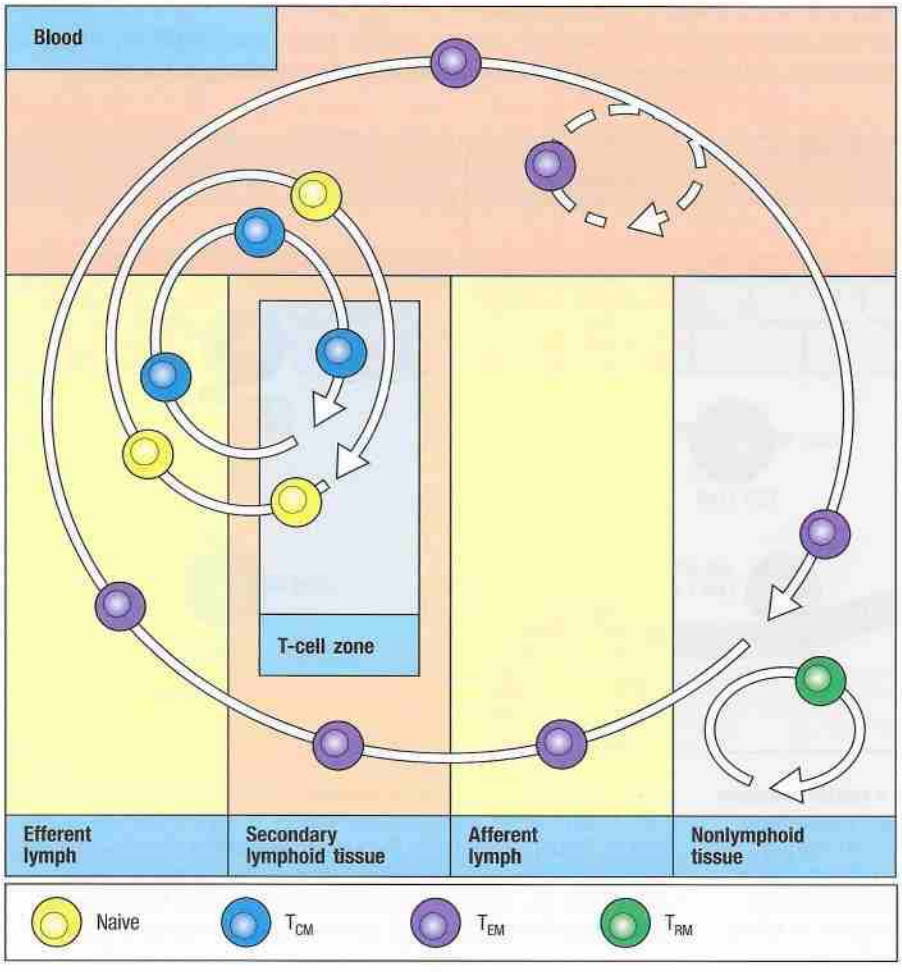

Fig. 11.26 Naive and memory T cells have distinct migratory patterns, enabling their surveillance of different tissue compartments for infection. Like naive T cells, T_{CM} cells recirculate between blood, the T-cell zones of secondary lymphoid organs, and lymph. T_{EM} cells recirculate between nonlymphoid tissues, lymph, lymph nodes (where they might pass through via the sinuses without entering the T-cell zone), and blood; some T_{EM} cells remain in blood circulation and migrate only through the spleen. T_{RM} cells do not recirculate but rather are confined to a single tissue.

recirculate primarily in blood, bypassing secondary lymphoid organs, except the spleen, altogether. However, a recently identified subset of T_{EM} cells that is distinguished by expression of intermediate levels of the chemokine receptor CX3CR1 ($CX3CR1^{int}$) can migrate at steady state from the blood into peripheral nonlymphoid tissues, and then via lymphatics and secondary lymphoid tissues back to blood (see Fig. 11.26). This subset of T_{EM} cells, referred to as peripheral memory T (T_{PM}) cells, has been described only for CD8 T cells and would appear suited for surveillance of nonlymphoid tissues.

In contrast to central and effector memory cells, T_{RM} cells compose a substantial fraction of memory T cells that do not migrate, but rather take up long-term residency in various barrier sites (see Fig. 11.26 and **Fig. 11.27**). Like T_{EM} cells, T_{RM} cells lack CCR7 but express other chemokine receptors (for example, CXCR3, CCR9) that allow migration into peripheral tissues, such as the dermis or lamina propria of the intestine. In these sites, T_{RM} cells express CD69, which reduces S1PR1 expression, thereby promoting retention in tissues. Some T_{RM} cells, particularly CD8 T_{RM} cells, can enter and reside within the epithelium of barrier tissues (for example, skin and GI tract). TGF-β production by epithelial cells induces T_{RM} to express integrin $\alpha_E\beta_7$ (CD103), which binds E-cadherin expressed by the epithelium and is required for T_{RM} retention. Because T_{RM} cells resemble effector T cells in being rapidly responsive to either TCR signaling or cytokines (see Section 11-13), they function in many ways like ILCs. That is, they are tissue-resident, sensor-responder cells that provide local tissue surveillance and can initiate a particular immune module response locally and rapidly upon pathogen challenge—whether by the same pathogen to which they initially responded or by other pathogens of the same class. However, unlike ILCs, T_{RM} cells are not seeded into nonlymphoid tissues developmentally, rather they seed nonlymphoid tissues only after a T-cell effector response in that tissue. Although T_{RM} cells are confined to nonlymphoid tissues, they are not static within these tissues; they continually migrate slowly within their nonlymphoid tissue of residence, actively surveying for signals that indicate a pathogen threat.

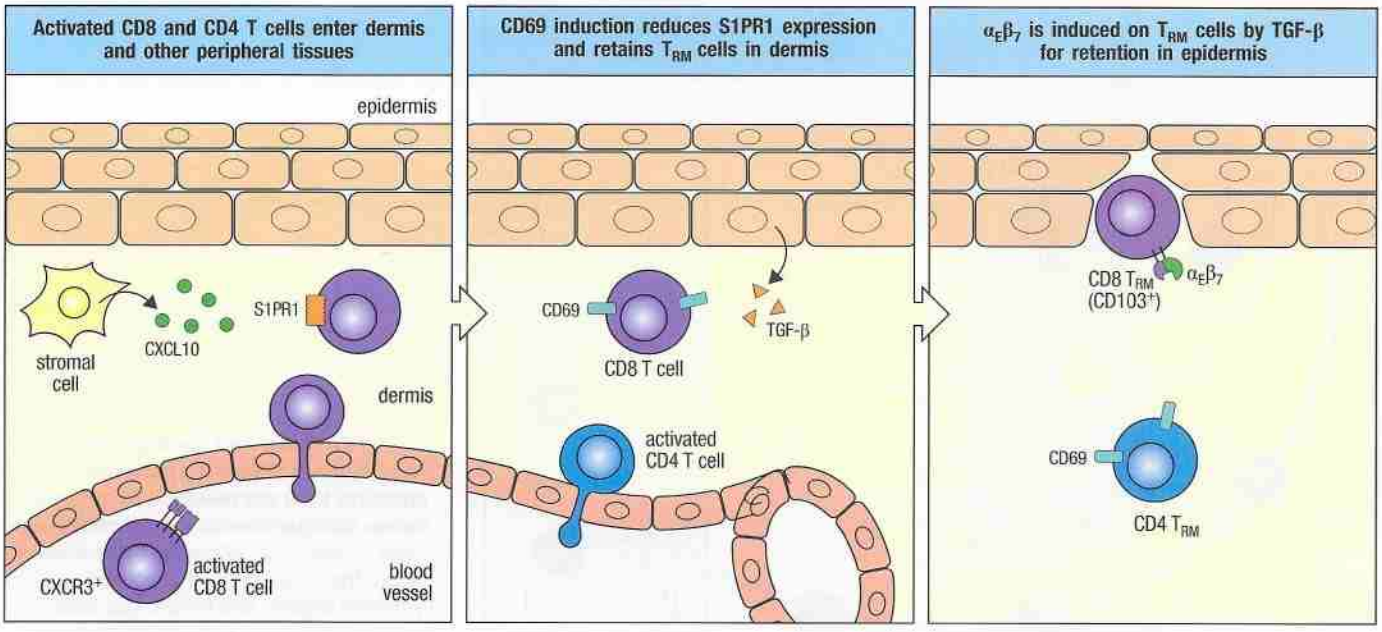

Fig. 11.27 Tissue-resident memory T cells are a major immune compartment that surveys peripheral tissues for reinfection by pathogens. After activation and priming in lymphoid tissues, activated CD8 and CD4 T cells enter the blood and enter tissues in response to various chemokines, as shown here for entry into the dermis, guided by expression of CXCR3. The reexpression of CD69 by T cells caused by antigen or other unknown signals leads to decreased S1PR1 surface expression, promoting retention of these cells in the dermis. In response to TGF-β, some cells induce integrin $\alpha_E\beta_7$ (CD103), which binds E-cadherin expressed by epithelial cells, promoting entry and retention of T cells in the epidermis, where many CD8 T_{RM} cells reside. Estimates indicate that T_{RM} cells may outnumber the recirculating T cells that migrate through the body.

The distinction between T_{CM}, T_{EM}, and T_{RM} memory populations has been made both in humans and in the mouse. However, within each subset there may be further heterogeneity. For example, among the CCR7-expressing T_{CM} population are cells with differing expression of other markers, particularly chemokine receptors. A subset of the CCR7-positive T_{CM} cells also expresses CXCR5, similarly to T_{FH} cells, although it is not yet clear whether these memory cells can provide help to B cells in the germinal center. Moreover, there is interconversion between memory T-cell subsets. Thus, on restimulation by cognate antigen, T_{CM} cells can rapidly lose expression of CCR7 and differentiate into T_{EM} cells. T_{EM} cells are also heterogeneous in the chemokine receptors they express and have been classified according to chemokine receptors typical of T_H1 cells (CCR5), T_H17 cells (CCR6), and T_H2 cells (CCR4). T_{CM} cells do not appear committed to particular effector lineages, and even T_{EM} cells are not fully committed to the T_H1, T_H17, or T_H2 lineage, although there is some correlation between their eventual output of T_H1, T_H17, or T_H2 cells and the chemokine receptors expressed. Further stimulation with antigen seems to drive the differentiation of T_{EM} cells gradually into the distinct effector T-cell lineages.

11-21 Circulating memory T cells acquire heightened sensitivity to IL-7 and/or IL-15 and undergo metabolic reprogramming to survive long-term.

A principal feature of circulating memory T cells (T_{CM} and T_{EM} cells) is their longevity without a requirement for antigenic stimulation. They share with naive T cells two attributes that promote their long-term survival: expression of receptors for pro-survival cytokines and altered metabolic programming. Like naive T cells, circulating memory T cells express the α subunit of the IL-7 receptor (IL-7Rα, or CD127), which pairs with constitutively expressed common γ chain (γ_c; CD132) to allow them to respond to the pro-survival cytokine IL-7. Expression of IL-7Rα is down-regulated during effector T-cell differentiation but is retained or reacquired by those cells destined to become memory T cells. The importance of IL-7Rα in the maintenance of T cells that become long-term survivors after their response to antigen has been demonstrated in multiple studies. For example, the experiment shown in Fig. 11.28 examines mice infected with lymphocytic choriomeningitis virus (LCMV). Around day 7

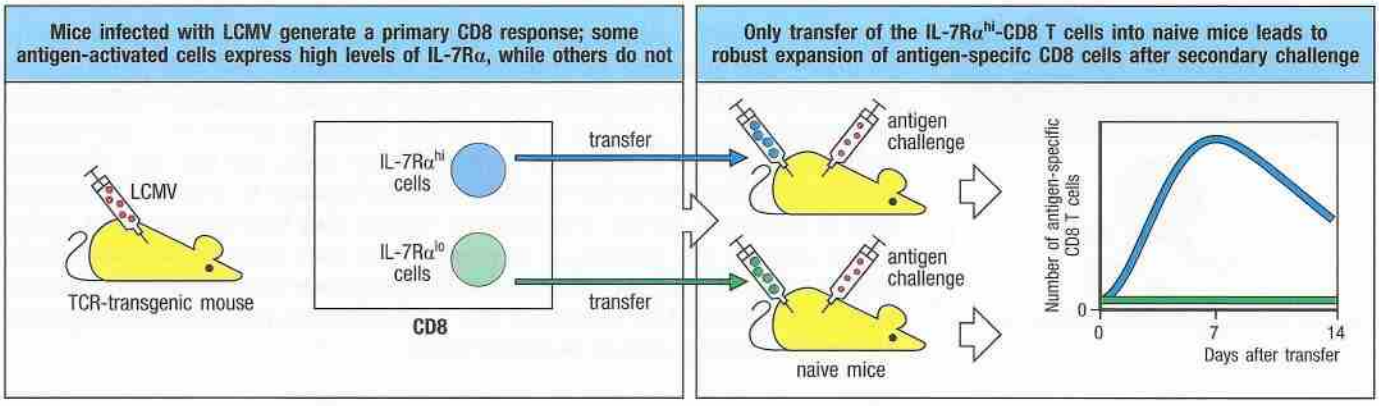

Fig. 11.28 Expression of the IL-7 receptor (IL- 7Rα) indicates which CD8 effector T cells can generate robust memory responses. Mice expressing a T-cell receptor (TCR) transgene specific for a viral antigen from lymphocytic choriomeningitis virus (LCMV) were infected with the virus, and effector cells were collected on day 11. Effector CD8 T cells expressing high levels of IL-7Rα (IL-7Rα^{hi}; blue) were separated and transferred into one group of naive mice, and effector CD8 T cells expressing low IL-7Rα (IL-7Rα^{lo}; green) were transferred into another group. Three weeks after transfer, the mice were challenged with a bacterium engineered to express the original viral antigen, and the numbers of responding transferred T cells (detected by their expression of the transgenic TCR) were measured at various times after challenge. Only the transferred IL-7Rα^{hi} effector cells could generate a robust expansion of CD8 T cells after the secondary challenge.

Fig. 11.29 Memory and naive T cells have different requirements for survival. For their survival in the periphery, naive T cells require periodic stimulation with the cytokine IL-7 and with self antigens presented by self MHC molecules. On priming with its specific antigen, a naive T cell divides and differentiates. Most of the progeny differentiate into relatively short-lived effector cells that have lost expression of the IL-7 receptor (green), but some effector cells retain or reexpress the receptor and become long-lived memory T cells. These cells can be maintained by IL-7 (and in some cases, IL-15; not shown) and are less dependent on contact with self peptide:self MHC complexes for survival compared with naive T cells. APC, antigen-presenting cell.

after infection, a small population of approximately 5% of CD8 antigen-activated T cells express high levels of IL-7Rα. Adoptive transfer of these IL-7Rα^{hi} cells, but not IL-7Rα^{lo} effector T cells, provided functional CD8 T-cell memory to uninfected mice. This experiment suggests that memory T cells arise from effector T cells that maintain or reexpress IL-7Rα, perhaps because they compete more effectively for the survival signals delivered by IL-7. Indeed, memory T cells are more sensitive to IL-7 signaling than are naive T cells, due at least in part to their higher expression of IL-7Rα (see Fig. 11.25). As discussed in Section 11-16, this leads to increased expression of the anti-apoptotic factor Bcl-2, which is also increased in memory T cells compared to naive T cells.

In addition to IL-7, a subset of memory CD8 T cells also requires IL-15 for survival. Consequently, whereas both CD4 and CD8 circulating memory T cells require IL-7 for survival, some CD8 T cells also require IL-15 for survival. Further, as illustrated in **11.29**, while naive T cells require contact with self peptide:self MHC complexes in addition to cytokine stimulation for their long-term survival, it appears that memory T cells are less dependent on contact with self peptide:self MHC than are naive T cells. Nevertheless, memory T cells still respond to contact with peptide:MHC complexes to become reactivated during a secondary encounter with pathogen, but they are more sensitive to restimulation by antigen than are naive T cells, at least in part due to their higher expression of the co-stimulatory receptor CD28. As noted previously, memory T cells, particularly T_{RM} cells, may be activated in a 'bystander' manner by certain inflammatory cytokines; that is, without a requirement for antigen stimulation—akin to ILCs.

As discussed in Chapter 9, a shift in T-cell metabolism accompanies the developmental transition from naive to effector T cells (see Section 9-9). Naive T cells are quiescent and depend primarily on glycolysis for oxidative phosphorylation (OXPHOS) (**Fig. 11.30**). Shortly after activation, they undergo a metabolic switch to both increase aerobic glycolysis, which sacrifices the efficiency of ATP production in favor of producing glucose-derived intermediates that promote macromolecule biosynthesis and cell growth, and increase OXPHOS to meet increased energy demands. Memory T cells that are generated with the decline of an effector response revert to a low-energy metabolism, which is primarily fueled by fatty acids, not glucose. However, memory T cells retain an increased respiratory capacity to enable a more rapid shift to increased energy consumption should they become activated again. It also appears that subsets of memory T cells may differ in their metabolic requirements. Thus, T_{RM} cells are able to up-regulate mechanisms to enhance uptake of substrates for enhanced fatty acid oxidation, perhaps reflecting their higher surveillance activity at homeostasis.

11-22 CD4 T-cell help is required for CD8 T-cell memory and involves CD40 and IL-2 signaling.

There is experimental evidence that CD4 T cells play an important role in programming optimal CD8 T-cell memory. In the experiment shown in **Fig. 11.31**, the primary and memory CD8 T-cell responses were compared between wild-type mice and mice that lack expression of MHC class II, and which therefore

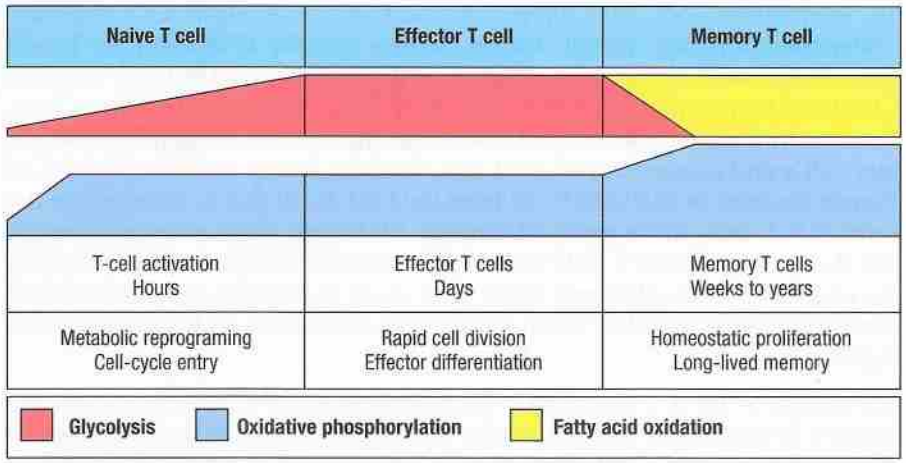

Fig. 11.30 The differentiation of naive T cells into effector and memory T cells is accompanied by shifts in their metabolism. Naive T cells have very low energetic demands that are met by a low-level oxidative phosphorylation (OXPHOS; represented by blue shading) within mitochondria of pyruvate that is derived from the breakdown (glycolysis; red shading) of glucose—their principal energy source—but also from a limited oxidation of acetyl-CoA that is derived from fatty acids (fatty acid oxidation, or FAO; yellow). Upon activation, T cells undergo a shift from a catabolic to anabolic metabolism to accommodate their impending transition to rapid cell division necessary for clonal expansion and effector differentiation. The increased need for macromolecule biosynthesis (for example, DNA, ribosomal RNA, proteins) is met by an increase in glycolysis, which, together with an increase in OXPHOS, provides the increased biosynthetic and energetic needs of developing effector T cells. (The height of the colored panels denotes the relative capacity of the indicated pathways.) As the T-cell response wanes, the surviving memory T cells shift their metabolism back to a catabolic state dominated by low energy consumption fueled principally by FAO, not glycolysis. However, memory T cells retain an increased number and functional reserve of mitochondria, and thus greater respiratory capacity to enable long-term survival and a rapid transition to a proliferative, anabolic metabolism upon antigen reencounter.

have a defect in CD4 T cells. In this experiment, the CD8 T-cell response was measured against a protein, ovalbumin, carried by an experimental strain of *Listeria monocytogenes*. After 7 days of infection, both types of mice showed equivalent expansion and activity of antigen-specific effector CD8 T cells. But mice with a defect in CD4 T cells generated much weaker secondary responses, characterized by the presence of far fewer expanding memory CD8 T cells after a secondary challenge. These results imply a role for CD4 T cells either in the initial programming of CD8 T cells or during the secondary memory response.

Further experiments suggest that this CD4 T-cell help for generation of memory CD8 T cells is necessary during the initial priming of naive CD8 T cells. Memory CD8 T cells that developed in the absence of CD4 help were transferred into wild-type mice. After transfer, the recipient mice were challenged again, whereupon the CD8 T cells showed a reduced ability to proliferate even though the recipient mice expressed MHC class II. This result indicates that CD4 T-cell help is required during the priming of CD8 T cells and not simply at the time of secondary responses. This requirement for CD4 help in CD8 memory generation has also been demonstrated by experiments in which CD4 T cells were depleted by treatment with antibody or in which mice were deficient in the CD4 gene.

Fig. 11.31 CD4 T cells are required for the development of functional CD8 memory T cells. Mice that do not express MHC class II molecules (MHC class II deficient) fail to develop CD4 T cells. Wild-type and MHC class II–deficient mice were infected with *Listeria monocytogenes* expressing the model antigen ovalbumin (LM-OVA). After 7 days, the number of OVA-specific CD8 T cells can be measured by using specific MHC tetramers that contain an OVA peptide, and therefore bind to T-cell receptors that react with this antigen. After 7 days of infection, mice lacking CD4 T cells were found to have the same number of OVA-specific CD8 T cells as wild-type mice. However, when mice were allowed to recover for 60 days—a time during which memory T cells could develop—and were then re-challenged with LM-OVA, the mice lacking CD4 T cells failed to expand CD8 memory cells specific to OVA, whereas there was a strong CD8 memory response in the wild-type mice.

Fig. 11.32 CD4 T cells promote the maintenance of CD8 memory cells. The dependence of memory CD8 T cells on CD4 T cells is shown by the different lifetimes of the memory cells after their transfer into host mice that either have normal CD4 T cells (wild type) or lack CD4 T cells (MHC class II deficient). In the absence of MHC class II proteins, CD4 T cells fail to develop in the thymus. When CD8 memory T cells specific for LCMV were isolated from donor mice 35 days after infection with the virus and transferred into these hosts, memory cells were maintained only in mice that had CD4 T cells. The basis for this action of CD4 T cells is not yet clear but has implications for conditions such as HIV/AIDS in which the number of CD4 T cells is diminished.

The mechanism underlying this requirement for CD4 T cells is not completely understood, although recent studies indicate that the CD8 and CD4 T cells must be activated by the same dendritic cell. Specifically, CD4 T-cell 'help' for CD8 T-cell memory generation appears to occur in the context of antigen presentation by lymph-node resident cDC1 cells that receive antigen from migratory cDCs and recruit primed CD4 cells for help. It may involve two types of signals received by the CD8 T cell from the CD4 T cell that is activated on the same cDC1 cell—those received through CD40 and those received through the IL-2 receptor. CD8 T cells that do not express CD40 are unable to generate memory T cells. Although many cells could potentially express the CD40 ligand needed to stimulate CD40, CD4 T cells are most likely the source of this signal.

A requirement for IL-2 signaling in the programming of CD8 memory was discovered by using CD8 T cells that were unable to respond to IL-2 because of a genetic deficiency in the IL-2Rα subunit. Because IL-2Rα signaling is required for the development of T_{reg} cells, mice lacking IL-2Rα develop a lymphoproliferative disorder. However, this disorder does not develop in mice that are mixed bone-marrow chimeras harboring both wild-type and IL-2Rα–deficient cells, and these chimeras can be used to study the behavior of IL-2Rα–deficient cells. When these chimeric mice were infected with LCMV and their responses were tested, memory CD8 responses were found to be defective specifically in the T cells lacking IL-2Rα.

The experiment shown in Fig. 11.32 indicates that distinct from their effect in programming naive CD8 T cells, CD4 T cells also provide help in maintaining the number of CD8 memory T cells. In this case, CD8 memory T cells that had been programmed in normal mice were transferred into immunologically naive mice that either expressed or lacked MHC class II. Transfer of CD8 memory cells into mice lacking MHC class II resulted in a more rapid decrease in the number of memory CD8 T cells in comparison with a similar transfer into wild-type mice. In addition, CD8 effector cells transferred into mice lacking MHC class II had a relative impairment of CD8 effector functions. These experiments imply that CD4 T cells activated by MHC class II–expressing antigen-presenting cells during an immune response have a significant impact on the quantity and quality of the CD8 T-cell response, even when they are not needed for the initial CD8 T-cell activation. Thus, CD4 T cells help to program naive CD8 T cells to generate memory T cells, help to promote efficient effector activity, and help to maintain memory T-cell numbers.

11-23 Memory B-cell responses are more rapid and have higher affinity for antigen compared with responses of naive B cells.

Immunological memory in B cells can be examined *in vitro* by isolating B cells from immunized or unimmunized mice and restimulating them with antigen in the presence of CD4 T cells specific for the same antigen. As is the case for T cells, B cells from immunized mice produce responses that differ both quantitatively and qualitatively compared with those of naive B cells from unimmunized mice (Fig. 11.33). Akin to T cells, antigen-specific B cells increase in frequency by up to 100-fold after their initial priming in the primary immune response. Further, because of the process of affinity maturation (described in Chapter 10), antibodies produced by B cells of immunized mice typically have a higher affinity for antigen than that of antibodies produced by unprimed B lymphocytes. The response from immunized mice is due to **memory B cells** that arise in the primary response.

Memory B cells can arise from the germinal center reaction during a primary response and may have undergone isotype switching and somatic mutations there. But memory B cells can also arise independently of the germinal center reaction from short-lived, antibody-producing cells produced in the primary

	Source of B cells	
	Unimmunized donor Primary response	Immunized donor Secondary response
Frequency of antigen-specific B cells	$1:10^4$ to $1:10^5$	$1:10^2$ to $1:10^3$
Isotype of antibody produced	IgM > IgG	IgG, IgA
Affinity of antibody	Low	High
Somatic hypermutation	Low	High

Fig. 11.33 The generation of secondary antibody responses from memory B cells is distinct from the generation of the primary antibody response. These responses can be studied and compared by isolating B cells from immunized and unimmunized donor mice and stimulating them in culture in the presence of antigen-specific effector T cells. The primary response usually consists of antibody molecules made by plasma cells derived from a quite diverse population of precursor B cells specific for different epitopes of the antigen and with receptors that have a range of affinities for the antigen. The antibodies are of relatively low affinity overall, with few somatic mutations. The secondary response derives from a far more limited population of high-affinity B cells that have undergone significant clonal expansion. Their receptors and antibodies have high affinity for the antigen and show extensive somatic mutation. The overall effect is that although there is usually only a 10- to 100-fold increase in the frequency of activatable B cells after priming, the quality of the antibody response is radically altered, in that these precursors induce a far more intense and effective response.

response. In either case, they circulate through the blood and take up residence in the spleen and lymph nodes, where they are poised to generate more rapid and robust antibody production in recall responses. Memory B cells express some markers that distinguish them from naive B cells and plasma cells. One marker of memory B cells is simply the expression of a class-switched surface immunoglobulin isotype (that is, IgG, IgA, or IgE); naive B cells express only surface IgM and IgD. In contrast, plasma cells have very low surface immunoglobulin altogether. In humans, a useful marker of memory B cells is **CD27**, a member of the TNF receptor family that is also expressed by naive T cells and binds the TNF family ligand **CD70**, which is expressed by dendritic cells (see Section 9-13).

A primary antibody response is characterized by the initial, rapid production of IgM and a slightly delayed IgG response due to time required for class switching (Fig. 11.34). The secondary antibody response is characterized in its first few days by the production of relatively small amounts of IgM antibody and much larger amounts of IgG antibody, with some IgA and IgE. At the beginning of the secondary response, antibodies are made by memory B cells that were generated in the primary response and have already switched from IgM

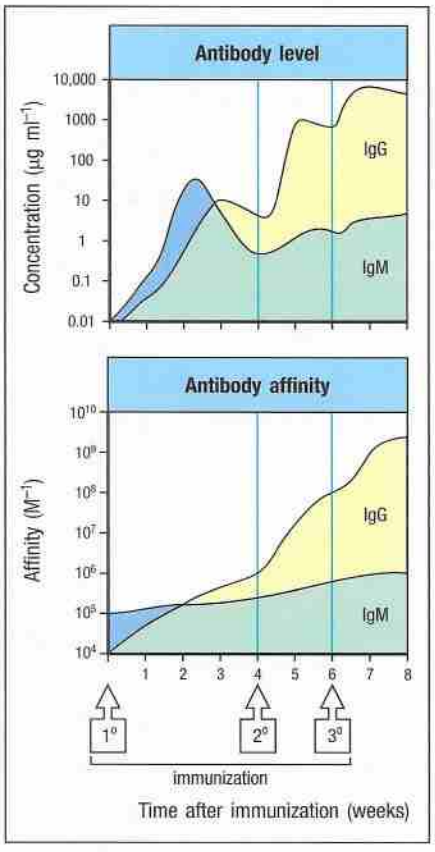

Fig. 11.34 Both the affinity and the amount of antibody increase with repeated immunization. The upper panel shows the increase in antibody concentration with time after primary (1°), secondary (2°), and tertiary (3°) immunizations. The lower panel shows the increase in the affinity of the antibodies (affinity maturation). Affinity maturation is seen largely in IgG antibody (as well as in IgA and IgE, which are not shown) coming from mature B cells that have undergone isotype switching and somatic hypermutation to yield higher-affinity antibodies. The blue shading represents IgM on its own, the yellow shading IgG, and the green shading the presence of both IgG and IgM. Although some affinity maturation occurs in the primary antibody response, most arises in later responses to repeated antigen injections. Note that these graphs are on a logarithmic scale; it would otherwise be impossible to represent the overall increase of around 1 millionfold in the concentration of specific IgG antibody from its initial level.

to another isotype (IgG, IgA, or IgE) that is expressed on their surface. This is reminiscent of the accelerated effector T-cell responses made by CD4 T_{EM} cells that are generated in a primary response and activated to generate a rapid T_H1, T_H2, or T_H17 cytokine response upon recall. Memory B cells express somewhat higher levels of MHC class II molecules and the co-stimulatory ligand B7.1 than do naive B cells. This helps memory B cells acquire and present antigen more efficiently to T_{FH} cells than do naive B cells, thereby recruiting more rapid and robust T-cell help to accelerate and increase antibody production compared with primary responses. The secondary response is characterized by a more vigorous and earlier generation of plasma cells than in the primary response, thus accounting for the almost immediate abundant production of IgG (see Fig. 11.34).

11-24 Memory B cells can reenter germinal centers and undergo additional somatic hypermutation and affinity maturation during secondary immune responses.

During a secondary exposure to infection, antibodies persisting from a primary immune response are available immediately to bind the pathogen and mark it for degradation by complement or by phagocytes. If the antibody can completely neutralize the pathogen, a secondary immune response may not occur. Otherwise, excess antigens will bind to receptors on B cells and initiate a secondary response in the secondary lymphoid organs. Memory B cells recirculate through the same secondary lymphoid compartments as naive B cells, principally the follicles of the spleen, lymph nodes, and the Peyer's patches of the gut mucosa. B cells with the highest avidity for antigen are activated first. Thus, memory B cells, which were selected previously for their avidity to antigen, make up a substantial component of the secondary response.

Besides responding more rapidly, memory B cells can reenter germinal centers during secondary immune responses and undergo additional somatic hypermutation and affinity maturation, as described in Sections 10-6 through 10-8. As in primary responses, secondary B-cell responses begin at the interface between the T-cell and B-cell zones, where memory B cells that have acquired antigen can present peptide:MHC class II complexes to helper T cells. This interaction initiates proliferation of both the B cells and T cells. Reactivated memory B cells that have not yet undergone differentiation into plasma cells migrate into the follicle and become germinal center B cells, undergoing additional rounds of proliferation and somatic hypermutation before differentiating into antibody-secreting plasma cells. Because B cells with the higher-affinity antigen receptors will more efficiently acquire and present antigen to antigen-specific T_{FH} cells in the germinal center, the affinity of the antibodies produced during secondary and tertiary responses rises progressively (see Fig. 10.14).

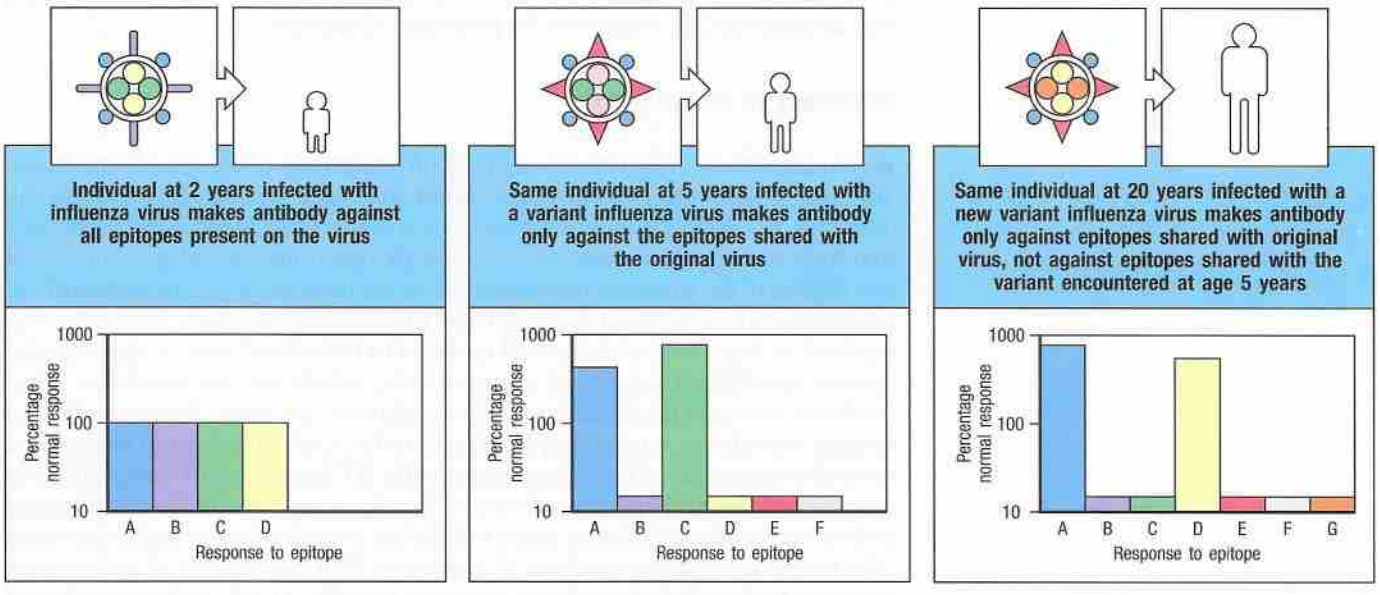
11-25 In immune individuals, secondary and subsequent responses are mainly attributable to memory lymphocytes.

In the normal course of an infection, a pathogen proliferates to a level sufficient to elicit an adaptive immune response and then stimulates the production of effector T cells and antibodies that eliminate the pathogen from the body. Most of the effector T cells then die, and antibody levels gradually decline, because the antigens that elicited the response are no longer present at the level needed to sustain it. We can think of this as feedback inhibition of the response. Memory T and B cells remain, however, and maintain a heightened ability to mount a response to a recurrence of infection with the same pathogen.

Antibody and memory lymphocytes remaining in an immunized individual can have the effect of reducing the activation of naive T and B cells on a

subsequent encounter with the same antigen. In fact, passively transferring antibody to a naive recipient can be used to inhibit naive B-cell responses to that same antigen. This phenomenon has been put to practical use to prevent Rh^- mothers from making an immune response to an Rh^+ fetus, which can result in **hemolytic disease of the newborn** (see Appendix I, Section A-7). If anti-Rh antibody is given to the mother before she is first exposed to her child's Rh^+ red blood cells, her response will be inhibited. The mechanism of this suppression is likely to involve the antibody-mediated clearance and destruction of fetal red blood cells that have entered the mother, thus preventing naive T cells and B cells from mounting an immune response. Presumably, the anti-Rh antibody is in excess over antigen, so that not only is antigen eliminated, but immune complexes are not formed to stimulate naive B cells through Fc receptors. Memory B-cell responses are, however, not inhibited by antibody, so the Rh^- mothers at risk must be identified and treated before a primary response has occurred. Because of their high affinity for antigen and alterations in their B-cell receptor signaling requirements, memory B cells are much more sensitive to the small amounts of antigen that cannot be efficiently cleared by the passive anti-Rh antibody. The ability of memory B cells to be activated to produce antibody, even when exposed to preexisting antibody, also allows secondary antibody responses to occur in individuals who are already immune.

These suppressive mechanisms might also explain a phenomenon called **original antigenic sin**. This term was coined to describe the tendency of people to make antibodies only against the epitopes expressed on the first influenza virus variant to which they are exposed, even in subsequent infections with viral variants that have additional, highly immunogenic, epitopes (Fig. 11.35). Antibodies against the original virus will tend to suppress responses of naive B cells specific for the new epitopes. This might benefit the host by using only those B cells that can respond most rapidly and effectively to the virus. This pattern is broken only if the person is exposed to an influenza virus that lacks all epitopes seen in the original infection, because now no preexisting antibodies bind the virus, and naive B cells are able to respond.



Individual at 2 years infected with influenza virus makes antibody against all epitopes present on the virus
Same individual at 5 years infected with a variant influenza virus makes antibody only against the epitopes shared with the original virus
Same individual at 20 years infected with a new variant influenza virus makes antibody only against epitopes shared with original virus, not against epitopes shared with the variant encountered at age 5 years

Response to epitope

Fig. 11.35 When individuals who have been infected with one variant of influenza virus are infected with a second or third variant, they make antibodies only against epitopes that were present on the initial virus. A child infected for the first time with an influenza virus at 2 years of age makes a response to all epitopes (left panel). At age 5 years, the same child exposed to a different influenza virus responds preferentially to those epitopes shared with the original virus and makes a smaller than normal response to new epitopes on the virus (center panel). Even at age 20 years, this commitment to respond to epitopes shared with the original virus, and the subnormal response to new epitopes, is retained (right panel). This phenomenon is called original antigenic sin.

A similar suppression of naive T-cell responses by antigen-specific memory T cells can occur in the setting of infection by LCMV in the mouse or dengue virus in humans. Mice that were primed with one strain of LCMV responded to a subsequent infection with a second strain of LCMV by expanding CD8 T cells that reacted to antigens specific for the first strain. However, this type of effect was not observed when responses to variable ovalbumin antigenic epitopes were examined in the setting of recurrent infections using the bacterial pathogen *Listeria monocytogenes*, suggesting that the suppression caused by 'original antigenic sin' does not occur in all immune responses.

Summary.

Protective immunity against reinfection is one of the most important consequences of adaptive immunity and results from the establishment of populations of long-lived memory B cells and memory T cells. These antigen-specific memory cells arise from the populations of lymphocytes that expand dramatically during the primary infection and survive at higher frequencies than naive lymphocytes. Both their increased frequency and their capacity to respond more rapidly to restimulation by the same antigen contribute to protective immunity, which can be transferred to naive recipients by memory B and T cells. Memory lymphocytes are maintained by their expression of receptors for cytokines, such as IL-7 and IL-15, that provide survival signals. Memory B cells can be distinguished by changes in their immunoglobulin genes that are due to isotype switching and somatic hypermutation; secondary and subsequent immune responses are characterized by antibodies with increasing affinity for the antigen. The advent of receptor-specific reagents, such as MHC tetramers and TCR transgenic mice, has allowed for the direct analysis of the expansion and differentiation of effector and memory T cells. We now recognize that T-cell memory is complex, and memory T cells are quite heterogeneous, having central memory, effector memory, and tissue-resident memory subtypes. While CD8 T cells can generate effective primary responses in the absence of help from CD4 T cells, CD4 T cells have an integral role in regulating CD8 T-cell memory. These issues will be critical in understanding, for example, how to design more effective vaccines for diseases such as HIV/AIDS that depend on CTL responses for pathogen clearance.

Summary to Chapter 11.

Vertebrates resist infection by pathogenic microorganisms in several ways. The innate defenses can act immediately and may succeed in repelling the infection, but if not, they are followed by a series of induced early responses that help to contain the infection as adaptive immunity develops. These first two phases of the immune response rely on the nonclonotypic receptors of the innate immune system to recognize the presence of infection. They are summarized in **Fig. 11.36** and covered in detail in Chapters 2 and 3, respectively. Several specialized subsets of immune cells, which can be viewed as intermediates between innate and adaptive immunity, act next. These specialized subsets include the innate lymphoid cells, or ILCs, which are rapid responders to cytokines produced by innate sensor cells. ILCs produce, in turn, cytokines that they share with specific subsets of T cells to coordinate the recruitment and/or activation of different types of resident and circulating innate immune cells to initiate distinct modules of immunity. The third phase of an immune response is the adaptive immune response (see Fig. 11.36), which is mounted in the secondary lymphoid tissue that serves the particular site of infection and takes several days to develop—reflecting the time required for antigen-activated T lymphocytes to proliferate and differentiate into effector cells of

	Phases of the immune response		
	Innate phase (Immediate: 0–4 hours)	**Induced innate phase (Early: 4–96 hours)**	**Adaptive immune phase (Late: >96 hours)**
	Nonspecific Innate No memory No specific T cells	Nonspecific + specific Inducible No memory No specific T cells	Specific Inducible Memory Specific T cells
Barrier functions	Skin, epithelia, mucins, acid	Local inflammation (C5a) Local TNF-α	IgA antibody in luminal spaces IgE antibody on mast cells Local inflammation
Response to extracellular pathogens	Phagocytes Alternative and MBL complement pathway Lysozyme Lactoferrin Peroxidase Defensins	Mannose-binding lectin C-reactive protein T-independent B-cell antibody Complement	IgG antibody and Fc receptor–bearing cells IgG, IgM antibody + classical complement pathway
Response to intracellular bacteria	Macrophages	Activated NK-dependent macrophage activation IL-1, IL-6, TNF-α, IL-12	T-cell activation of macrophages by IFN-γ
Response to virus-infected cells	Natural killer (NK) cells	IFN-α and IFN-β IL-12–activated NK cells	Cytotoxic T cells IFN-γ

Fig. 11.36 The components of the three phases of the immune response against different classes of microorganisms. The mechanisms of innate immunity that operate in the first two phases of the immune response are described in Chapters 2 and 3, and thymus-independent (T-independent) B-cell responses are covered in Chapter 10. The immediate and early phases contribute to the initiation of adaptive immunity, and they influence the functional character of the antigen-specific effector T cells and antibodies that appear on the scene in the late phase of the response. There are striking similarities in the effector mechanisms at each phase of the response; the main change is in the recognition structure used.

different subsets and for T_{FH} cells to migrate to B-cell zones to provide help for B cells. Once an adaptive immune response has developed, the effector T cells and antibodies are dispersed via the circulation and recruited into the infected tissues; the infection is usually controlled, and the pathogen is contained or eliminated. The final effector mechanisms used to clear an infection depend on the type of infectious agent and the corresponding immune module elicited, such that the type of T cells or antibodies produced in the adaptive immune phase are tailored for the elimination of the type of inciting pathogen (see Fig. 11.36).

An effective adaptive immune response leads to a state of protective immunity. This state consists of the presence of effector cells and molecules produced in the initial (or primary) response and of immunological memory. Immunological memory is manifested as a heightened ability to respond to pathogens that have previously been encountered and successfully eliminated. Memory T and B lymphocytes have the property of being able to transfer immune memory to naive recipients. The mechanisms that maintain immunological memory include certain cytokines, such as IL-7 and IL-15, as well as homeostatic interactions between the T-cell receptors on memory cells and self peptide:self MHC complexes. The artificial induction of immunological memory and long-lived protective immunity by vaccination is one of the most outstanding accomplishments of immunology in the field of medicine, as will be discussed further in Chapter 16. However, as we will see in Chapter 13, many pathogens do not induce protective immunity that completely eliminates the pathogen, so we will need to learn what prevents this before we can prepare effective vaccines against these pathogens.

Discussion Questions

11.1 Subsets of innate lymphoid cells (ILCs) and T cells share a number of developmental and functional features. What are the cytokines produced by innate sensor cells that target different subsets of ILCs and effector T cells, and what are the principal cellular sources of theses cytokines? What cytokines are elicited from ILCs and effector T cells activated by these inductive cytokines? What innate effector cells are preferentially targeted by the cytokines that are produced by different ILCs and activated effector T cells? What key transcription factors are shared between ILCs and T-cell subsets?

11.2 Chemokine networks are key to the coordination of innate and adaptive immune-cell recruitment to sites of infection. Describe the sets of chemokines and their receptors that distinguish different immune modules, and identify the innate and adaptive immune cells that express them.

11.3 Although there are similarities in functionalities of subsets of ILCs and the CD4 and CD8 effector T cells, there are also important differences. Describe how these types of cells differ, and speculate how these differences may confer unique functional features on each cell population.

11.4 What are the changes in expression of trafficking molecules that accompany the transitions from naive to effector and effector to memory phenotypes of CD4 and CD8 T cells? What trafficking molecules direct T cells to different tissues?

11.5 Why have some subsets of CD4 T cells evolved to retain greater developmental plasticity? How might this contribute to host defense? Immune regulation? Immune-mediated disease?

11.6 Describe the two prevailing models for the development of memory T cells. How might these different models affect strategies for vaccine development?

11.7 Describe the role of antibody isotypes in conferring antigen recognition on different innate immune effector cells. How does this integration of innate and adaptive immune functions converge to eradicate pathogens?

12 The Barrier Immune System

IN THIS CHAPTER

Organization of the mucosal immune system.

Innate immune defenses of the intestinal immune system.

The role of adaptive immunity in regulating the intestinal mucosal immune system at homeostasis.

The intestinal immune response in host defense and immune-mediated disease.

Immunity at other barrier tissues.

Previous chapters have focused on the immune response against pathogens, primarily examining responses in peripheral lymph nodes that drain infected tissues. Although most internal tissues are normally free of microbes, the barrier tissues of the body—the skin and various mucosal tissues, such as the gastrointestinal, respiratory, and urogenital tracts—are in continual contact with the external world and have ongoing encounters with microbes beginning immediately after birth and persisting throughout life. In addition to providing the greatest surface area across which pathogens can invade, these tissues are normally populated by a diverse community of resident microorganisms—the **commensal microbiota**. The requirement to contend with the commensal microbiota while performing physiological functions that expose these tissues to a wide range of environmental antigens (for example, ingestion of dietary antigens in the gastrointestinal tract; inspiration of airborne antigens in the respiratory tract) presents unique challenges to the maintenance of immune homeostasis at these sites; immune cells in barrier tissues must tolerate the commensal microbiota while maintaining the ability to mount robust responses against pathogenic microbes. In this chapter we consider specialized features of the immune system at these barrier tissues, with primary emphasis on those features invested by the mucosae—the **mucosal immune system**.

The mucosal immune system—in particular, that of the gut—may well have been the first part of the adaptive immune system to arise in evolution, possibly developing to contend with the vast populations of commensal microorganisms that coevolved with vertebrates to provide nutrient and nonnutrient benefits: primarily bacteria, but also fungi, viruses, and parasites, particularly worms (helminths). Organized lymphoid tissues and antibodies are first found in vertebrates in the gut of primitive cartilaginous fishes, and two important central lymphoid organs—the **thymus** and the avian **bursa of Fabricius**—have developmental origins related to the gut. It has therefore been suggested that the mucosal immune system of the gut represents the original vertebrate immune system, and that the spleen and lymph nodes are later specializations. Here we consider the unique features of the barrier immune system, focusing primarily on the gastrointestinal tract but also considering other barrier tissues such as the pulmonary tract and the nonmucosal barrier tissue, skin.

Organization of the mucosal immune system.

The main line of defense against invasion by microbes at mucosal tissues is the epithelium that covers their surfaces. In some sites the mucosal epithelium is composed of multiple layers (for example, oral cavity, nasal cavity, nasopharynx), but in sites such as the intestines and the lower airways of the respiratory tract, the epithelium is a single cell layer thick to facilitate nutrient uptake and gas exchange, respectively. Especially in these sites, where the physiological role of the tissue depends on free exchange of molecules between the 'outside' and 'inside,' the epithelium can be breached relatively easily. Epithelial barrier function is therefore supplemented by molecules provided by the epithelium itself, such as mucus and antimicrobial peptides, as well as the cells and molecules of the mucosal immune system. Each of these components is integrated

into a layered defense that restrains the entry of microbes while allowing physiological activities to proceed.

The epithelium is not just a passive barrier between the external and internal environments; it is central to sensing the environment and communicating with immune cells to induce mucosal immune responses. Throughout this chapter, we focus on the unique relationship of the mucosal epithelia with the innate and adaptive mucosal immune systems and on how these two arms of immunity are integrated with epithelial function at homeostasis and in host defense. Many of the anatomic and immunological principles underlying the mucosal immune system apply to all mucosal tissues. Here we will focus primarily on the intestines as our main example, as it is the largest and best-studied mucosal immune system. Unique aspects of respiratory mucosa and skin barrier immunity will be considered later.

12-1 The mucosal immune system protects the internal surfaces of the body.

The mucosal immune system comprises the internal body surfaces that are lined by a mucus-covered epithelium—the gastrointestinal (GI) tract, the upper and lower respiratory tract, and the urogenital tract. It also includes the biliary tract, middle ear, and exocrine glands, such as the conjunctivae and lacrimal glands of the eye, the salivary glands, and the lactating breast (Fig. 12.1). The surfaces of mucosal tissues are covered by epithelia that range from a single cell layer thick—such as the simple columnar epithelium composed of **enterocytes**, or intestinal epithelial cells, that line the intestines—to multiple layers, such as the nonkeratinized stratified squamous epithelium of the esophagus and vagina (Fig. 12.2). The mucosal surfaces represent an enormous area to be protected. Collectively, the mucosal tissues of humans have a surface area of almost 400 m^2, roughly 200 times that of the skin. Although

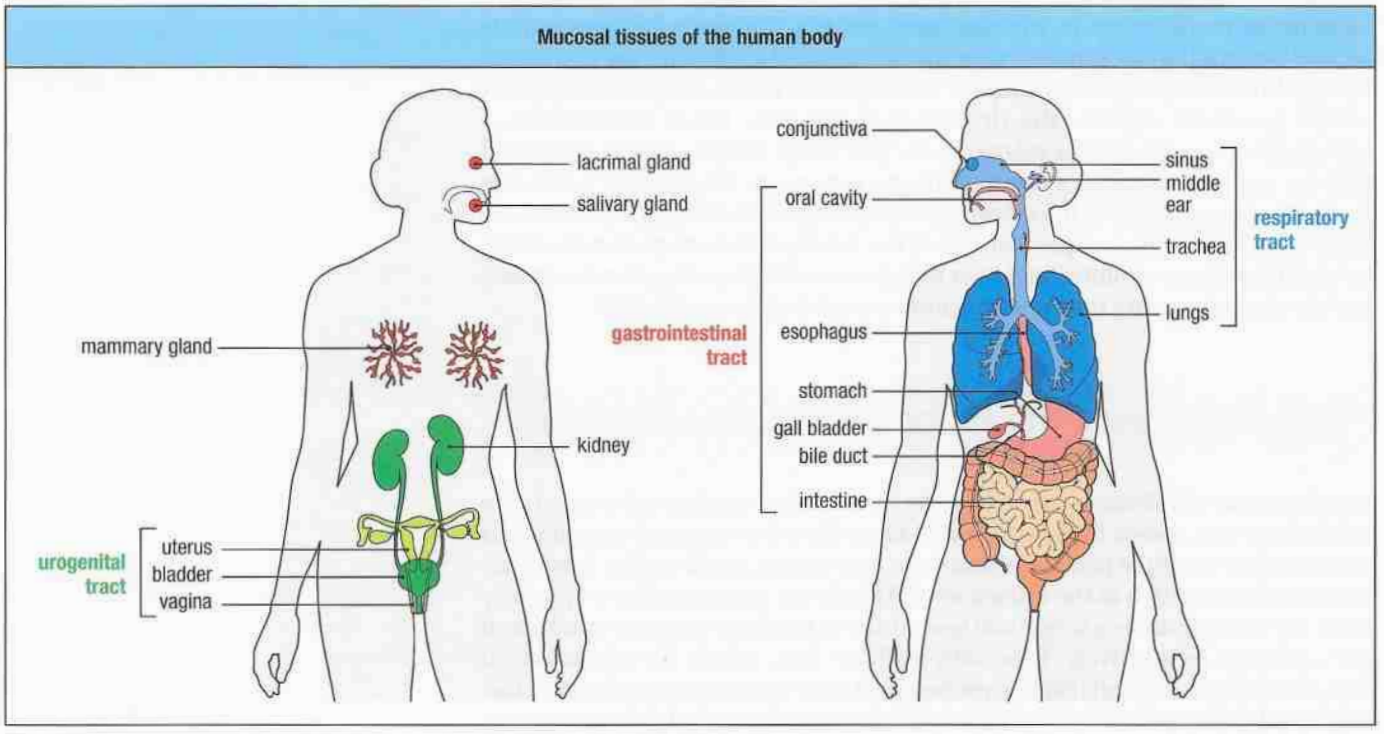

Fig. 12.1 The mucosal immune system. The tissues of the mucosal immune system are the lymphoid organs and cells associated with the gastrointestinal, respiratory, and urogenital tracts, as well as the oral cavity, pharynx, middle ear, and the glands associated with these tissues, such as the salivary glands and lacrimal glands. The lactating breast is also considered part of the mucosal immune system.

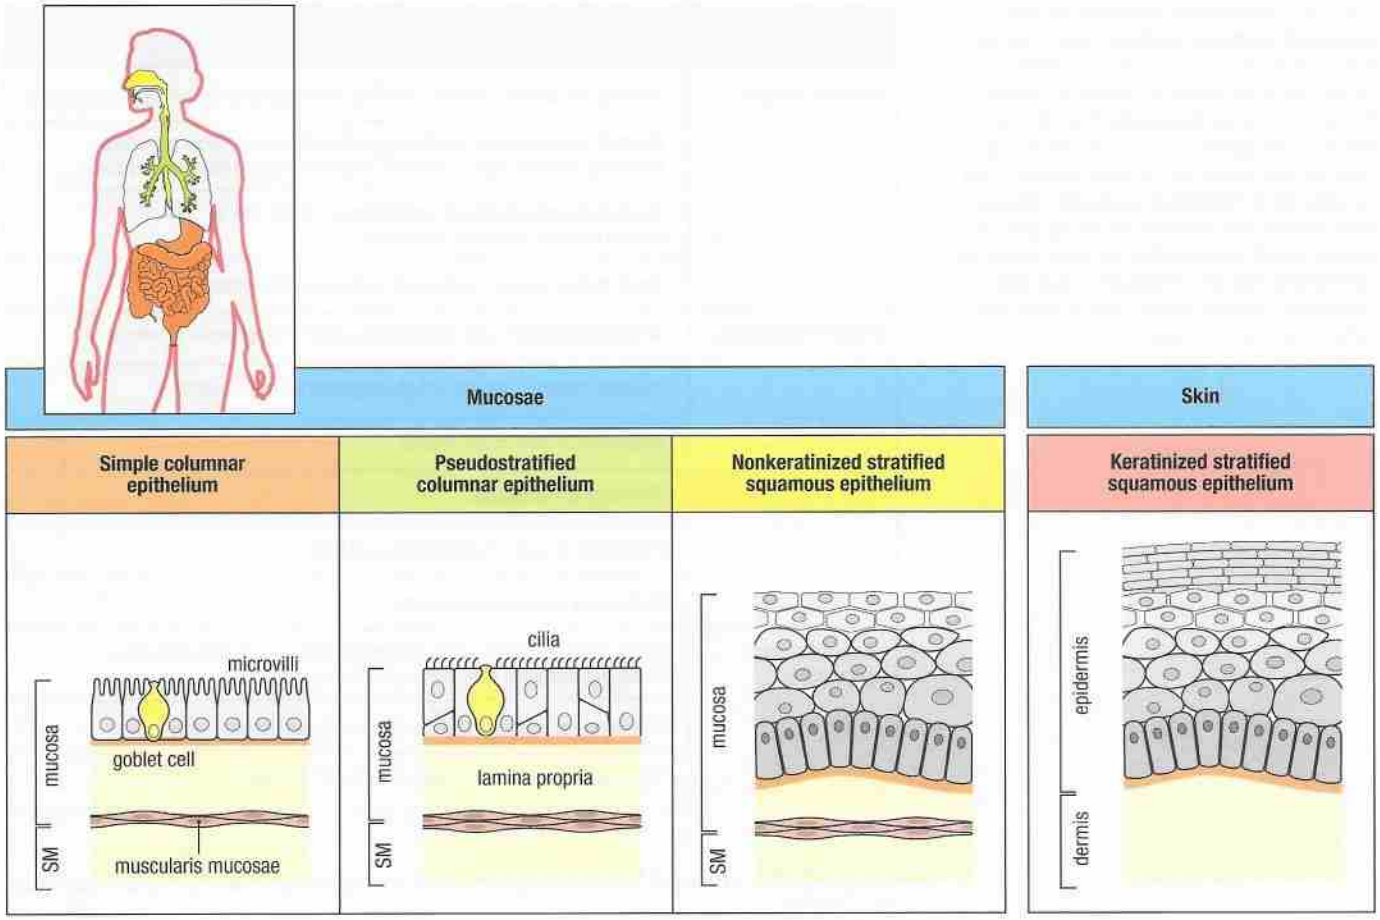

Fig. 12.2 A variety of different types of epithelium line the barrier tissues. Shown are the major types of epithelium that cover different barrier tissues of the body. Each type of epithelium has a relatively high cell-turnover rate (several days to a few weeks), reflecting exposure to environmental injury. All basal epithelial cells rest on a basement membrane that separates the epithelium from the underlying tissue, such as the lamina propria of the intestinal tract or the dermis of the skin. In several tissues, more than one type of epithelium is found. In the gastrointestinal (GI) tract, the major segments are covered by a simple columnar epithelium that is a single cell layer thick (for example, stomach, intestines, biliary tract), whereas the oral cavity, esophagus, and rectum are covered by nonkeratinized stratified squamous epithelium composed of multiple layers of epithelial cells. Similarly, the upper respiratory tract (nasal sinuses, tonsils, pharynx, and larynx) is covered by nonkeratinized stratified squamous epithelium, whereas the branching conducting airways (trachea, bronchi, bronchioles) are covered by pseudostratified columnar epithelium that is generally one to two cells thick. Note that the epithelium covering alveoli, the small terminal pockets in the lung where gas exchange occurs, is primarily a very thin simple squamous epithelium (one cell layer thick; not shown) to facilitate movement of O_2 and CO_2 across the epithelium. In the female genital tract (not shown), the uterus and cervical canal are covered by columnar epithelium, whereas the vagina is covered by nonkeratinized stratified squamous epithelium. A characteristic of the simple columnar and pseudostratified mucosal epithelia is the presence of mucus-producing goblet cells. The skin is composed of two major compartments—the epidermis and the dermis—which are separated by the basement membrane. The epidermis is further subdivided into four layers of keratinocytes, so named because of the high content of the filamentous structural protein, keratin, that is increasingly abundant in these cells as they mature toward the surface of the skin. Keratin is highly abundant in the outer layer of dead cells and contributes to the skin's water impermeability and barrier. SM, submucosa.

the skin is a barrier tissue, it is not moist and mucus-covered, and hence not a mucosal tissue. It is covered instead by layers of dying and dead interdigitating 'squames' (literally, scales), or **keratinocytes**—flattened cells that compose its multilayered keratinized squamous epithelium (see Fig. 12.2), as will be discussed later.

In accord with the large surface area of mucosal tissues, the mucosal immune system forms the largest part of the body's immune tissues. Approximately three-quarters of all lymphocytes in the body are found in the mucosae and they produce the majority of immunoglobulin in healthy individuals. The mucosae are continually exposed to antigens and other materials that enter from the environment or are produced by resident microbes. When compared with lymph nodes and spleen (which we will refer to as the **systemic immune system** in this

Distinctive features of the mucosal immune system	
Anatomic features	Intimate interactions between mucosal polarized epithelia and lymphoid tissues
	Discrete compartments of diffuse lymphoid tissue and more organized structures such as Peyer's patches, isolated lymphoid follicles, and tonsils
	Specialized antigen-uptake mechanisms, e.g., M cells in Peyer's patches, adenoids, and tonsils
	Broad surface area in contact with environmental agents/microbes
Effector mechanisms	Activated/memory T cells predominate even in the absence of infection
	Multiple activated 'natural' effector/regulatory T cells present
	Production of mucins and mucus
	Secretory IgA antibodies
	Production of antimicrobial peptides (AMPs)
	Presence of distinctive microbiota
Immunoregulatory environment	Active down-regulation of immune responses (e.g., to food and other innocuous antigens) predominates at homeostasis
	Inhibitory macrophages and tolerance-inducing dendritic cells
	High number of FoxP3$^+$ T_{reg} cells and FoxP3$^-$ T_R1 cells

Fig. 12.3 Distinctive features of the mucosal immune system. The mucosal immune system is larger, encounters a wider range of antigens, and encounters them much more frequently than the rest of the immune system—what we call in this chapter the systemic immune system. This is reflected in distinctive anatomic features, specialized mechanisms for the uptake of antigen, and unusual effector and regulatory responses that are designed to prevent unwanted immune responses to food and other innocuous antigens.

chapter), the mucosal immune system has many unique and unusual features (Fig. 12.3).

Because of their physiological functions in food absorption (the intestines), gas exchange (the lungs), sensory activities (eyes, nose, mouth, and throat), and reproduction (prostate, uterus, and vagina), many mucosal surfaces are thin and permeable barriers to the interior of the body. The importance of these tissues to life means that effective defense mechanisms are essential to protect them from invasion. Equally significant is that their fragility and permeability create obvious vulnerability to infection, and it is not surprising that the vast majority of infectious agents invade via these routes. Diarrheal diseases, acute respiratory infections, pulmonary tuberculosis, measles, whooping cough, and worm infestations continue to be the major causes of death throughout the world, especially in infants in developing countries. To these must be added the human immunodeficiency virus (HIV), a pathogen whose natural route of entry via a mucosal surface is often overlooked, as well as other sexually transmitted infections, such as syphilis (Fig. 12.4).

The mucosal surfaces are also portals of entry for a vast array of foreign antigens that must be tolerated to prevent untoward immune activation and immune-mediated disease. This is perhaps best illustrated by the gut, which is exposed to enormous quantities of food proteins—an estimated 30–35 kg per year per person. Moreover, the healthy large and small intestines are colonized by hundreds of species of microbes that live in symbiosis with their host, known as commensal microorganisms, or commensal microbiota. The microbiota consists of complex communities that have coevolved with their mammalian hosts over hundreds of millions of years. Bacteria dominate the commensal microbiota, and at least 10^{13} bacteria are present in the colon contents, making them the most numerous cells in the body—outnumbering the total number of cells of the host. Substantial populations of archaea, fungi, and bacterial viruses (bacteriophages) are also found in the healthy intestine, as are parasites such as worms (helminths) in countries with less advanced

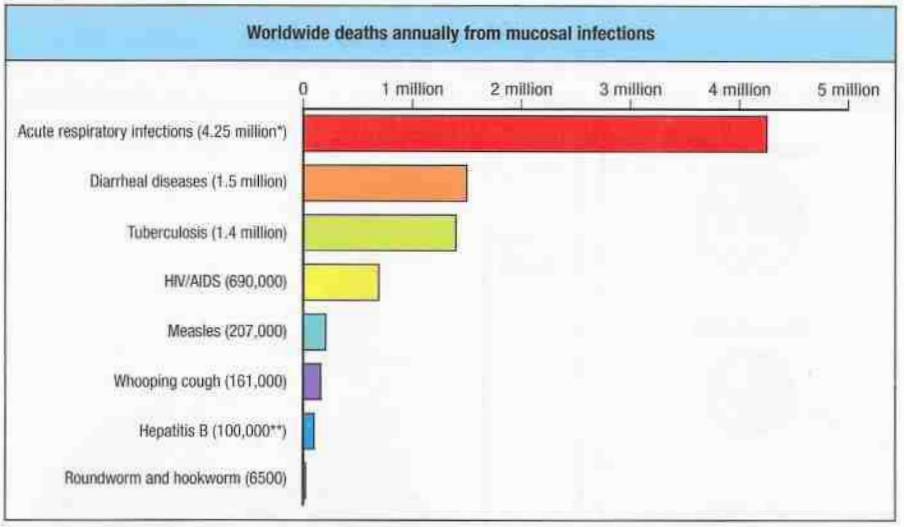

Fig. 12.4 Mucosal infections are one of the biggest health problems worldwide. Most of the pathogens that cause death throughout the world either infect mucosal surfaces or enter the body through the mucosae. Respiratory infections are caused by numerous bacteria (such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, which cause pneumonia; and *Bordetella pertussis*, the cause of whooping cough) and viruses (such as influenza, SARS-CoV-2, and respiratory syncytial virus). The bacterium *Mycobacterium tuberculosis*, which causes tuberculosis, also enters through the respiratory tract. Measles manifests itself as a systemic disease, but it originally enters via the oral or respiratory route. A variety of diarrheal diseases (for example, rotavirus, *Vibrio cholerae*, and *Shigella*) are transmitted via the fecal–oral route, often by contaminated food or drinking water. The human immunodeficiency virus (HIV) that causes AIDS is sexually transmitted through the mucosa of the urogenital or lower intestinal tracts or is secreted into breast milk and passed from mother to child in this way. Hepatitis B is also a sexually transmitted virus. Both HIV and hepatitis B can also be transmitted via IV drug use, although this is not a mucosal route of infection. Finally, parasitic worms inhabiting the intestine cause chronic debilitating disease and premature death. Most of these deaths, especially those from acute respiratory and diarrheal diseases, occur in children under 5 years old in the developing world, and there are still no effective vaccines against many of these pathogens. Numbers shown are best estimates for 2019 based on data from multiple sources (e.g., The Global Burden of Disease; World Health Organization; U.S. Centers for Disease Control and Prevention).
*Note that this estimate predates the SARS-CoV-2 pandemic.
**Does not include deaths from liver cancer or cirrhosis resulting from chronic hepatitis infections.

sanitation. The host provides the microbiota with a warm, nutrient-rich environment, and in return, the microbiota provides key functions that benefit the host. In normal circumstances these organisms do no harm, and many are beneficial to their hosts, having important metabolic functions, as well as being essential for normal immune function and providing a buffer against potential pathogens. Other mucosal tissues are also colonized by substantial populations of resident commensal organisms, as is the skin (Fig. 12.5).

Because food and the commensal microbiota contain many foreign antigens, they can be recognized by the adaptive immune system and normally induce antigen-specific immune tolerance. Inappropriate responses to these antigens are potentially damaging to the host and are the cause of a number of common diseases, including **celiac disease** (caused by an aberrant immune response to the wheat protein **gluten**; discussed in Chapter 14) and inflammatory bowel diseases such as **Crohn's disease** (due to a dysregulated response to commensal bacteria; discussed further later and in Chapter 15). As we shall see, the innate and adaptive mucosal immune systems of the intestinal immune system have developed multiple strategies to accommodate these 'friendly' antigens while retaining robust host defense against pathogens, including opportunistic pathogens that are normal constituents of the commensal microbiota. Similar issues are faced at other mucosal surfaces, such as the respiratory tract

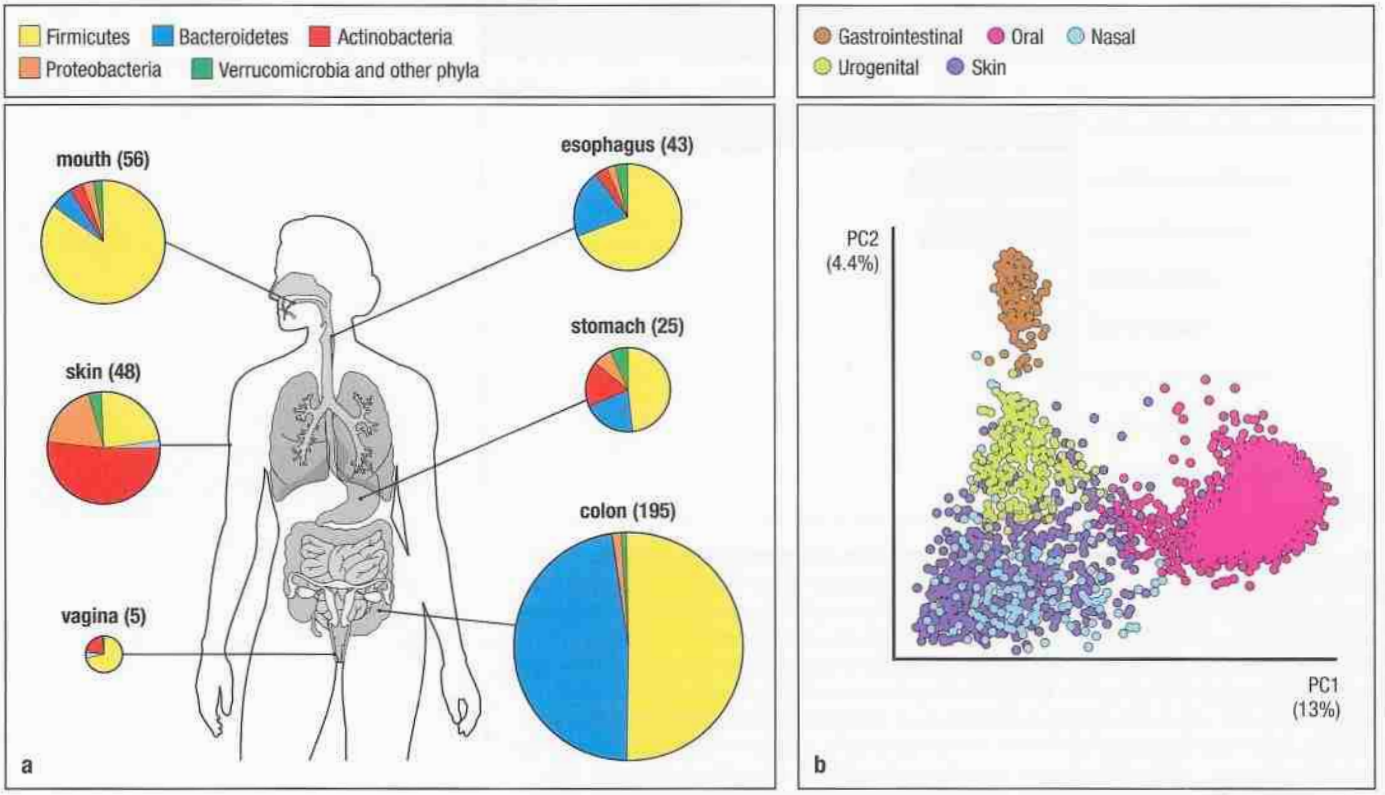

Fig. 12.5 Composition of the commensal microbiota at different barrier surfaces in healthy humans. Panel a: The different sizes of the pie charts for different sites reflect the number of distinct bacterial phyla typically present at those sites. The color key indicates the five bacterial phyla that make up the majority of commensal species. Ubiquitous commensal bacteria include *Lactobacillus* and *Clostridium* spp. (Firmicutes), *Bacteroides fragilis* (Bacteroidetes), *Bifidobacterium* spp. (Actinobacteria), *Escherichia coli* (Proteobacteria), and *Akkermansia* spp. (Verrucomicrobia). The numbers in parentheses denote the number of independent strains. Panel b: Principal component analysis of the microbiota isolated from the indicated human tissues in different individuals, plotting the first and second principal components (PC1 and PC2, respectively). The primary component of microbiota variation between individuals is body area (that is, site location) and accounts for 13% of the variation in microbial identity among site-specific samples taken from different individuals. The colon contains the greatest number of different species (more than 1000 as estimated from individual surveys). Although not shown because it is more difficult to sample, the commensal microbiota of the human small intestine are distinct from and less diverse than those of the large intestine, dominated by members of Firmicutes and Proteobacteria phyla, particularly Lactobacillaceae and Enterobacteriaceae family members, respectively. Note that the values shown are derived from surveys of the Western countries/Western diets; the microbiota composition shifts contingent on diet and other factors.

and genital tract. Here, protective immunity against pathogens is essential, but many of the antigens entering these tissues are harmless, being derived from commensal organisms, pollen, other innocuous environmental material, and, in the lower urogenital tract, seminal fluid.

12-2 Immune cells of the mucosal immune system are located both within and outside of specialized lymphoid tissues in proximity to the epithelium.

The deployment of immune cells in mucosal tissues can be divided into inductive and effector sites—that is, sites where immune cells are initially activated and sites where they act directly in support of the barrier function of the epithelium. Like all other tissues in the body, lymphatics that drain the mucosal tissues deliver antigens to regional lymph nodes, such as the **mesenteric lymph nodes**, which serve as inductive sites for the small intestine and proximal colon, or the cervical lymph nodes, which serve as inductive sites for the oral and nasal cavities, for example. In addition, the mucosae contain inductive sites with organizational features similar to those of other peripheral lymphoid tissues, but they lack afferent lymphatics and receive antigens directly across the overlying epithelium with which they are in direct contact, as will

Components of the mucosa-associated lymphoid tissue (MALT)		
Region	**Components**	**Regional lymph nodes**
GALT (gut-associated lymphoid tissue)	Peyer's patches, cecal patch (mice), appendix (human), and isolated lymphoid follicles (ILFs) or solitary intestinal lymphoid tissue (SILT)	Mesenteric lymph nodes (small intestine, cecum, proximal and middle colon), caudal and iliac lymph nodes (distal colon)
NALT (nasal-associated lymphoid tissue)	Tonsils of Waldeyer's ring (encircling the nasopharynx and oropharynx in humans and composed of nasopharyngeal, tubal, palatine, and lingual tonsils) and ILFs in nasal mucosa. Mice lack tonsils but do have paired NALT structures in floor of nasal cavity	Cervical lymph nodes
BALT (bronchus-associated lymphoid tissue)	Not typically present in uninfected adults, as the lower airways are sterile, but develops in respiratory infections	Peribronchial and mediastinal lymph nodes

Fig. 12.6 Components of the mucosa-associated lymphoid tissue (MALT).

be discussed below; these are collectively referred to as **mucosa-associated lymphoid tissue (MALT)** (Fig. 12.6). Although organized lymphoid tissue is not typically present in the nose or lower respiratory tract in adult humans (unless infection is present), it is present in children and in some species such as mice; in the nose it is called the **nasal- (or nasopharynx-) associated lymphoid tissue (NALT)**, while in the lower respiratory tract it is known as the **bronchus-associated lymphoid tissue (BALT)**. The best-studied mucosal lymphoid tissue—and the largest in mass—is that associated with the gastrointestinal tract, or gut, known as the **gut-associated lymphoid tissue (GALT)**, the bulk of which resides in the intestines. Because the intestines comprise several anatomically defined segments with distinct functions—extending in the small intestine from the duodenum to jejunum and ileum, and in the large intestine from cecum to colon (Fig. 12.7)—there are regional differences in the environmental exposure and response of the associated immune tissues. There are also microanatomic differences that reflect regional specialization and affect the local immune response.

The GALT includes the **Peyer's patches**, which are most prevalent in the distal small intestine; **isolated lymphoid follicles (ILFs)**, also known as solitary isolated lymphoid tissue (SILT), which are smaller structures found throughout the small and large intestine; and, in humans, the **appendix** (Fig. 12.8; and see Fig. 12.7). (Similar to the human appendix is the cecal patch in mice, found near the tip of the blind pouch, or cecum, that is the beginning part of the large intestine; *cecum* is derived from the Latin for 'blind.') Each of these components of the GALT is located within the wall of the intestine; the patches and larger ILFs extend from the intestinal epithelium through the full thickness of the mucosa to the submucosa, whereas smaller ILFs are fully contained within the mucosa; that is, bound below by the muscularis mucosa. In mice, but not typically in humans, Peyer's patches (and the cecal patch) are visible to the naked eye and have a distinctive appearance, forming dome-like aggregates of lymphoid cells that project into the intestinal lumen (see Fig. 1.24). There are approximately 100–300 Peyer's patches in the human small intestine, concentrated in the distal small intestine, or ileum. Peyer's patches are much richer in B cells than the systemic peripheral lymphoid organs, with each consisting of multiple B-cell follicles that contain active germinal centers (that is, secondary B-cell follicles). T-cell zones are situated between and immediately below the follicles. This is in contrast to ILFs, which typically contain a single follicle or a less organized aggregate of B cells, without a distinct T-cell zone. In humans, Peyer's patches may consist of more than a hundred B-cell follicles, although they vary in size with age, peaking in adolescence and declining thereafter.

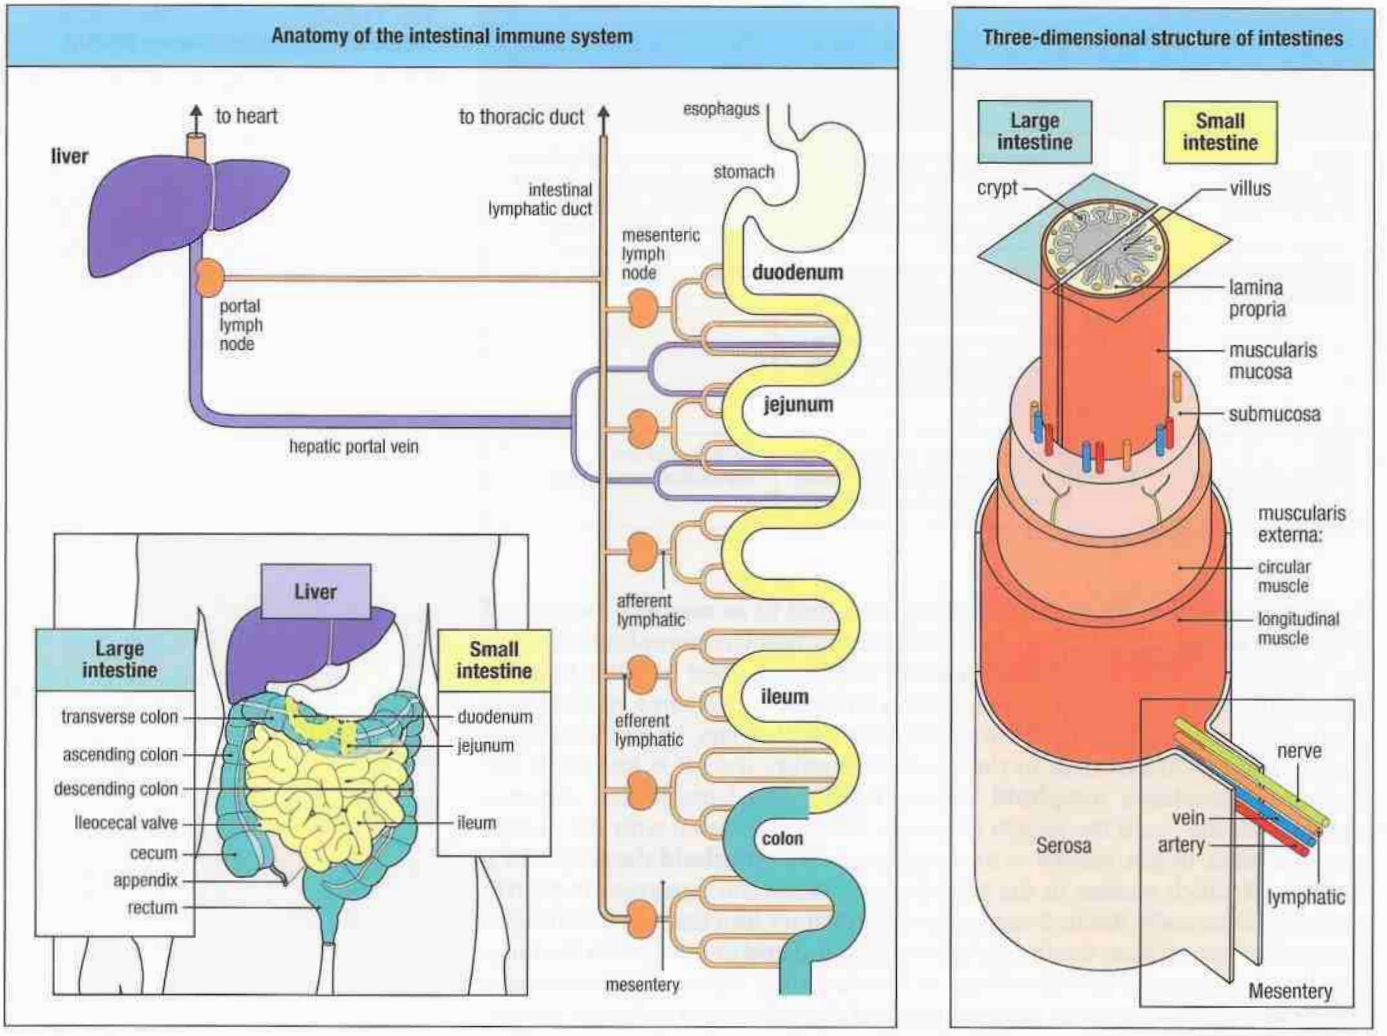

Fig. 12.7 Anatomy of the gastrointestinal tract. Left panel: Shown are the different tissues of the gastrointestinal tract, extending from the end of the esophagus to the rectum. The different segments of the small intestine (duodenum, jejunum, and ileum) generally lack discrete transition zones, as do the segments of the large intestine (cecum, ascending colon, transverse colon, descending colon, and rectum), although the duodenum refers to the C-shaped segment that receives bile and pancreatic enzymes as it courses around the head of the pancreas (not shown) before connecting to the jejunum at the duodenojejunal flexure. The cecum is delimited from the colon at the level of the ileocecal valve, which delivers contents of the ileum to the large intestine. The major lymphatic drainage of the intestines, from mid-duodenum through mid-colon, flows to the mesenteric lymph nodes then to the intestinal lymphatic duct and thoracic duct before reentering the bloodstream. The vascular drainage of the intestines is unusual in that it is first delivered to the liver via the hepatic portal vein prior to returning to the right side of the heart. The liver therefore processes the entire venous drainage of the intestines and plays a contributory role in restraining immune responses to the commensal microbiota. Right panel: Schematic of the layers of the small and large intestine, highlighting relationships between the mucosa (encompassing the epithelium, lamina propria, and the thin, inner layer of muscle—the muscularis mucosa), the submucosa (between the muscularis mucosa and the thicker, outer circular and longitudinal muscle layers—the muscularis externa), the thin serosa that forms the outer surface of the intestines, and the mesentery, which supports the intestines along one edge and through which the major blood vessels, lymphatics, and nerves that serve the intestines pass. The larger arteries, veins, lymphatic vessels, and nerves that supply the intestine from the mesentery penetrate the outer muscle layers and travel through the submucosa, sending smaller branches through the muscularis mucosa to supply the lamina propria. As the name implies, the mesenteric lymph nodes are embedded within adipose tissue that fills the mesentery (not shown).

A feature common to all MALT, including GALT, that distinguishes it from conventional lymph nodes is the absence of afferent lymphatics or a capsule. This organization is essential to the function of the GALT as an important site for the initiation of immune responses in the gut, enabling direct sampling of luminal antigens that are transported across the specialized epithelium overlying the Peyer's patches and ILFs—the **follicle-associated epithelium (FAE)**. Contained within the FAE are specialized epithelial cells called **microfold cells**

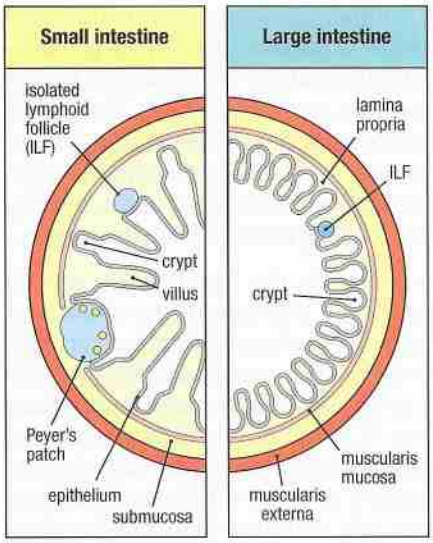

Fig. 12.8 Architecture of the small and large intestinal mucosae. Illustrated here is a cross section of the small and large intestines, highlighting the organization of tissue compartments and the relationship of the gut-associated lymphoid tissue—Peyer's patches in the small intestine and isolated lymphoid follicles in the small and large intestine—to the epithelium, the mucosa, and the submucosa. The mucosae of the small (left panel) and large (right panel) intestines are distinguished by the organization of the former into numerous villi (fingerlike projections into the intestinal lumen that increase the surface area for digestion of food and nutrient absorption), which alternate with crypts. This is in contrast to the large intestine, which generally lacks villi and is composed of crypts that are separated by very limited lamina propria. The epithelium comprises a single cell layer that is replaced continually by new cells derived from stem cells in the base of the crypts. The tissue layer bounded by the epithelium above and a slender layer of smooth muscle below (the muscularis mucosa) is called the lamina propria. Lymphocytes are found in several discrete compartments in the intestine, with the organized lymphoid tissues such as Peyer's patches and isolated lymphoid follicles forming what is known as the gut-associated lymphoid tissue (GALT). These tissues lie within the wall of the intestine itself, separated from the contents of the intestinal lumen by the single layer of epithelium. The draining lymph nodes for most of the small and large intestines are the mesenteric lymph nodes, which are connected to Peyer's patches and the intestinal mucosa by afferent lymphatic vessels; they are the largest collection of lymph nodes in the body. The outer wall of the small and large intestines is composed of thicker external muscle layers—a circular and a longitudinal layer that are known collectively as the muscularis externa—that provide the propulsive force, or peristalsis, that moves the luminal contents along the intestinal tract.

(M cells) (Fig. 12.9; and see Fig. 1.24 and Section 12-4), which transport intact bacteria, abiotic particulates, and soluble antigens within vacuoles across their cell bodies. The area immediately beneath the FAE, the subepithelial dome, is rich in dendritic cells and lymphocytes, which are in intimate contact with the FAE. Unlike the enterocytes that make up the rest of the intestinal epithelium,

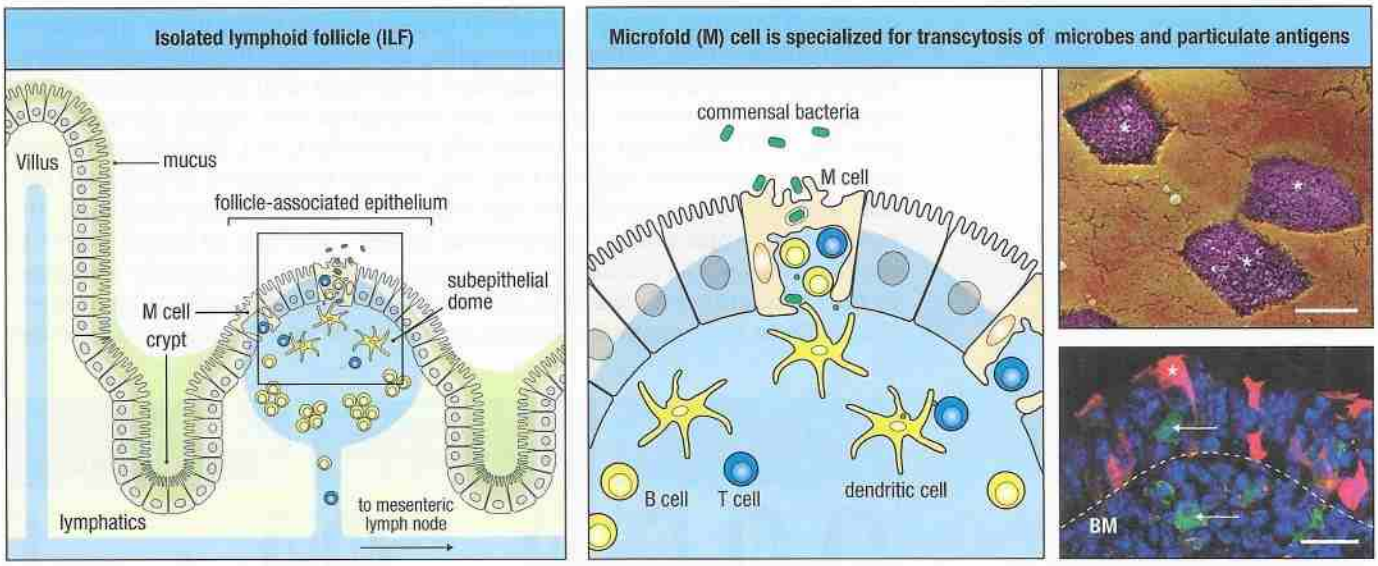

Fig. 12.9 The epithelium overlying lymphoid tissues within the intestinal mucosa is specialized for uptake of particulate antigens. The left panel depicts the continuous epithelium of the small intestine, here seen overlying a villus, crypts, and an isolated lymphoid follicle, or ILF. The epithelium over the ILF, similar to that overlying Peyer's patches (not shown), is referred to as follicle-associated epithelium, or FAE, and contains isolated microfold (M) cells. M cells, highlighted in the middle panel, are specialized for the transport of intact microbes and large particles in vacuoles across their cell bodies to be released to convoluted basolateral membranes that form 'pockets' within the epithelial layer, allowing close contact with lymphocytes and other cells. This favors the local transport of antigens that have been taken up from the intestine by the M cells and their delivery to dendritic cells for antigen presentation. The top right micrograph shows a scanning electron microscopy (SEM) image that highlights microvilli differences in M cells (identified by asterisks; pseudocolored purple) relative to neighboring enterocytes (pseudocolored tan) on the luminal surface of a Peyer's patch. At bottom right, an immunofluorescence micrograph of Peyer's patch follicle epithelium shows M cells identified by expression of peptidoglycan recognition protein-S (PGRP-S; red, example highlighted by asterisk) interacting with processes extended across the basement membrane (BM; indicated by dotted line) by CX3CR1-expressing myeloid cells (green; arrows). M-cell pockets in the epithelium are inferred from the presence of basolateral B and T cells (DAPI; blue). The white scale bars indicate 12.5 μm (top right micrograph) and 25 μm (bottom right micrograph), respectively. Photomicrographs courtesy of Dr. David Lo.

cells that compose the follicle-associated epithelium do not secrete digestive enzymes or mucins, and so lack the thick layer of surface mucus (the glycocalyx) found covering conventional epithelial cells, and the M cells have a folded luminal surface instead of microvilli (see Fig. 1.24 and Section 12.4). These cells are therefore directly exposed to microorganisms and particles within the gut lumen and, because of their ability to transport large antigenic particles and intact microbes across their cell bodies within vesicles, are a preferred route by which microbes and their antigens enter the Peyer's patches from the lumen.

Unlike Peyer's patches, which are found mainly in the distal ileum, several thousand ILFs can be identified microscopically throughout the small and large intestines, but they are more abundant in the large intestine, correlating with the greater load of commensal microorganisms there. Like Peyer's patches, these follicles are also covered by a follicle-associated epithelium containing M cells (see Fig. 12.9). However, ILFs contain mainly B cells and develop only after birth in response to antigen stimulation due to colonization of the gut by commensal microorganisms (Fig. 12.10). Peyer's patches, in contrast, are already present in the fetal gut, although their full development is completed only after colonization by the intestinal microbiota after birth. In the mouse gut, and perhaps in humans, isolated lymphoid follicles arise from small aggregates in the intestinal wall called **cryptopatches**, which are composed of dendritic cells and **lymphoid tissue inducer (LTi) cells**, a type of ILC3 (see Section 9-2 and Section 11-3). Cryptopatches undergo maturation into ILFs only after signals from the developing microbiota stimulate the recruitment of B cells. Peyer's patches and ILFs are connected by efferent lymphatics to regional lymph nodes, such as the mesenteric lymph nodes. This allows antigens taken up across the FAE to stimulate local responses in the Peyer's patch or ILF, as well as distally in the draining lymph node.

The small intestine and the proximal large intestine drain to the mesenteric lymph nodes, which, as the name implies, are located in the mesentery, a connective tissue that tethers the intestine to the rear wall of the abdomen and contains the vasculature, nerves, and lymphatics that supply the intestines (see Fig. 12.7). Although not technically part of the GALT, these lymph nodes are in communication with the GALT via efferent lymphatics, as indicated earlier. They also drain the effector sites within the intestine, described later. The mesenteric lymph nodes represent the largest collection of lymph nodes in the body and play a crucial role in initiating and shaping immune responses to intestinal antigens. The ILFs and lamina propria of the distal large intestine drain to separate nodes known as the caudal and inguinal lymph nodes

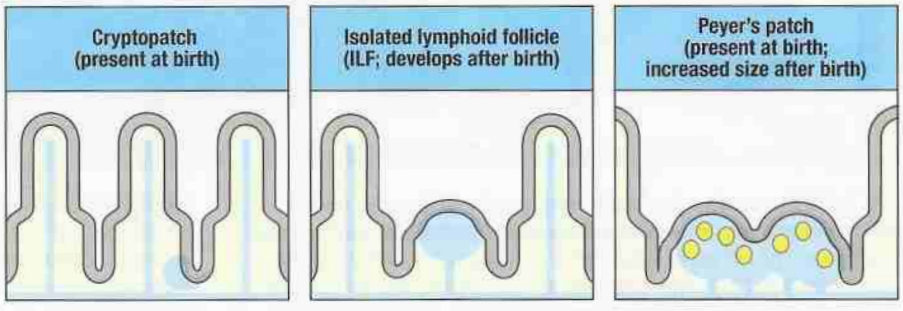

Fig. 12.10 Inductive sites of the GALT. The inductive sites of the GALT include cryptopatches (first panel), which are collections of dendritic cells and lymphoid tissue inducer (LTi) cells clustered near the bases of intestinal crypts at the time of birth that mature in response to signals from the developing microbiota after birth; isolated lymphoid follicles (ILFs), or solitary isolated lymphoid tissue (SILT) (second panel), which are single aggregates of lymphoid tissue that arise from cryptopatches and are found within the mucosa throughout the small and large intestine; and Peyer's patches (third panel), which are present in the distal ileum and are composed of larger aggregates of lymphoid tissue that contain multiple germinal centers.

found close to the bifurcation of the descending aorta on the posterior wall of the lower abdominal cavity. The mesenteric lymph nodes and Peyer's patches differentiate independently of the systemic immune system during fetal development, and their development involves distinct chemokines and receptors of the tumor necrosis factor (TNF) family (see Section 9-2). The differences between the GALT and the systemic lymphoid organs are thus imprinted early in life.

In addition to the inductive sites discussed above, the barrier function of the intestines is supported by effector sites that contain innate and adaptive immune cells that migrate through or reside within the intestinal epithelium itself or in the underlying layer of connective tissue called the intestinal lamina propria (Fig. 12.11; see also Fig. 12.8). The intestinal epithelium and lamina propria are referred to as effector sites because the preponderance of

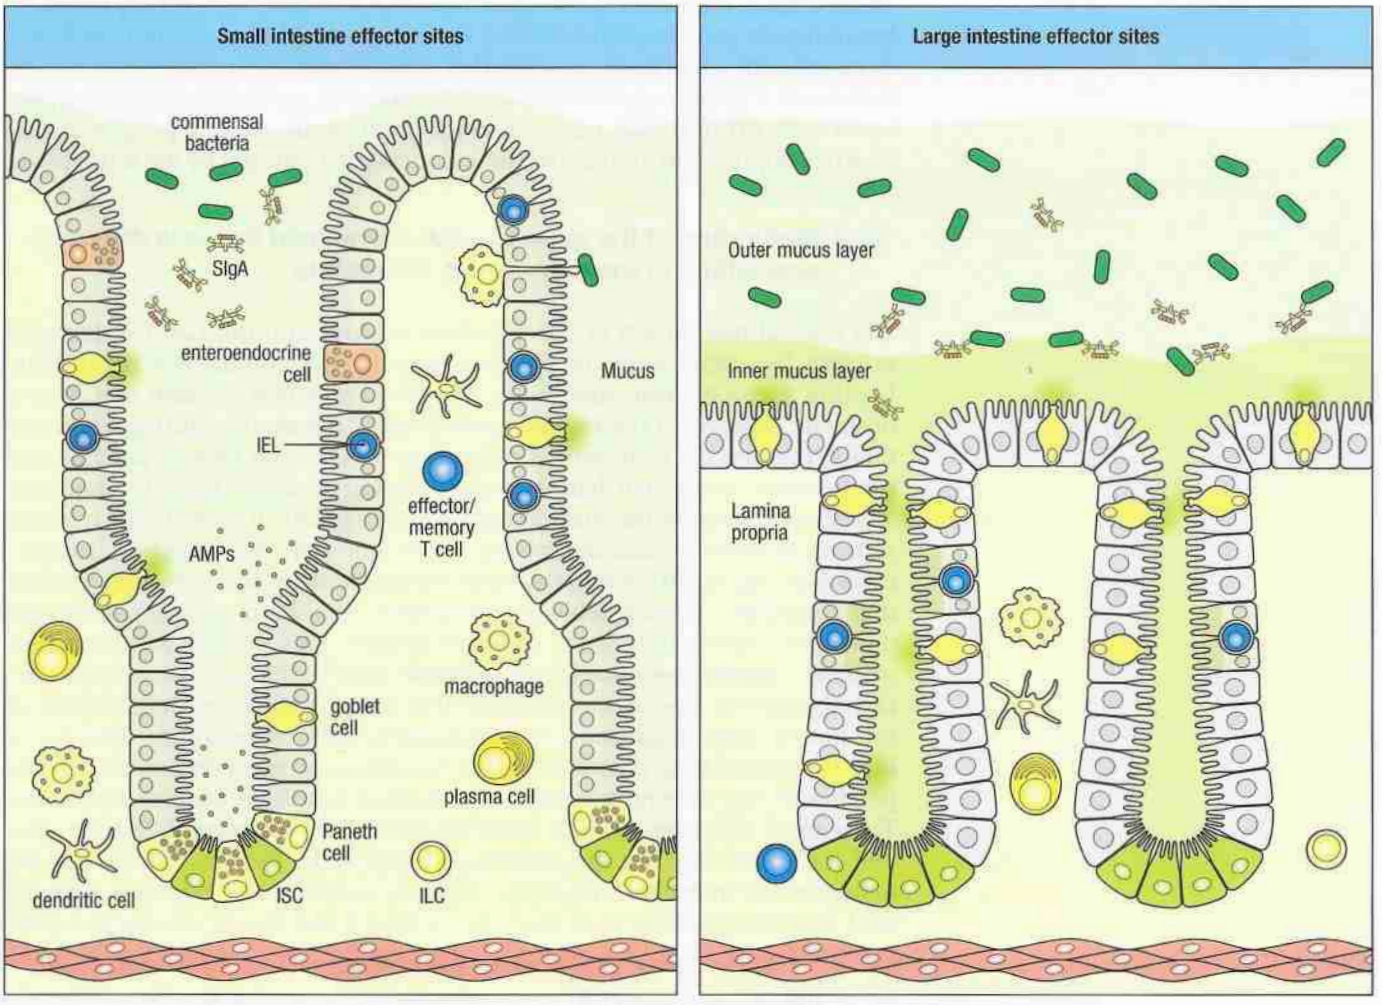

Fig. 12.11 Effector sites of the GALT. The effector sites of the small (left panel) and large (right panel) intestine include the single-cell layer of the intestinal epithelium, in which resides a variety of conventional and unconventional T cells, the so-called intraepithelial lymphocytes (IELs); and the lamina propria, which is populated by innate immune cells (for example, macrophages, dendritic cells) and effector T cells, as well as antibody-secreting cells (plasma cells). (Note that because B cells are not present in the epithelium, the alternate term, intraepithelial T cells, or IETs, is increasingly gaining favor, although we will use the conventional term, IELs, here.) There are also smaller numbers of ILCs, mast cells, and eosinophils in the lamina propria. Lymphatics drain from the lamina propria to the regional lymph nodes (for example, mesenteric lymph nodes). Although not strictly an effector site, the mucus layers overlying the intestinal epithelium (a single layer in the small intestine and two layers in the large intestine) contain antimicrobial peptides (AMPs; primarily small intestine), secreted lectins (for example, peptidoglycan protein ZG16; primarily large intestine), and secreted immunoglobulins (for example, SIgA) that provide an important barrier against interactions between luminal microbes and the mucosa. Note that different types of epithelial cells highlighted here (for example, goblet cells, Paneth cells, enteroendocrine cells, and so forth) will be discussed later in Section 12-4). SIgA, secretory immunoglobulin A; ISC, intestinal stem cell.

adaptive immune cells within them are effector cells that either have migrated there after recognition of antigen in inductive lymphoid tissues of the GALT or regional lymph nodes or, in the case of the epithelium, have populated the site directly from the thymus as functionally competent effector cells around the time of birth. The intestinal epithelium harbors a substantial number of conventional and unconventional T cells, so-called **intraepithelial lymphocytes (IELs)**, as well as some innate lymphoid cells (ILCs), which will be discussed further in Section 12-5. The intestinal lamina propria is diffusely populated by macrophages and dendritic cells that are strategically located beneath the epithelium, and it also contains antigen-experienced effector and regulatory T cells, as well as antibody-producing plasma cells, which are most numerous in the small intestine. Indeed, at homeostasis the largest number of effector T cells and antibody-producing B cells is found in the intestinal mucosa. The intestinal lamina propria also contains smaller numbers of ILCs and type 2 innate effector cells, including eosinophils, basophils, and mast cells, which are also more abundant in the small intestine. In addition, a variety of innate lymphocytes and lymphoid cells on the innate-adaptive spectrum are found in gut effector sites. These are cells that express invariant antigenic receptors, such as γδ T cells, invariant NKT (iNKT) cells, and mucosal-associated invariant T cells (MAIT cells), many of which populate the lamina propria during fetal development in preparation for colonization of the gut by the microbiota.

12-3 Maturation of the gut-associated lymphoid tissue is driven by acquisition of the commensal microbiota.

The normal maturation of the intestinal mucosa and the GALT is initiated at birth by colonization of the intestines by the commensal microbiota. Lacking a commensal microbiota, the preterm infant is germ-free, but is normally exposed to the vaginal microbiota of the mother during birth, initiating the process of intestinal colonization. Although Peyer's patches and the intestine-associated lymph nodes develop *in utero*, ILFs develop only after colonization by the commensal microbiota, and all of the GALT requires sensing of the intestinal microbiota to become fully populated by lymphocytes (see Fig. 12.10). Similarly, other components of the intestinal mucosa that contribute to the establishment of host–microbiota commensalism are driven by colonization of the neonate at birth. This process has been best studied in **germ-free mice** (or **gnotobiotic mice**), which are raised in a contained, microbe-free environment so that there is either no colonization of the gut by microorganisms or colonization only by microbes introduced into the gnotobiotic chamber. In the intestines of germ-free mice, Peyer's patches do not develop normally, and isolated lymphoid follicles are absent. These mice also have severely reduced numbers of intestinal T lymphocytes and ILCs, and very few IgA-secreting plasma cells. They also have reduced mediators of intestinal immunity, such as antimicrobial peptides, retinoic acid, and the cytokines IL-7, IL-22, IL-25, IL-33, and thymic stromal lymphopoietin (TSLP).

As we learned in Chapter 9 (see Section 9-2), preparation for the adaptation to microbial colonization requires the actions of lymphoid tissue inducer (LTi) cells. This subset of ILC3 cells is instrumental in organizing development of the GALT, as well as other lymphoid tissues in the body (see Fig. 9.2). During fetal development, LTi cells disseminate to sites of future lymphoid tissue development in the gut, recruited by the chemokine CXCL13, a product of specialized stromal cells. Activation of these stromal cells by lymphotoxin (LT-$\alpha_1\beta_2$) expressed on LTi cells initiates the development of structural components of the Peyer's patches, as well as the recruitment and partitioning of B and T cells into B-cell follicles and T-cell zones. ILF development is similarly dependent on LTi cells but is initiated after birth when cells in cryptopatches

are stimulated to recruit lymphocytes in response to microbial stimuli from the developing microbiota (see Fig. 12.10). Thus, ILFs develop from cryptopatches only after colonization by the intestinal microbiota. As discussed later, LTi cells continue to contribute to the intestinal response to the microbiota beyond their role in the perinatal development of the GALT, as do other subsets of ILCs that seed the intestines—and other barrier tissues—during the perinatal period.

Like the GALT, the intestinal epithelium of the newborn undergoes changes to accommodate to the microbiota. For example, expression of TLR-4, the receptor for lipopolysaccharide (LPS)—a major pathogen-associated molecular pattern (PAMP) expressed by Gram-negative bacteria—is significantly upregulated prior to birth. Soon after exposure to the developing microbiota, however, intestinal epithelial cells (IECs) rapidly down-regulate TLR-4 and other components of its signaling apparatus to attenuate signaling at the IEC apical membrane. Nevertheless, TLR-4 remains expressed within endocytic vesicles where it can sense bacterial invasion and induce a pro-inflammatory response. An additional immune mechanism that prepares the neonate for microbial colonization is the seeding of the intestinal epithelium by intraepithelial lymphocytes (IELs) before birth. As we will see in Section 12-5, localization of IELs within the epithelium enables them to respond rapidly to help limit bacterial translocation, maintain epithelial barrier integrity, and promote repair of the epithelium after injury.

At maturity, the intestines maintain the largest number and diversity of commensal microbes in or on the body, harboring several hundred species of commensal bacteria alone. The greatest density of microbiota along the intestinal tract is in the distal ileum and large intestine, particularly in the cecum. Over the first year or so of life, however, there are marked and often erratic shifts in the intestinal microbiota as it transitions from a more limited consortium dominated by so-called **pioneer bacterial species**—primarily facultative anaerobes dominated by Proteobacteria, such as *E. coli*, which can thrive in a more aerobic microbiota-naive intestine—to a more diverse consortium dominated by strict anaerobes, such as Firmicutes (for example, *Clostridium* spp.) and Bacteroidetes (for example, *Bacteroides fragilis*), that occurs in concert with a reduction of oxygen levels in the superficial intestinal mucosa and the lumen (Fig. 12.12).

Another major driver of maturation of the intestinal microbiota is the transition from a liquid to solid diet that occurs with weaning from breast milk. Prior to the introduction of solid food, breast milk provides a specialized mix of nutrients and antimicrobial proteins that influence the ecology of the neonatal microbiota, as well as maternal secretory IgA (SIgA), the specificities of which have been shaped by the mother's microbiota. In essence, the mother's mucosal immune memory is transmitted to her child. Thus, in infants delivered transvaginally, the intestinal microbiota not only is seeded by maternal

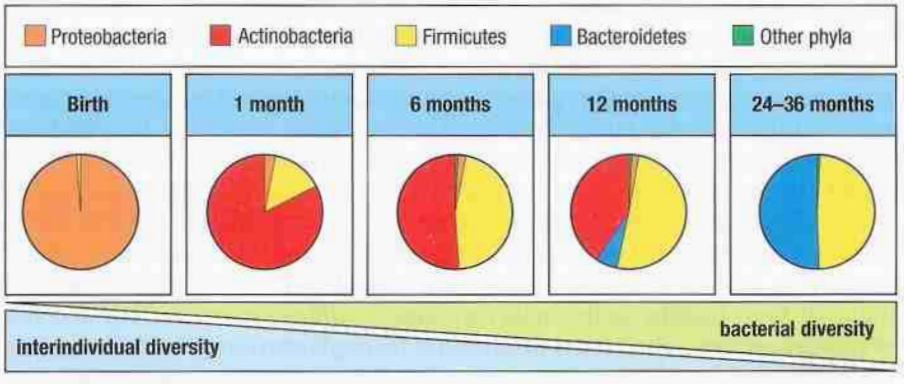

Fig. 12.12 Stages of microbial colonization of the neonatal intestines after birth. The newborn human begins to be colonized with commensal microbes during the process of birth and immediately after. The large-intestinal microbiota is initially colonized by members of the Proteobacteria phylum, particularly Enterobacteriaceae, which are facultative anaerobes that can thrive in the relatively oxygen-rich intestinal environment of the newborn. Initially, the bacterial composition is dominated by relatively few species. In the days to weeks that follow, strict anaerobic bacteria come to dominate the microbial community, and the number of different species grows. During the first month, Actinobacteria, particularly Bifidobacteriaceae, begin to predominate, but the introduction of solid foods at around 4–6 months is accompanied by an expansion of members of the Firmicutes phylum, dominated by clostridial species of the Lachnospiraceae, Clostridiaceae, and Ruminococcaceae families. Members of the Ruminococcaceae family continue to increase in abundance over the ensuing months. By 2–3 years of age, the composition of the large intestinal microbiota consists mainly of members of the Bacteroidetes (for example, Bacteroidaceae) and Firmicutes (for example, Lachnospiraceae and Ruminococcaceae) phyla, strict anaerobes that continue to stably dominate the microbiota into adulthood. Relative proportions of major bacterial phyla are depicted in circles at each stage of development. Note that although there is relatively less diversity in the species that compose the intestinal microbiota early after birth compared to later (bacterial diversity), there is greater variability in composition between individuals early after birth compared to later (interindividual diversity).

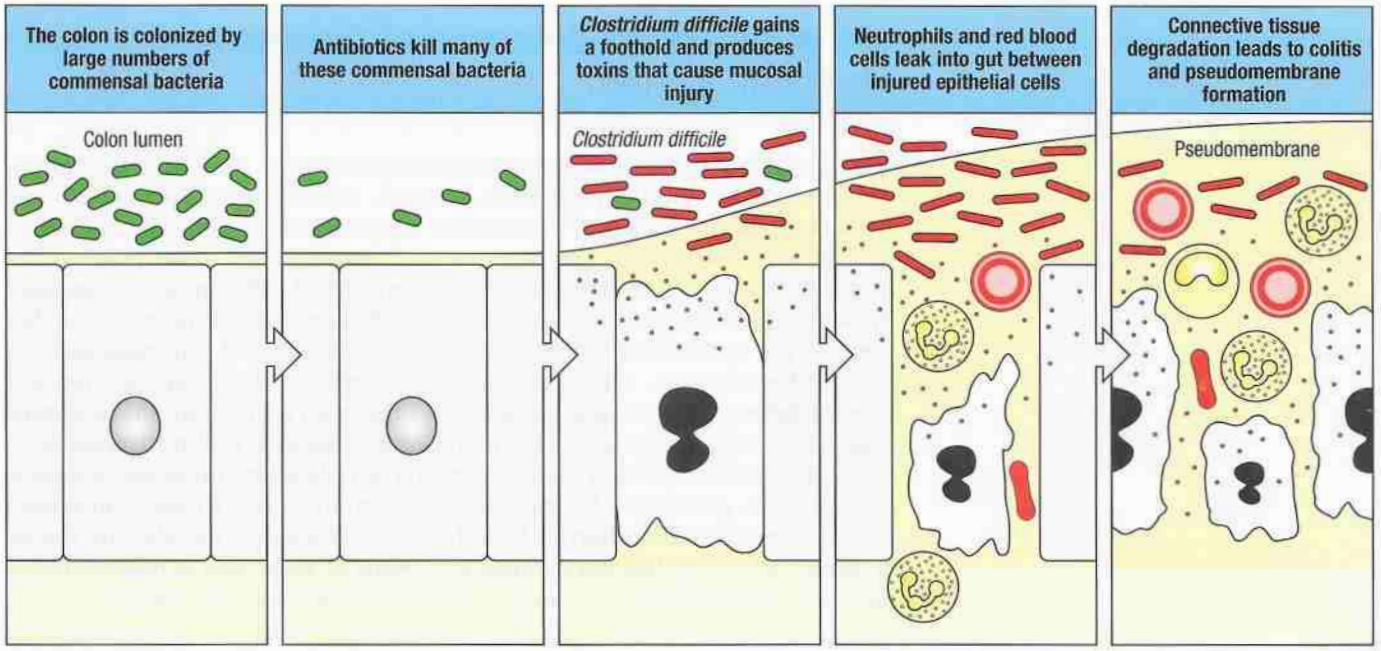
bacteria, but also its composition may be shaped by maternal SIgA, which is influenced, in turn, by the mother's microbiota. The transition to solid foods introduces new substrates, such as complex carbohydrates, that serve as fuel for a transition of the microbiota to its mature composition. As different constituents of the microbiota have different nutrient and metabolic features, the foods ingested can result in marked alterations in the composition of the microbiota.

In humans, two major phyla of anaerobic bacteria—Firmicutes and Bacteroidetes—come to dominate the mature intestinal microbiota, although significant Proteobacteria, Actinobacteria, Verrucomicrobia, and Archaea are also found (see Fig. 12.5). Trillions of these microorganisms normally exist in a beneficial symbiotic relationship with the host known as **mutualism**, reflecting the benefits that both microbes and host derive from their sharing of resources. Microbiota–host mutualism dates back almost 500 million years to the rise of jawed vertebrates, with the result that the microbiota has coevolved with their hosts over many millennia. Indeed, it is speculated that the development of an adaptive immune system in vertebrates may have allowed them to accommodate to a complex intestinal microbiota and generate the bacterial bioreactor as a mechanism to extend the range of foods from which they derive energy, providing a competitive survival advantage. This has produced, in essence, a superorganism that includes humans and their microbiota.

The microbiota has an essential role in maintaining health. Its collective genome, or **microbiome**, contains more than 10 times the number of genes encoded in the human genome, including many genes that encode enzymes that metabolize dietary constituents such as cellulose and produce essential cofactors such as vitamin K_1. **Short-chain fatty acids (SCFAs)**, such as acetate, propionate, and especially **butyrate**, produced by anaerobic commensal bacteria during the metabolism (fermentation) of complex dietary carbohydrates, are an essential source of energy for colonic enterocytes as substrates for the tricarboxylic acid (TCA) cycle. Host benefits derived from the commensal microbiota extend beyond those related to nutrition, however. The microbiota also plays an important role in protection against pathogens by competing for colonization niches and nutrient resources, collectively referred to as **colonization resistance**. Indeed, the normal microbiota contains bacterial species that can cause pathology if not continually restrained by other members of the collective. These **opportunistic pathogens** include a number of Gram-negative and Gram-positive bacteria of the Enterobacteriaceae family, such as *E. coli*, *Klebsiella pneumoniae*, and *Proteus mirabilis*, which can cause serious disease if they extend beyond the confines of the intestinal lumen.

This protective role of the intestinal microbiota is dramatically illustrated by the adverse effects of broad-spectrum antibiotics, which can kill large numbers of commensal gut bacteria, thereby creating an ecological niche for bacteria that would not otherwise be able to successfully compete. The disproportionate expansion of relatively minor constituents of the microbiota that are normally restrained by the collective is called **dysbiosis**, which can disrupt the normal metabolic function of the intestines and even cause serious disease. One example of a bacterium that grows in the antibiotic-treated gut and can cause severe disease is the spore-forming, Gram-positive anaerobe ***Clostridium difficile*** (Fig. 12.13). This organism is an increasing problem in countries where broad-spectrum antibiotic use is prevalent, as it produces toxins that cause severe diarrhea and intestinal mucosal injury. In many cases, treatment of this infection by additional antibiotics is not effective. In these cases, it has been found that providing a normal intestinal microbiota by a transplant of fecal material from healthy individuals can cure *C. difficile* infection. The success of this procedure, called **fecal microbiota transplantation (FMT)**, in treating antibiotic-resistant *C. difficile* infection has led to a growing consideration of



The colon is colonized by large numbers of commensal bacteria
Colon lumen
Antibiotics kill many of these commensal bacteria
Clostridium difficile gains a foothold and produces toxins that cause mucosal injury
Clostridium difficile
Neutrophils and red blood cells leak into gut between injured epithelial cells
Connective tissue degradation leads to colitis and pseudomembrane formation
Pseudomembrane

Fig. 12.13 Infection by *Clostridium difficile*. Treatment with antibiotics can cause massive disruption of the intestinal microbiota by killing many commensal bacteria that normally colonize the colon and contribute to colonization resistance. This allows pathogenic bacteria to proliferate and to occupy an ecological niche that is normally occupied by harmless commensal bacteria. *Clostridium difficile* is an example of a toxic pathogen that can cause severe bloody diarrhea in patients treated with antibiotics. Damage to the epithelium leads to an exudate of necrotic material and fibrin that forms a thin yellow-white layer on the luminal surface of the colon, referred to as a pseudomembrane. This infection is often treated with antibiotics that target *C. difficile*, but newer therapies aimed at restoring the normal composition of the microbiota by transplantation of feces from normal donors (fecal microbiota transplantation, or FMT) have shown considerable promise.

its use for the treatment of other gastrointestinal and extraintestinal diseases thought to be linked to a dysbiotic microbiota, including inflammatory bowel disease (IBD), obesity, metabolic syndrome, and diabetes, and even CNS disorders such as Parkinson's disease and multiple sclerosis.

Summary.

The barrier tissues of the body are continually exposed to an enormous diversity of antigens derived from the environment and the commensal microbiota. While *in utero*, the developing fetus is largely insulated from these antigens, but immediately after birth, the newborn must contend with them, beginning an interaction that affects the development and function of the mucosal immune system and persists throughout life. Specializations of the immune system at mucosal tissues facilitate free interactions with these antigens while maintaining the epithelial integrity to prevent microbes from breaching the epithelium.

The anatomy of the epithelium differs regionally, but most of the surface of mucosal tissues is covered by a single layer of epithelial cells. A unique adaptation of mucosal tissues is their deployment of inductive lymphoid tissues, such as Peyer's patches and isolated lymphoid follicles, which lack afferent lymphatics and instead receive antigens directly across specialized epithelial cells that separate them from the lumens of the mucosae. These components of the mucosa-associated lymphoid tissue, or MALT, complete their development in response to microbes that populate the mucosae after birth and are central to the lifelong maintenance of immune tolerance to the commensal microbiota. Maintenance of the commensal microbiota confers benefits to the host, including certain nutrients and vitamins and colonization resistance against potential pathogens, but dysregulation of the microbiota, or dysbiosis, can lead to disease. The mucosal tissues are also major sites of entry of pathogens, and, as in other tissues, draining lymph nodes also serve the mucosal tissues as sites for the induction of adaptive immunity against pathogens and commensals alike. As a reflection of their important role on the front lines, barrier tissues contain the largest number of effector B and T cells in the body and produce the largest quantity of antibody.

Innate immune defenses of the intestinal immune system.

The GI tract is one of the body's most extensive portals for the entry of microbes, whether commensals or pathogens. As such, it has evolved specialized barrier defenses with which to restrain the microbiota and minimize pathogen threats while maintaining its functions of nutrient and water uptake. The innate defenses in the gut are also tuned toward anti-inflammatory responses through regulatory networks that promote efficient removal of microbes that traverse the epithelium without untoward production of pro-inflammatory factors (for example, cytokines and chemokines). The strategy is one of a layered defense that integrates the mucus layer; an epithelium that contains resident immune cells, produces antimicrobial factors, and transports antibodies into the lumen; and a lamina propria populated by innate and adaptive immune cells positioned for rapid responses to microbial threats and poised for tissue repair should barrier breaches occur. Here we consider the innate components of this layered defense and examine their role in maintaining a defensive posture while promoting coexistence with the microbiota.

12-4 The intestines are lined by a diversity of epithelial cell types that develop from a common progenitor and play distinct roles in mucosal immunity.

Central to intestinal host defense is the epithelium, which is an active sensor of, and conduit for, interactions between the host and the 'external' environment; that is, the contents of the intestinal lumen—both ingested (food) and resident (commensal microbiota). The intestinal epithelium is a simple columnar epithelium that is one cell thick and is polarized such that it distinguishes the external and internal environments. It performs a complex role in balancing the uptake of nutrients and water with its barrier function of excluding commensal and pathogenic microbes. It is composed of a diversity of cell types that, although derived from a common stem-cell precursor, play distinct roles in these varied functions. The mix of intestinal epithelial cell (IEC) types varies along the length of the intestines, as does the microanatomy of their deployment, corresponding to regional variation in the dominant functions of segments of the small and large intestines. In the small intestine, the epithelium covers fingerlike projections, or villi, which markedly increase the surface area for absorption of food (Fig. 12.14). The height of villi is greatest in the proximal small intestine and decreases progressively along the axis from the duodenum to the ileum, reflecting the greater role of the proximal and middle small intestine in nutrient uptake. Each villus is supported by a dense network of small blood vessels, nerves, and a single **lacteal**—a closed-ended lymphatic vessel that conducts lymph and immune cells, as well as absorbed nutrients (for example, lipids), from the lamina propria to regional lymph nodes (see Fig. 12.14). Individual villi are surrounded by multiple invaginations, called crypts, which are shared by surrounding villi and are sites for the production of new epithelial cells, as we will consider momentarily. In the large intestine, villi are scarce; most of the large intestinal mucosa is composed of tightly apposed crypts between which there is scant lamina propria at homeostasis. The absorptive surface of the large intestine is therefore reduced, reflecting its more limited role in nutrient uptake in favor of its role in water regulation and waste elimination, as well as support of the commensal microbiota.

In both the small and large intestine, the crypts are the 'nursery' for production of new epithelial cells (Fig. 12.15; and see Fig. 12.11). Because of the substantial mechanical, chemical, and microbial stresses to which the intestinal

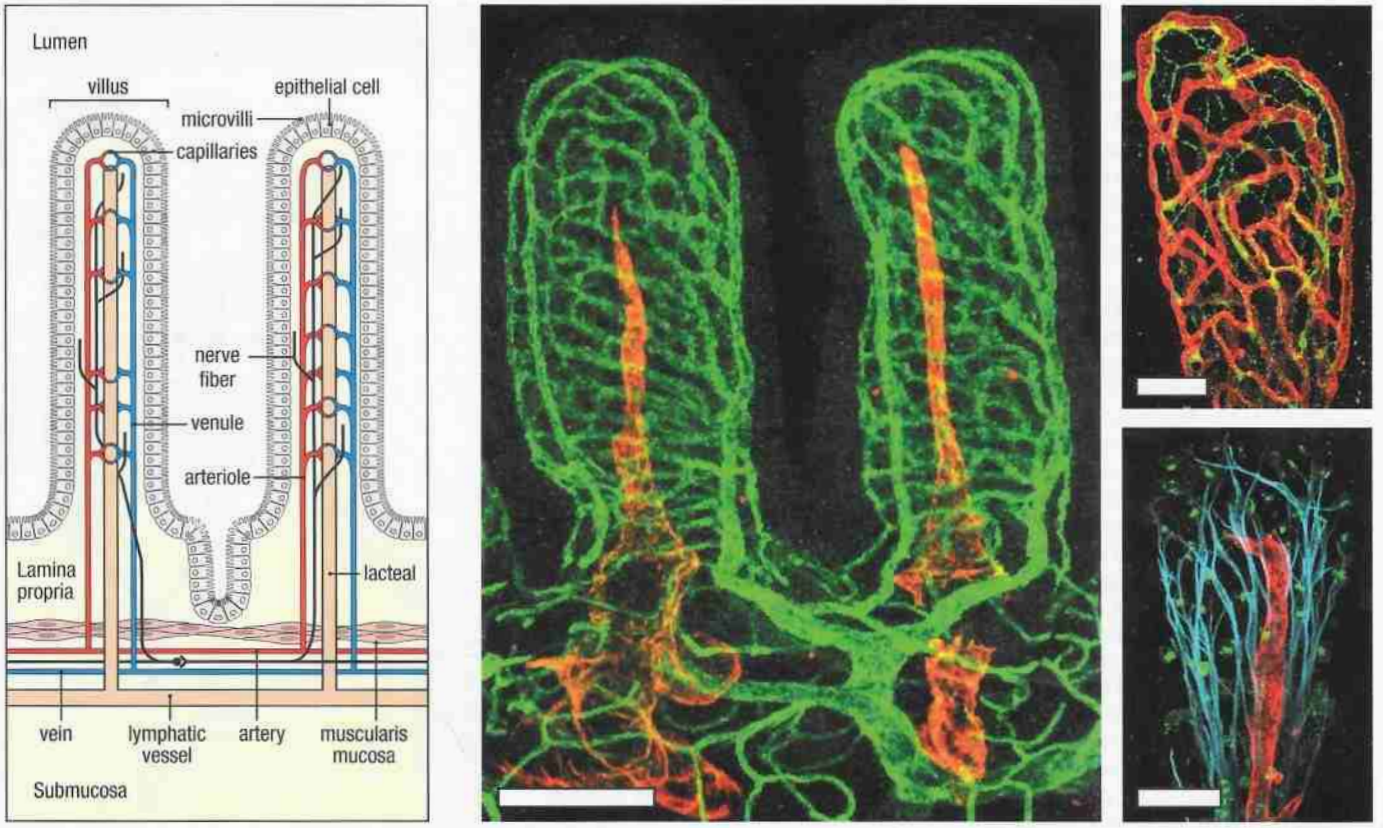


Fig. 12.14 Relationship of the vasculature, lymphatics, and nerve fibers in the intestinal mucosa. The intestines are specialized for nutrient uptake and fluid regulation while performing immunoregulatory functions and defense against potential enteric pathogens. Supporting these various functions is a network of vascular, lymphatic, and nervous system components that supply the different layers of the intestines. Small branches from the network of small arteries and veins that course along the submucosa penetrate the muscularis mucosa to generate an intricate network of arterioles, capillaries, and venules that supply the lamina propria and through which innate immune cells and effector lymphocytes are delivered. Small lymphatic vessels originate in the lamina propria and course through the submucosa and the mesentery to deliver lymph and immune cells to regional lymph nodes (for example, mesenteric lymph nodes). Shown in these panels is the relationship of these structures in small intestinal villi. Generally, a single blind lymphatic vessel called a lacteal is found centrally in the villus and invested by a capillary network and nerve fibers. Dietary fat absorption is also carried out by lacteals and is uniquely promoted by lacteal contractions that are controlled by the autonomic nervous system. Left panel: Schematic of the relationship of the intestinal epithelium to the vascular and lymphatic vessels and nerve fibers. Middle panel: Intestinal whole-mount immunofluorescence image showing lacteals (red) and blood capillaries and venules (green). Right panel: Upper, immunostaining of villus blood capillaries (red) and nerve fibers (green) highlighting the close association of nerve fibers and capillaries; lower, immunostaining of an intestinal villus lacteal (red), smooth muscle cells (blue), and macrophages (green). The white scale bars indicate 100 μm (middle panel) and 50 μm (upper and lower right panels), respectively.

epithelium is subjected, its turnover is among the most rapid in the body, with the lifetime of most IECs averaging 3–5 days from their generation in the depths of crypts to their shedding into the lumen from the mucosal surface. Regeneration is from a small population of continually cycling, self-renewing stem cells, called **intestinal stem cells (ISCs)**, or crypt base columnar (CBC) cells, which reside at the bottom, or base, of the crypts and are identified by their expression of leucine-rich repeat–containing G protein–coupled receptor 5 (LGR5), which recognizes the R-spondin family of ligands. The strategic location of these cells as distant as anatomically possible from the intestinal lumen and the small opening through which the crypt connects with the intestinal lumen are thought to protect ISCs from insults and reflects their critical role in resupplying the epithelium at both homeostasis and during infection. Progeny of ISCs destined for differentiation into mature IECs are rapidly dividing cells that populate the lower and middle crypts, so-called transit-amplifying (TA) cells, which, in turn, give rise to the two major groups of IECs: absorptive IECs and secretory IECs. Within these two major subsets of differentiated IECs, at least six cell types are recognized: absorptive enterocytes and

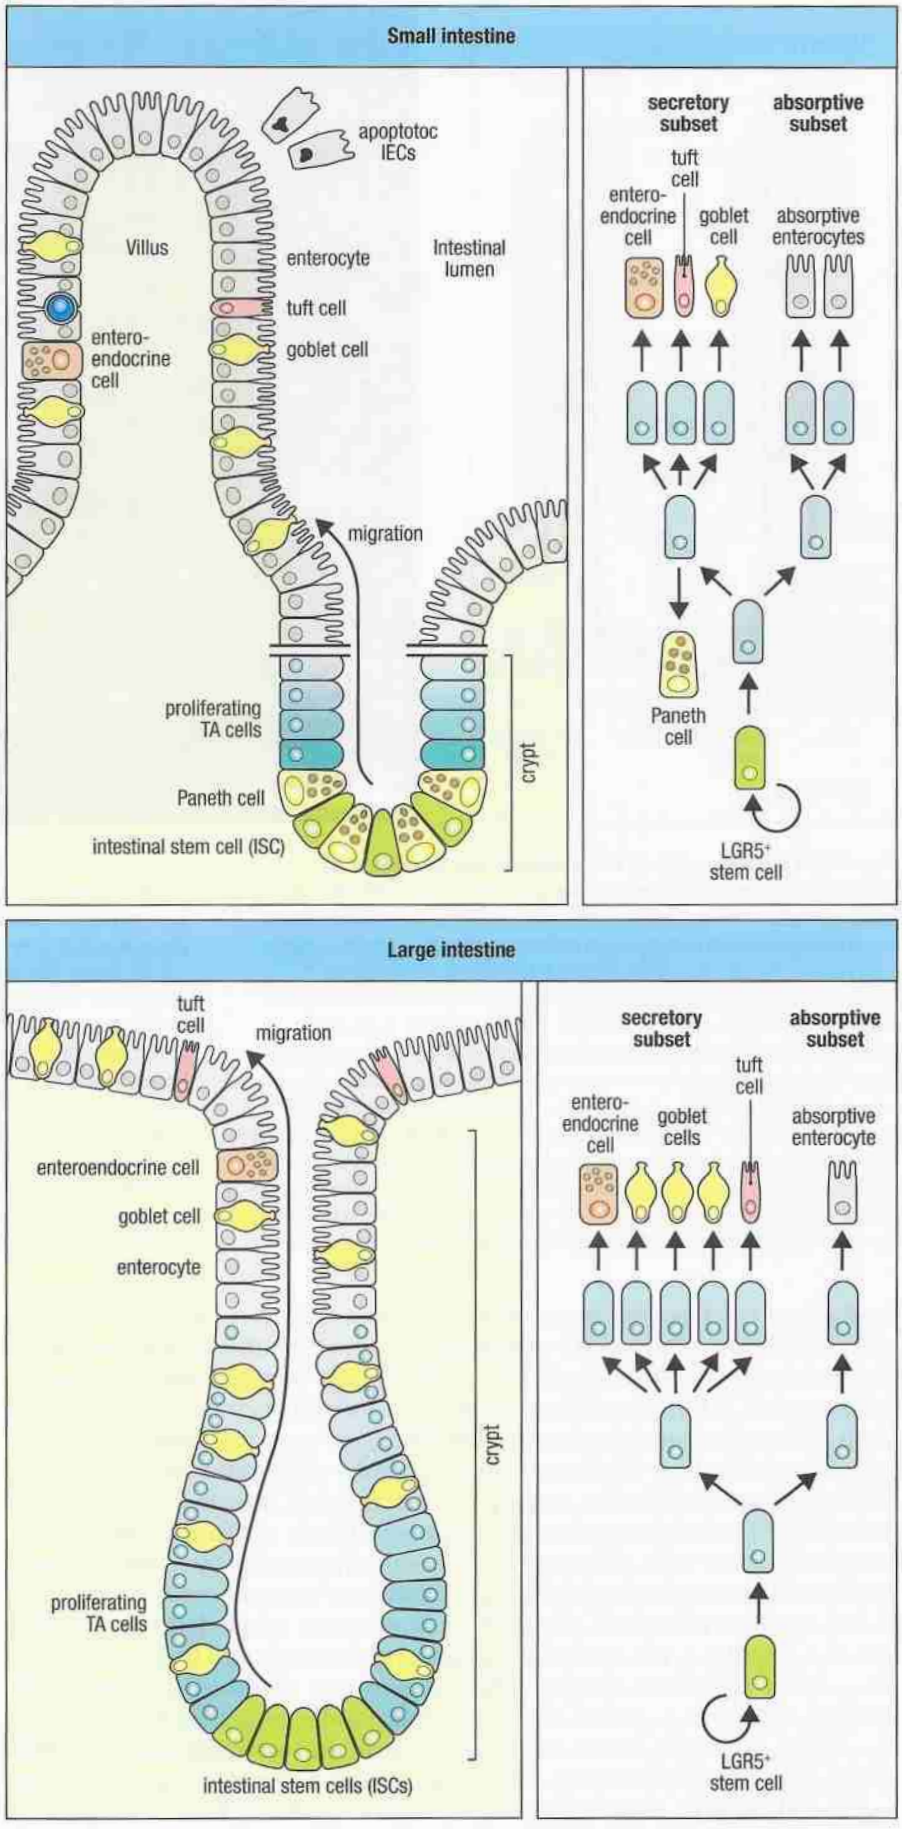

Fig. 12.15 Development of intestinal epithelial cells (IECs). In the intestines, stem cells marked by expression of LGR5 (leucine-rich repeat–containing G protein–coupled receptor 5; a component of the WNT receptor) reside in the base of each crypt and give rise to progeny that develop as they ascend along the crypt walls (curved arrows). The stem cells divide continually to generate rapidly proliferating transit-amplifying (TA) cells, which occupy much of the remainder of the base of the crypts (lower third to half of crypt). Developing TA cells are fated to one of two major subsets of mature IECs: absorptive or secretory cells. Notch signals determine whether stem cells differentiate toward the absorptive fate (Notch on) or toward the secretory fate (Notch off). The absorptive subset includes mature enterocytes and microfold (M) cells (not shown). The secretory subset includes goblet cells, tuft cells, enteroendocrine cells, and, in the small intestines, Paneth cells. Epithelial turnover occurs every 3–5 days in the small intestine and 5–7 days in the large intestine, with senescent cells being lost at the tips of villi in the small intestine (upper panel) or from the surface between adjacent crypts in the large intestine (lower panel) by a process referred to as anoikis. Anoikis is a form of apoptotic or programmed cell death that is induced when anchorage-dependent epithelial cells detach from the basement membrane. The hierarchy of cell differentiation is shown in the tree on the right of each panel and indicates the predominance of absorptive enterocytes in the small intestine and goblet cells in the colon. In the small intestine, new Paneth cells are supplied from TA cells every 3–6 weeks and migrate to position themselves between the LGR5⁺ stem cells, where they provide a niche that supports the survival and differentiation of the stem cells.

Features of intestinal epithelial cell types				
Cell	**Lineage**	**Cell markers**	**Tissue site(s)**	**Major functions**
Crypt base columnar (CBC)	Intestinal stem cell	LGR5	Small intestine Large intestine	Self-renewal Production of all intestinal epithelial cell types
Absorptive enterocyte	Absorptive	Sucrose isomaltase Lactase	Small intestine Large intestine	Uptake of nutrients and fluids Microbial and metabolic sensing Transport of secretory immunoglobulins
Microfold (M) cell	Absorptive	RANK	Small intestine Large intestine	Antigen uptake Bacterial translocation
Goblet cell	Secretory	MUC2, Trefoil factor	Small intestine Large intestine	Production of mucins Antigen uptake
Paneth cell	Secretory	Lysozyme	Small intestine	Support for intestinal stem cells Secretion of antimicrobial peptides (AMPs)
Tuft cell	Secretory	IL-25	Small intestine Large intestine	Sensing of helminthic odorants and succinate Mobilization of type 2 ILCs via IL-25 and eicosanoid release
Enteroendocrine cell	Secretory	Chromogranin A	Small intestine Large intestine	Respond to multiple nutrient and microbial-secreted products to release hormones and neurotransmitters

Fig. 12.16 Features of intestinal epithelial cell subsets.

M cells (absorptive subset); and goblet cells, Paneth cells, enteroendocrine cells, and tuft cells (secretory subset) (Fig. 12.15 and Fig. 12.16).

In accord with its specialization for nutrient and fluid uptake, the absorptive enterocyte, or simply enterocyte (from the Greek *enterikos*, meaning 'intestine'), is the most abundant cell type in both small and large intestines (see Figs. 12.15 and 12.16). To enhance its absorptive function, the enterocyte projects microvilli toward the intestinal lumen to increase surface area, and it expresses a range of enzymes and transporters tasked with breaking down and taking up nutrients from food. Enterocytes also are critical sensor cells of the innate immune system, reflecting their dominance on the front line separating the external from internal environments. As for all IECs, an important aspect of the barrier function is the network of intercellular junctions that bind individual cells to each other (Fig. 12.17). Organized near the luminal surface of IECs, these tight junctions are formed by complexes of a number of members of the claudin and occludin families of junctional transmembrane proteins that are linked to the epithelial-cell cytoskeleton to form a continuous seal between adjacent cells. This results in a selective, semipermeable structure that generally restricts the passage of molecules between IECs to ions, small solutes, and water. In addition to regulating the flow of these molecules across the epithelium, tight junctions organize the polarity of IECs and create an 'outside,' or apical, surface of enterocytes that faces the intestinal lumen and an 'inside,' or basolateral, surface, which rests on a basement membrane and enables communication with the underlying lamina propria.

This partitioning of the cell surface of IECs is important for its responses to microbial threats, as different pattern-recognition receptors (PRRs), such as TLRs, are differentially arrayed between the apical and basolateral cell membranes. As an example, **TLR-5**, which senses bacterial flagellins—a component of the flagella that provide motility for bacteria and are often expressed by pathogenic strains—is preferentially arrayed on the basolateral surface of enterocytes where it can detect microbes that have breached the barrier and alert the IECs to secrete antimicrobial factors, such as antimicrobial peptides (AMPs), as well as cytokines and alarmins that activate innate and adaptive

Fig. 12.17 Polarization of IECs is organized by a set of cell–cell adhesion molecules that compose tight junctions. Adjacent IECs form tight junctions that are essential to the function of the intestinal barrier and the regulation of movement of ions, solutes, and water across the intestinal epithelium. Tight junctions also partition the plasma membrane and embedded proteins into apical and basolateral domains that have distinct functions in epithelial sensing of microbes, transepithelial signaling, and immune functions (left panel). Tight junctions are primarily composed of claudins and occludins, transmembrane proteins that undergo homotypic adhesions between adjacent IECs near their apical surfaces to form a continuous 'ribbon' that seals the intercellular junction (middle panel). The intracellular domains of these complexes are linked to the IEC actin filament network via zonulin (ZO) proteins, allowing reorganization of the actin skeleton to regulate the permeability of the tight junctions.

immune cells. Thus, in addition to their role in nutrient uptake, enterocytes are active participants in immune responses in the intestines, acting as critical innate sensor and effector cells.

Although the IECs that compose the follicle-associated epithelium (FAE) are a subset of enterocytes, the developmental relationship of microfold (M) cells to enterocytes is less clear. M cells represent a small fraction of all IECs (<1%). Their development is controlled by local B cells and RANK ligand (RANKL), a member of the tumor necrosis factor (TNF) superfamily (see Section 7-23). As indicated earlier (see Section 12-2), M cells are highly specialized for sampling particulate antigens from the intestinal lumen. In contrast to absorptive enterocytes, the apical surface of M cells is devoid of microvilli and lacks a glycocalyx, and because M cells reside in the mucus-depleted follicle-associated epithelium, they are in direct contact with the luminal contents so as to facilitate sampling of the molecules and microbes found there (see Fig. 12.9). M cells also express receptors that bind SIgA, facilitating the uptake of bacteria coated with SIgA (see Section 12.9). M cells have a remarkable ability to shuttle intact microbes across the epithelium in vesicles that deliver their contents to the subepithelial dome where they can be sampled by dendritic cells, a process referred to as **transcytosis** (meaning literally 'across the cell'). The basolateral surfaces of M cells are highly invaginated to form large pockets typically occupied by B and T cells, as well as dendritic cells. This enables the immune system to actively interrogate the microbiota as part of the general mechanism to promote tolerance to nonharmful components of the consortium by inducing regulatory T cells (T_{reg} cells) or SIgA to antigens of commensal microbes, as we will discuss further later (see Section 12-10). As we will also see, some pathogens utilize the M cell as a ferry to cross the epithelial barrier and gain access to the host, even though this feeds them into the heart of the intestinal adaptive immune system.

The second most abundant IEC is the **goblet cell**, so named because of the large secretory vacuole that occupies much of the cytoplasmic space in mature cells (see Figs. 12.15 and 12.16). The goblet cell's primary function is the production of mucins, which are heavily charged, glycosylated, secreted or cell-associated glycoproteins that are organized into the gel-like mucus layer that coats the intestinal epithelium (Fig. 12.18); because mucus is the defining feature of mucosal tissues, the goblet cell is the defining secretory cell of the mucosae. The physicochemical properties of mucus—both slippery and sticky—make

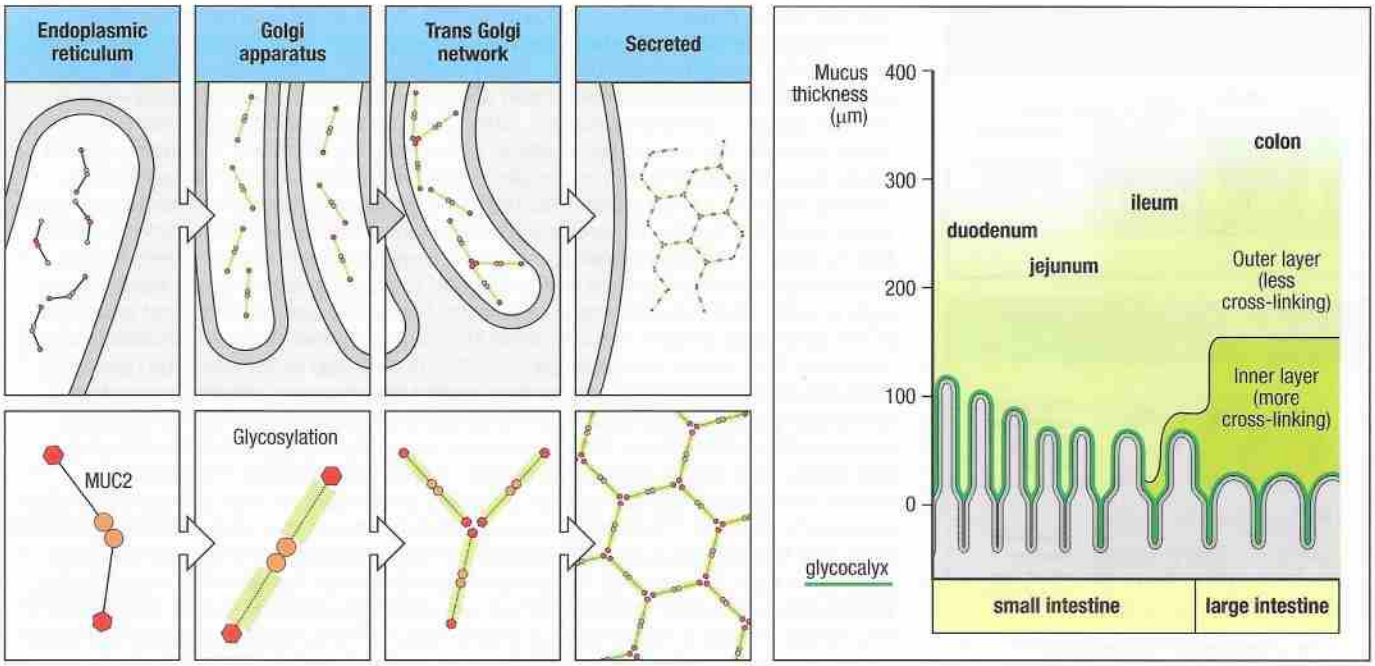

Fig. 12.18 Structure and organization of mucins and mucus. The defining feature of most mucosal tissues is their production of mucus, which is composed of different mucins, glycoproteins with greater than 50% of their mass contributed by O-glycans. There are two major types of mucins: transmembrane mucins, which are anchored to the surface of mucosal epithelial cells, and gel-forming mucins, which are released from the cell surface. Mucus is produced by goblet cells, which are specialized for the production of mucins and for assembly and secretion of mucin polymers that form mucus. Left panel: The major mucin in the intestines is MUC2, a gel-forming mucin. Monomers of MUC2 have C- and N-terminal domains that enable homodimerization and homotrimerization, respectively, and an elongated central portion that is rich in prolines, as well as serines and threonines that undergo heavy O-glycosylation during synthesis to form a rigid rod with a bottlebrush-like structure that binds water and gives mucus its lubricating gel-like properties. Shown in the series of left panels is the assembly of the MUC2 mucin into dimeric forms via disulfide bonding of C-termini cysteine knot domains in the endoplasmic reticulum (ER), O-glycosylation (green; protein core black) in the Golgi apparatus, formation of a netlike sheet by trimerization of N-terminal domains via disulfide bonds in the trans Golgi network (TGN), and a schematic picture of the secreted MUC2 polymer. The polymerized mucin is compacted in the goblet-cell granules and undergoes expansion upon secretion to form extended sheets that can be further cross-linked to produce a netlike, three-dimensional lattice. The MUC2 mucin is anchored in the goblet cells such that the mucus remains attached until cleaved by a host protease (meprin-β in the small intestine) to release the gel lattice from the cell. Right panel: The thickness and structure of mucus is different along the length of the intestines, correlating somewhat with the density of the commensal microbiota from which the epithelium is protected.

it a lubricant that reduces mechanical stress on the epithelium by the flow of material in the lumen while also trapping microbes to block their interaction with the epithelium and facilitate their removal by the normal, rhythmic muscular contractions of the intestines, termed peristalsis. Mucus also provides a scaffolding for retention of SIgA and AMPs that reinforce this physical barrier. Intestinal mucus also serves as a substrate for colonization of harmless commensal bacteria that provide a microbial buffer against pathogens.

Mucus thickness varies along the duodenal–colonic axis of the intestines (Fig. 12.18 and Fig. 12.19). The mucus layer is thinner and focally discontinuous in the proximal small intestine, becoming thicker and continuous in the ileum. In the large intestine, the mucus layer becomes thicker still, several times thicker than in the proximal small intestine. This correlates with the density of goblet cells in the different regions of the intestine, which generally has an inverse relationship with the length of villi (and therefore absorptive function) and a direct relationship with the abundance of commensal bacteria; the density of both goblet cells and bacteria is greatest in the large intestine, and the density of each declines proximally. Also, in the large intestine there are two functionally distinct mucus layers: a thinner, more compact, firmly adherent inner layer that is generally devoid of microbes, and a thicker, more loosely structured, nonadherent outer layer that can be colonized by microbes. The inner, compact layer is generally lacking in the small intestine.

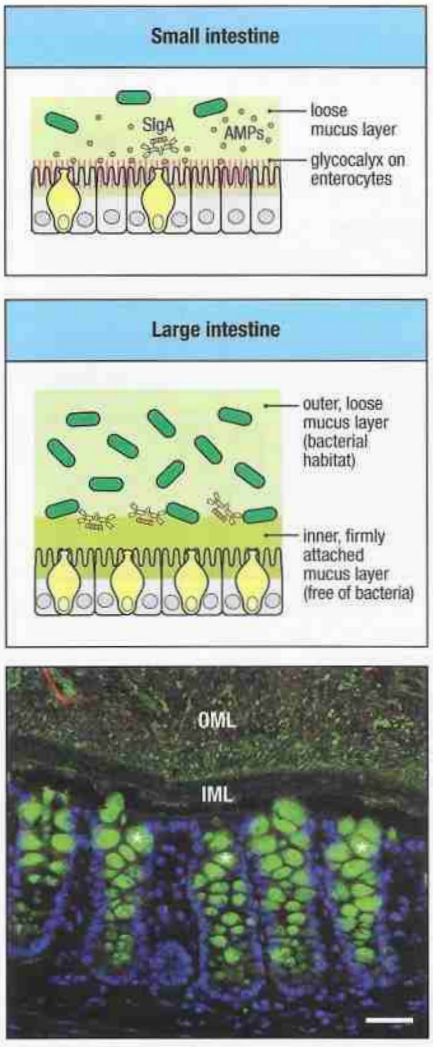

Fig. 12.19 The organization of mucus differs in the small and large intestine. Enterocytes, the major cell type in the intestinal epithelium, have transmembrane mucins covering their apical cell membrane. These mucins reach further out into the intestinal lumen than any other membrane protein and generate a local, attached glycan-rich diffusion barrier, called the glycocalyx, which protects the enterocyte cell membrane. Upper panel: In the upper small intestine, where most digestion and absorption of food takes place, the MUC2 mucin is typically cleaved and detached from the cell surface, allowing the mucus to be transported distally. The mucus lattice is also less densely cross-linked, such that the mucus layer is relatively porous, enabling efficient nutritional uptake. Middle panel: In the large intestine, mucus is composed of two distinct layers: a more densely cross-linked inner layer that is attached to the cells, and an outer, more porous layer in which commensal bacteria can reside. The inner mucus layer is most prominent in the distal colon where it has a stratified structure of layered sheets composed of MUC2 multimers. This dense, well-organized structure is anchored to the epithelium and limits bacterial penetration by having pore sizes smaller than bacteria, creating a zone that is almost completely free from bacteria. Remarkably, the inner mucus layer of the colon can be replaced every hour. The inner colonic mucus layer is converted to a detached, less dense outer mucus layer by the actions of secreted proteases. This allows the mucus to move with the fecal stream, providing lubrication to protect the epithelium from mechanical damage. The mucin glycans of the outer mucus layer also create a specialized niche that fosters colonization by harmless commensal bacteria that harvest the mucin glycans for food. Lower panel: Immunostaining of the colon highlights the mucus layers. Goblet cells in the colon are identified with an anti-MUC2 antibody (green). The section is counterstained with 4′,6-diamidino-2-phenylindole (DAPI) to visualize epithelial-cell nuclei (pale blue). Note that the inner stratified mucus layer is linked via MUC2-stained threads to the goblet cells of the surface epithelia. OML, outer mucus layer; IML, inner mucus layer. Asterisks indicate representative goblet-cell vacuoles. The white scale bar in the lower panel indicates 25 μm.

Although bacteria can penetrate the loose, outer layer of mucus, they are normally kept away from the surface of the epithelial cells, and the cross-linking of the inner layer in the large intestine is such that the pores generated are too small for bacteria to penetrate. Defects in this structure compromise antimicrobial defense, and some enteric pathogens produce mucolytic enzymes that allow them to disrupt the mucus structure to invade.

Although there are many different mucins, the dominant mucin in the intestines is the secreted mucin **MUC2**, which undergoes cross-linking with itself and membrane-bound mucins to form the compact inner layer (see Figs. 12.18 and 12.19). Proteolytic cleavage of the MUC2 polypeptide backbone in the outer layer results in a less compact structure that is amenable to colonization by components of the microbiota. Indeed, mucin glycans serve as nutrients for several keystone anaerobic bacterial species of the large intestinal commensal microbiota (for example, *Bifidobacterium* and *Bacteroides* spp.). The breakdown of these glycans by bacterial fermentation generates short-chain fatty acids (SCFAs), such as propionate and butyrate, which are principal fuel sources for IECs, representing a positive IEC–microbiota feedback loop that promotes retention of these protective bacterial species in the healthy gut. Other fermentation products of mucin degradation (for example, acetate and lactate) that are generated by commensal bacteria are toxic to some pathogenic bacteria, providing an indirect mechanism by which mucus participates in host defense. In contrast to most of the intestinal epithelium, the follicle-associated epithelium that is associated with Peyer's patches and isolated lymphoid follicles is devoid of goblet cells and is not covered by mucus, thereby facilitating sampling of the luminal contents. Notably, there is functional heterogeneity among goblet cells. In the large intestine, the entrance to the colonic crypts is bordered by so-called **sentinel goblet cells**, which, upon sensing pathogens, stimulate a simultaneous release of mucins from other goblet cells in the crypt that is under assault, resulting in an expulsive jet of mucus that flushes the crypt to eject invading microbes. This phenomenon appears to be coordinated by cell-to-cell communication via gap junctions, which are distinct from tight junctions and are specialized structures that provide regulable

Antimicrobial proteins produced in the intestinal mucosa			
Family (examples)	**Mechanism of action**	**Cellular source**	**Microbial targets**
α-Defensins (humans) Cryptidins (mice)	Cell membrane disruption	Paneth cells Neutrophils Macrophages	Gram+ and Gram– bacteria, fungi, protozoa, viruses
β-Defensins (e.g., BD1, BD2, BD3)	Cell membrane disruption	Enterocytes	Gram+ and Gram– bacteria, fungi, protozoa, viruses
Calprotectin (S100A8–S100A9)	Metal chelation	Enterocytes Neutrophils	Gram+ and Gram– bacteria, fungi, viruses
C-type lectins (e.g., REG3β, REG3γ)	Cell membrane disruption	Paneth cells Enterocytes	Gram+ and Gram– bacteria
Lysozyme	Cleavage of bacterial cell wall peptidoglycan	Paneth cells	Gram+ > Gram– bacteria
Phospholipase A_2	Cleavage of bacterial cell membrane phospholipids	Paneth cells Macrophages	Gram+ bacteria

Fig. 12.20 Antimicrobial proteins that contribute to innate defense of the intestinal mucosa. A variety of antimicrobial proteins are produced in the intestinal mucosa. These include small, typically cationic antimicrobial peptides (AMPs) that insert into bacterial cell walls (e.g., defensins), as well as enzymes (e.g., lysozyme) that cleave components of bacterial cell walls or cell membranes. These proteins are produced by both intestinal epithelial cells (IECs), including Paneth cells of the small intestine and non-Paneth epithelial cells in the small and large intestines, and myeloid cells, such as macrophages and neutrophils that infiltrate the intestines during inflammation.

pores between adjacent IECs to enable rapid cell-to-cell communication. Also, as we will detail later (see Section 12-9), goblet cells play an important role in the delivery of soluble antigens across the epithelium to underlying dendritic cells.

Paneth cells are a population of secretory IECs that reside in the base of crypts in the small intestine, where they are intercalated between ISCs (see Figs. 12.11, 12.15, and 12.16). They develop from early secretory cell progenitors and have two major functions: the production of antimicrobial peptides, both at homeostasis and in response to pathogen-induced activation; and the provision of maintenance signals for ISCs. Paneth cells are characterized by an abundance of intracytoplasmic secretory granules containing a diversity of antimicrobial factors (Fig. 12.20), some of which are secreted at homeostasis and appear to help in maintaining a sterile crypt and reinforcing the mucus layer to restrain bacterial incursion and protect the ISCs (Fig. 12.21). Paneth cells can also respond directly to PAMPs, as they express TLRs and NODs and they are highly autophagic. Defects in Paneth-cell function lead to reduced bacterial defense and are believed to be important in susceptibility to inflammatory bowel disease in humans due to the penetration of microbes across the mucus barrier (see Section 15-17). Notably, Paneth cells are not found in the large intestine. However, a similar cell has been identified in contact with ISCs in colonic crypts, and it appears to serve Paneth-like cell functions, although it lacks the large cytoplasmic granules characteristic of Paneth cells.

Intestinal **tuft cells**, so named for the characteristic 'tuft' of microvilli they project into the lumen, are a chemosensory type of IEC related to odorant and taste receptors in the upper airways and tongue (see Figs. 12.15 and 12.16; see also Fig. 11.3). Tuft cells are specialized for recognition of molecules produced by helminths and are therefore key sensor IECs that promote type 2 immune responses (see Section 11-3). They are relatively rare, representing less than 1% of all IECs, although their numbers increase during helminthic infections.

Enteroendocrine cells (EECs) are a second type of chemosensory IEC that, like tuft cells, are primarily dispersed throughout the superficial, or lumen-facing, intestinal epithelium (see Figs. 12.11, 12.15, and 12.16). EECs are specialized for sensing a range of nutrients in the intestinal lumen that stimulate their release of hormones and/or neurotransmitters to regulate digestion, absorption, and satiety in the gut, as well as local and systemic metabolism. Like tuft cells, EECs compose less than 1% of all IECs, but because of the large number

In MyD88-deficient mice, microbes penetrate the mucus layer

Fig. 12.21 Microbial signals activate the production of antimicrobial peptides that restrain bacterial encroachment of the intestinal epithelium. The antimicrobial defense of the intestinal mucosa provided by mucus is enhanced by factors produced by both epithelial and immune cells. Particularly in the small intestine, with its thinner, more porous mucus layer and absence of a microbe-excluding inner mucus layer, bacteria are kept away from the epithelial cells by the continual renewal of mucus and presence of antibacterial agents, such as defensins and secretory IgA (SIgA), which form a gradient owing to their slow diffusion through the mucus. This produces a 'killing field' that bacteria must traverse if they are to reach the epithelium. The highest concentration of antimicrobial peptides (AMPs) is in the crypts and at the crypt openings, as these components are largely produced by the Paneth cells at the bottom of the crypts in the small intestine. The production of AMPs is contingent on recognition of microbial products—as shown in mice deficient in the TLR signaling component MyD88 in IECs, which results in the loss of physical separation of bacteria from the small intestinal epithelium (left through right panels). Similarly, deficiency of the antimicrobial C-type lectin REG3γ, which targets Gram-positive bacteria, allows these bacteria to penetrate the mucus layer (not shown). The two right panels show bacteria (green) detected by fluorescence *in situ* hybridization (FISH) and epithelial-cell nuclei (blue) labeled with DAPI. The white scale bars indicate 50 μm.

of cells in the intestinal epithelium, EECs represent the largest collection of endocrine cells in the body. There is considerable heterogeneity in EECs, with at least eight subtypes that are distinguished by the nutrient receptors they express and the hormones and neurotransmitters they release when stimulated. Although the roles of EECs in intestinal immunity are still being defined, the innervation of some EECs by nerve fibers that communicate with the central nervous system suggests that, in addition to their roles in regulating intestinal physiology at homeostasis, EECs may also contribute to **neuroimmune interactions** that regulate certain immune responses.

12-5 The intestinal epithelium contains conventional and unconventional T cells that are focused on barrier maintenance and defense.

The epithelial cells of the intestines are not alone on the front line. Compared to most other epithelia in the body, the epithelium of barrier tissues, including the intestines, is unusual in harboring a substantial number of conventional and unconventional (innate-like) T cells, or intraepithelial lymphocytes (IELs), as well as small numbers of ILC1 cells (Fig. 12.22 and Fig. 12.23). At birth, unconventional T cells are the dominant IELs, as they populate the epithelium perinatally and expand in response to colonization by the intestinal microbiota immediately after birth. As an increasing number of antigen-experienced conventional T cells take up residency in the epithelium throughout life, the balance between unconventional and conventional IELs shifts, such that conventional T cells become a greater fraction of the total with age. Because population of the epithelium by conventional T cells is controlled more by the history of antigenic exposure, the ratios of

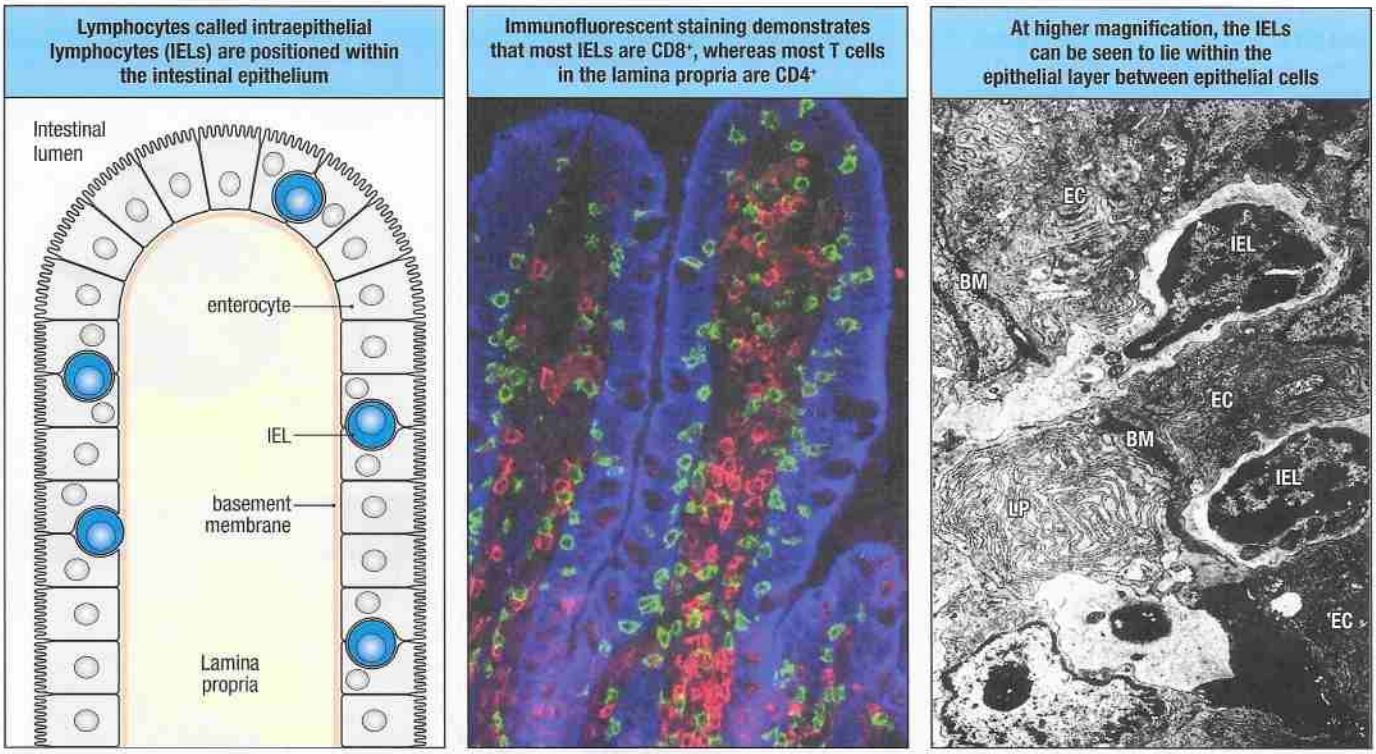

Fig. 12.22 Intraepithelial lymphocytes. The epithelium of the intestines contains a large population of lymphocytes known as intraepithelial lymphocytes (IELs; shown for small-intestinal villus in left panel). The immunofluorescent micrograph in the center panel is of a section of small-intestinal villi highlighting that most of the lymphocytes in the epithelium are CD8 T cells (green), whereas most in the underlying lamina propria are CD4 T cells (red). The intestinal epithelial cells (IECs) are stained blue. Those IECs with dark vacuoles are goblet cells; the dark vacuoles are the mucin-containing vacuoles. Magnification ×400. The electron micrograph in the right panel shows that the IELs lie between epithelial cells (EC) on the basement membrane (BM) separating the lamina propria (LP) from the epithelium. One IEL can be seen having crossed the basement membrane into the epithelium, leaving a trail of cytoplasm in its wake. Magnification ×8000.

conventional to unconventional IELs can vary considerably between individuals, and in the same individual, throughout life. Normally, very few IELs are actively dividing, and there is a limited contribution of circulating cells to the IEL compartment.

IELs are intercalated between and therefore are in immediate contact with IECs, situated beneath the tight junctions that bind IECs and above the basement membrane on which the IECs rest (see Fig. 12.22). The number and composition of IELs differs regionally along the intestinal tract; the highest density of IELs is found in the proximal small intestine and gradually decreases toward the ileum and the colon. In the healthy proximal small intestine, there is about one IEL for every 10 epithelial cells at homeostasis, the highest density of IELs among the barrier tissues. This number drops to about one IEL per 50 IECs in the colon. The difference in density largely reflects the greater proportion of non-crypt epithelium in the proximal small intestine, where the luminal or surface epithelium contains a greater density of IELs. Because of the tremendous surface area of the intestinal epithelium, IELs are one of the single largest populations of T cells in the body.

Notably, IELs are not static, rather they are highly motile within the intestinal epithelium, reflecting their surveillance function. Because of their disposition within the barrier epithelium itself and their fully mature effector status, IELs are both early sensors of changes in the epithelium resulting from environmental exposures and rapid responders that target epithelial cells for altered function or destruction so as to maintain barrier integrity. IELs participate in host defense against pathogens, in epithelial repair, and in homeostatic interactions with the epithelium, microbiota, and nutrients. They may play an important role in the removal of IECs that have sustained genotoxic stress or DNA damage that is not adequately repaired by the DNA damage response, thereby removing IECs at risk for malignant transformation. Here, we will focus on the populations of T cells that make up the large majority of IELs.

Innate-like, unconventional T cells (for example, invariant TCR$\gamma\delta$ and oligoclonal TCR$\alpha\beta$ T cells) take up residence within the intestinal epithelium

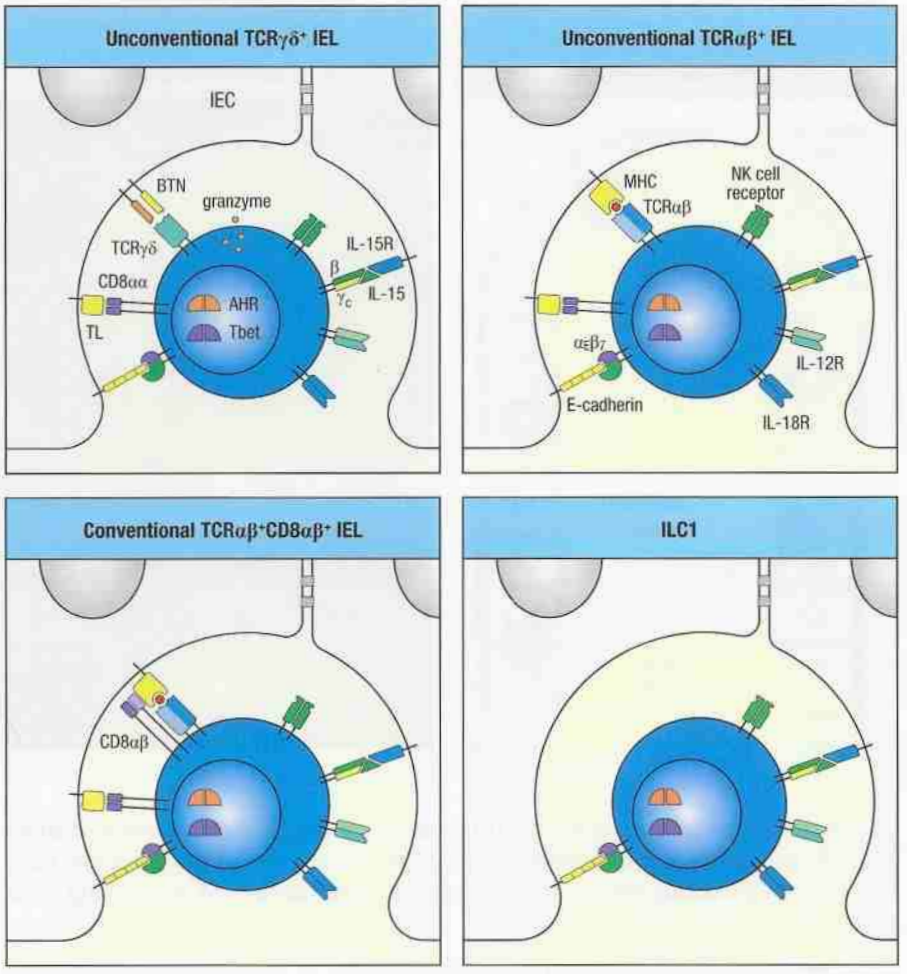

Fig. 12.23 Interactions between IECs and IELs. A variety of T cells are resident in the intestinal epithelium, including unconventional TCRγδ and TCRαβ cells that recognize butyrophilins (BTNs) and nonclassical MHC molecules (upper panels, left and right), as well as conventional TCRαβ cells that recognize peptide antigens presented by classical MHC molecules (lower left panel). Small numbers of ILC1 cells can also be found within the intestinal epithelium (lower right panel). Nearly all of these cells have cytocidal functions, irrespective of their recognition characteristics, and are mobile within the epithelial layer, allowing them to survey IECs for alterations that signal a need for IEC removal. TL, thymus leukemia antigen; β, IL-2Rβ; γ_c, common gamma chain; AHR, aryl hydrocarbon receptor.

immediately before and after birth. They are also referred to as thymic-derived, or natural, IELs (nIELs) (Fig. 12.23, upper panels, and Fig. 12.24), reflecting their development in, and immigration directly from, the thymus, without having to pass through organized lymphoid tissues to acquire their full effector functions (see Section 8-XX). In contrast, conventional T cells migrate into the intestinal epithelium only after their activation by specific antigen in the GALT or gut-associated lymph nodes; these T cells are therefore referred to as induced, or peripheral, IELs (pIELs) (Fig. 12.23, lower left panel, and Fig. 12.24). (Note that this terminology resembles that of the two major subsets of T_{reg} cells—natural, or thymic, and induced, or peripheral, T_{reg} cells.) pIELs derive from conventional CD4 and CD8 T cells, thus their T-cell receptors (TCRs) recognize foreign peptides bound to conventional MHC I or MHC II molecules, respectively. In contrast, TCRαβ nIELs are responsive to a diversity of MHC molecules, including MHC I and MHC II molecules as well as non-classical MHC I molecules (for example, MHC Ib), albeit through recognition mechanisms that do not appear to require specific peptides (see Chapter 6). Similarly, TCRγδ nIELs, which constitute the largest fraction of IELs in the intestines, are not activated by classical peptide:MHC recognition.

Although the variety of structures recognized by each type of nIEL is still an area of discovery, it is clear that this recognition diversity considerably expands the range of external and internal signals that can be sensed within the intestinal epithelial compartment. Nevertheless, most IEL types, both conventional and unconventional, share similar functionality in bolstering barrier defense and maintaining barrier function; most IELs are characterized by the expression of effector capabilities typical of innate and adaptive cells of the cytotoxicity

immune module (see Section 11-2) (Fig. 12.25). Thus, common properties of IELs are their cytolytic capability (reflected in their expression of perforin and granzyme B) and expression of type 1 cytokines (for example, IFN-γ, TNF-α and FasL), which are activated in response to antigen recognition or to the local production of the cytokines IL-12, IL-18, and IL-15. Accordingly, a major function of nIELs and pIELs is their recognition and destruction of IECs that display properties of infection, damage, or stress. IELs can also express antimicrobial peptides, and at least a subset of nIELs is programmed for IL-17 production when activated. Additionally, IELs can express epithelial growth factors, such as epidermal growth factor (EGF), which promotes epithelial proliferation and repair in response to IEC damage.

The developmental origins of conventional and unconventional IELs are distinct. Although both subsets undergo selection in the thymus, neither TCRγδ nor TCRαβ nIELs undergo typical positive and negative selection like conventional TCRαβ T cells. Like most TCRγδ cells in the body, TCRγδ cells destined for residence in the intestinal epithelium exit the thymus as double-negative T cells; that is, prior to the double-positive stage of thymic selection (see Section 8-18). This includes TCRγδ cells with invariant use of $V_\gamma7$, which represent the majority of intestinal nIELs in mice, as well as a smaller fraction of TCRγδ cells that express invariant $V_\gamma4$. Each of these populations arise as part of the second programmed wave of TCRγδ cell development around the time of birth (see Section 8-18).

In contrast to TCRγδ nIELs, positive selection of TCRαβ nIELs requires recognition of MHC molecules. However, unlike conventional TCRαβ cells, TCRαβ nIELs appear to recognize many MHCs, including nonclassical MHC I and MHC I–like molecules (for example, CD1), rather than just a single one. Their intrathymic selection by unrestricted MHC molecules has been termed **agonist selection**, indicating the absence of classical TCR recognition of a specific peptide:MHC ligand. Instead, the TCRs of TCRαβ nIELs appear to be promiscuous for a range of different MHC molecules and are therefore broadly cross-reactive with MHC, including nonself MHC molecules.

Concurrent with their selection in the thymus, unconventional TCRγδ and TCRαβ cells fated for the intestinal epithelium up-regulate the integrin $\alpha_4\beta_7$, which directs them to the intestines rather than to peripheral lymphoid organs. They also up-regulate **CCR9** or **CCR10**, which directs them to the epithelium of the small or large intestine in response to **CCL25** or **CCL28**, respectively. They remain double-negative in the intestine but are induced by the high local concentrations of TGF-β produced by IECs to express the **CD8αα** homodimer and

Fig. 12.25 Effector functions of intraepithelial lymphocytes. Peripheral IELs (pIELs; top panels) are generally conventional CD8 cytotoxic T cells that recognize peptides derived from viruses or other intracellular pathogens bound to classical MHC class I molecules on infected epithelial cells. pIELs express an αβ TCR and the CD8αβ heterodimer co-receptor. Natural IELs (nIELs) carrying the CD8αα homodimer (bottom panels) recognize MIC-A and MIC-B using the receptor NKG2D and are activated by IL-15. Human epithelial cells that have been stressed by infection or altered cell growth or by a toxic peptide from the protein α-gliadin (a component of gluten) up-regulate expression of the nonclassical MHC class I molecules MIC-A and MIC-B and produce IL-15. Both types of IELs can kill by releasing perforin and granzyme. Apoptosis of epithelial cells can also be induced by the binding of Fas ligand on the T cell to Fas on the epithelial cell.

α_E integrin (CD103), which pairs with β_7 integrin to form **$\alpha_E\beta_7$**, which, in turn, binds E-cadherin expressed by IECs (see Figs. 12.23 and 12.24). CD8αα binds the nonclassical MHC class Ib molecule **thymus leukemia antigen (TL)**, which is expressed by IECs. Indeed, nearly all intraepithelial T cells, both nIELs and pIELs, express CD8αα, which appears both to down-modulate TCR signaling to prevent overreactivity of IELs to IEC antigens and to promote NK-like killing of damaged or stressed IECs. CD8αα may also serve as a survival signal to IELs.

Unlike nIELs, pIELs arise extrathymically from conventional CD4 and CD8 T cells after cognate antigen recognition in lymphoid tissues associated with the intestines. The precise signals that determine whether antigen-induced CD4 or CD8 T cells will become intraepithelial residents is not completely understood, but critical to their homing to the epithelial compartment is their expression of $\alpha_E\beta_7$ integrin (CD103) and CD8αα induced by TGF-β signaling in the intestinal mucosa (see Figs. 12.23 and 12.24). In the case of CD4 pIELs, many appear to be derived from FoxP3$^+$ T_{reg} cells that down-regulate FoxP3, whereas CD8 T cells retain much of their transcriptional program. Because both CD4 and CD8 pIELs retain expression of their native co-receptor, they acquire CD4$^+$CD8αα$^+$ and CD8$^+$CD8αα$^+$ phenotypes and retain responsiveness to cognate peptide:MHC II and peptide:MHC I complexes, respectively. This implies IECs must have the capacity to process and present foreign antigens on MHC I and MHC II molecules. Indeed, in response to IFN-γ signaling, IECs can up-regulate CIITA, the master transcriptional regulator of classical antigen-presenting pathways, and thus appear able to gain antigen-presenting cell (APC) functions, thereby enabling recognition by CD8 or CD4 pIELs.

As discussed in Chapter 6, the ligands recognized by unconventional T cells are heterogeneous and include both unique recognition receptors and those shared with other immune cells (see Sections 6-16 through 6-20). Both subsets of nIELs express molecules typical of the NKG2 family of NK-cell receptors, including NKG2D, an activating receptor that recognizes a subset of nonclassical MHC Ib molecules that are induced on intestinal epithelial cells in response to cellular injury, stress, or ligation of TLRs (see Section 6-16). In addition, as indicated earlier, TCRαβ nIELs express cross-reactive TCRs capable of responding to broad changes in expression of classical and nonclassical MHC molecules in a cognate peptide–independent manner. This suggests TCRαβ nIELs may be activated by alterations in MHC expression in a manner akin to NK cells.

As for TCRγδ nIELs, it was recently shown that an important ligand for the dominant TCRVγ7 nIELs in mice is a heterodimer of BTNL1 and BTNL6, members of the **butyrophilin (BTN)** gene family. These ligands are structurally related to the B7 family of co-stimulatory molecules and are expressed on IECs but do not appear to engage receptors of the CD28 family. Rather, butyrophilins bind domains on invariant TCRs of some unconventional T cells, as has been shown for a subset of human TCRγδ cells, thereby providing an activating signal via the γδ TCR (**Fig. 12.26**). The TCR-liganding function of

Fig. 12.26 Butyrophilins activated by phosphoantigens mediate interactions between IECs and some γδ T cells. Most butyrophilins (BTNs) expressed by IECs contain a cytosolic B30.2 (PRYSPRY) domain, which, when bound by phosphoantigens derived from microbes taken up by IECs or from endogenous sources in transformed cells, induces heterodimerization of two different butyrophilin molecules (left panel). This causes a reorientation of the BTN extracellular domains, enabling recognition by γδ TCRs expressed by a subset of nIELs (middle panel), activating their cytolytic function and resulting in the killing of the IEC and its clearance by macrophages (right panel).

some butyrophilin family molecules is dependent on an intracellular domain, termed B30.2. This domain binds a variety of nonpeptide diphosphate (pyrophosphate)-containing molecules, or phosphoantigens, which are products of microbes or transformed epithelial cells. Butyrophilins thus appear to be a form of pattern-recognition receptor that can detect foreign or self phosphoantigens and generate an 'inside-out' signal; that is, the TCR recognizes metabolites inside IECs via allosteric modulation of the BTN extracellular domains. Exactly how these ligands are regulated on IECs and whether this family of ligands is generic for different TCR$\gamma\delta$ subsets is currently unknown. However, deletion of BTNL1 leads to selective loss of TCR Vγ7 nIELs in mice, indicating that this signal is required for their maintenance.

Important for both the development and maintenance of all subsets of nIELs and pIELs is expression by the epithelium of IL-15, which is produced in response to the microbiota and is 'trans-presented' to IELs in a complex with the IL-15Rα chain (see Fig. 12.23). That is, IL-15 produced by IECs is bound to the IEC surface by IL-15Rα, and this complex induces signaling via the IL-2Rβ and γc subunits expressed on IELs. The necessity for IL-15 in IEL maintenance is evident from the loss of IELs in either IL-15– or IL-15R–deficient mice. IL-15 signaling induces IEL expression of the **aryl hydrocarbon receptor (AHR)**, a transcription factor activated by various environmental ligands derived from cruciferous vegetables, microbiota metabolites, and xenobiotics that is expressed with subsets of ILC3 cells and T_H17 cells. IL-15 also induces IELs to express **Tbet**, which is also expressed by T_H1 cells and ILC1 cells. Both of these transcription factors are required for the maintenance and function of IELs. Mice that lack the AHR or Tbet have reduced numbers of IELs and show loss of nIELs, along with abnormalities in epithelial barrier repair, reinforcing the view that these unusual lymphocytes play important roles in the innate immune response to local materials in the intestine.

12-6 Innate lymphoid cells and unconventional lymphocytes are present in GALT and in the lamina propria and are rapid responders to microbes that breach the epithelium.

Just as the intestinal epithelium is populated by IELs in the perinatal period, so too are the GALT and intestinal lamina propria populated by tissue-resident innate lymphoid cells (ILCs) and innate-like lymphocytes. As discussed in Chapter 11 (see Section 11-3), in addition to cytotoxic ILCs (NK cells), three main groups of 'helper' ILCs are recognized (see Fig. 11.5)—ILC1, ILC2, and ILC3—each of which preferentially distributes to barrier tissues around birth. The composition of ILCs within the intestinal mucosa is dependent on the microbial exposure of the host, but in more industrialized countries where gastrointestinal worm infestation is less common, ILC3 cells are the most prominent. Most ILC3 cells are found in the GALT, but there are also ILC3 cells within the lamina propria.

Beyond the function of the LTi subset of ILC3 cells in the development of the GALT, ILCs play a central role in the early response to pathogen encroachment in the mature intestinal tissues and may also contribute to the homeostatic function of intestinal epithelial stem cells, although this is an area of ongoing study. There is an increasing appreciation of heterogeneity within ILC subsets, and at least two major mature ILC3 subsets are recognized: LTi-like ILC3 cells that lack NK receptors (NK-cell receptor negative, or NCR^-) and non-LTi ILC3 cells that express NK receptors (NK-cell receptor positive, or NRC^+). In humans, NCR^-, LTi-like ILC3 cells are thought to preferentially express IL-17, whereas NCR^+ ILC3 cells produce IL-22. In mice, there is greater overlap in cytokine expression profiles by these subsets. The development and function of both subsets is controlled by the transcription factors RORγt and AHR. Like all ILC3 cells, those in the intestines produce IL-17 and IL-22 in response to IL-23 and

IL-1β, which are produced primarily by local dendritic cells and inflammatory macrophages. As we will see in Section 12-20, IL-22 produced by ILC3 cells is indispensable for host protection in certain types of bacterial infections, where it acts on the epithelium to alter IEC development and stimulate production of antimicrobial peptides that restrain bacterial growth and prevent breach of the epithelium in advance of the adaptive response. Notably, similarly to T_H17 cells, with which they share many properties, ILC3 cells can be induced to transition to ILC1-type cells that lose expression of RORγt in favor of Tbet expression, resulting in a type 1 functional program. Indeed, most of the ILC1 cells that come to populate the intestinal mucosa appear to derive from ILC3 cells.

As we learned in Section 11-3, IL-5 and IL-13 produced by ILC2 cells in response to IL-33, TSLP, and IL-25 produced by enterocytes and/or tuft cells form an important layer of T cell–independent responses to helminth parasites in the intestine and may contribute to food allergies (see Chapter 14). CD1-restricted **invariant NKT (iNKT) cells** and **mucosal-associated invariant T (MAIT) cells** (see Sections 6-18 and 6-19) are also present in the lamina propria and account for 2–3% of lamina propria T cells in the human small intestine. As their names imply, both iNKT cells and MAIT cells express an invariant TCRα chain paired with a limited range of TCRβ chains. iNKT cells recognize lipids and glycolipids complexed with CD1d, whereas MAIT cells recognize metabolites of vitamin B derived mainly from the microbial riboflavin metabolism pathway complexed with MR1.

Summary.

The intestinal epithelium is composed of a diversity of cell types, each with specific functions in intestinal physiology and mucosal immunity. All intestinal epithelial cells (IECs) develop from common progenitors (intestinal stem cells, or ISCs) that reside in the base of the intestinal crypts and differentiate as they move from the base of the crypts toward the surface. There are two major developmental branches: absorptive and secretory. Absorptive enterocytes are most numerous and include absorptive enterocytes and M cells. Secretory enterocytes include goblet cells, Paneth cells (in the small intestine; not in the large intestine), tuft cells, and enteroendocrine cells. Each of these cell types contributes to innate immunity, albeit through mechanisms that reflect their specific functions. Most IECs have a high rate of turnover and must be continually replenished from the ISC pool.

A central feature of the intestinal mucosa—and other mucosal tissues—is the production of mucus, which is produced by goblet cells. Mucus plays an important role in protecting the epithelium from mechanical injury and from interactions with microbes. It provides a physical barrier but also retains molecules produced by or transported across the epithelium, including a diversity of antimicrobial peptides (AMPs) and secretory IgA (SIgA).

The integrity of the intestinal epithelium is supported by both innate and adaptive immune cells. The epithelium itself is populated by a range of natural and peripheral intraepithelial lymphocytes (nIELs and pIELs), including both conventional and unconventional TCRαβ and TCRγδ subsets. IELs actively survey the epithelium and respond by eliminating infected or damaged cells by cytolytic targeting. Beneath the epithelium there are substantial numbers of resident macrophages and dendritic cells that can take up microbes that traverse the epithelium and can eliminate them or ferry them to immune inductive sites to initiate adaptive immune responses. Intestinal phagocytes that sense pathogens can also release cytokines that activate innate lymphoid cells (ILCs) present within mucosal lymphoid tissues, such as in isolated lymphoid follicles (ILFs), as well as in the lamina propria.

The role of adaptive immunity in regulating the intestinal mucosal immune system at homeostasis.

As is evident from the foregoing discussion, three principal tasks of the intestinal mucosa are nutrient and water absorption, maintenance of the commensal microbiota, and defense against pathogens. The balance between nutrient uptake and accommodation to the microbiota, which are constant needs, and defense of the host, a less frequent need, represents a daunting challenge. The adaptive immune system plays a central role in navigating this balance, informed by signals from the epithelium and the array of innate immune cells that are integrated into the intestinal mucosa. Perhaps in no other tissue in the body is the necessity for the maintenance of immune tolerance more imperative: the diversity of foreign antigens present in food and the commensal bacteria is immense but must be tolerated.

A simple solution would be complete partitioning of these antigens from adaptive immune cells. Indeed, the innate defenses are sufficiently robust that much of the host response to the microbiota progresses without involvement of CD4 T cell–dependent responses. Further, a portion of the secretory IgA (SIgA) that contributes to the partitioning of commensal organisms away from the epithelium is generated in isolated lymphoid follicles (ILFs) without help from T cells. However, complete exclusion of foreign antigens within food and the microbiota is not possible, and in fact, the system has evolved to actively sample the luminal antigens through the specialized mucosal lymphoid tissues, such as Peyer's patches and ILFs. Accordingly, the mucosal immune system has acquired strategies to recognize and respond to innocuous antigens in a way that minimizes inflammation, unless absolutely necessary.

As the foreign antigens derived from food and the commensal microbiota are extracellular and therefore primarily presented by MHC II, it is the CD4 T-cell response that is central to the induction of homeostatic adaptive immunity in the intestines. As we will see, in the intestines, induction of T-cell immunity strongly favors the development of T_{reg} cells at homeostasis, reflecting unique properties of the antigen-presenting cells (APCs) in the gut and the route by which antigen is introduced—including the delivery of innocuous antigens to intestinal APCs via SIgA. Here, we will discuss mechanisms active in the intestinal mucosa that promote noninflammatory recognition of antigens by macrophages and dendritic cells, followed by a consideration of the induction of T_{reg} cells and SIgA-producing B cells.

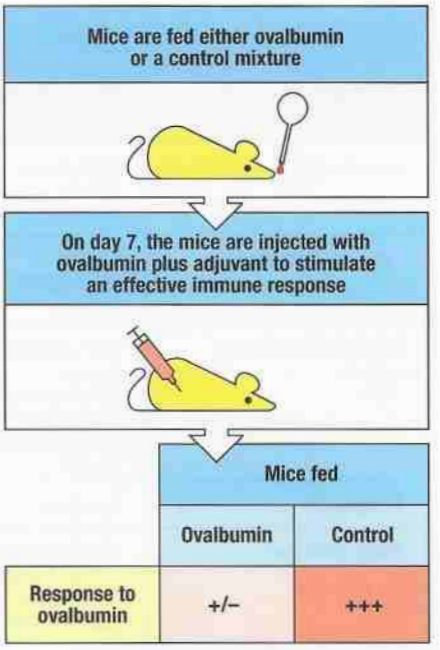
12-7 The mucosal immune system must establish and maintain tolerance to harmless foreign antigens.

Antigens within food and commensal bacteria normally do not induce an inflammatory immune response, despite the lack of central (thymic) tolerance to them (Fig. 12.27). The mucosal immune system's environment is inherently

	Protective immunity	Mucosal tolerance
Antigen	Invasive bacteria, viruses, toxins	Food proteins; commensal bacteria
Primary Ig production	Intestinal IgA and IgG Specific Ab present in serum	Some local IgA Low or no Ab in serum
Primary T-cell response	Local and systemic effector and memory T cells	pT_{reg} cell induction; no local effector T-cell response
Response to antigen reexposure	Enhanced (memory) response	Low or no response or systemic response

Fig. 12.27 Immune priming and tolerance are different outcomes of intestinal exposure to antigen. The intestinal immune system generates protective immunity against antigens that are presented during infections by pathogenic organisms. IgA antibodies are produced within the GALT, serum IgG and IgA are made in draining lymph nodes, and the appropriate effector T cells are activated in the intestine and elsewhere. When the antigen is encountered again, there is effective memory, ensuring rapid protection. Antigens from food proteins induce tolerance locally and systemically, with little or no IgA antibody production. T cells are not activated, and subsequent responses to challenge are suppressed. In the case of commensal bacteria, there is local secretory IgA (SIgA) production, but typically no systemic antibody responses, and peripheral regulatory T cells) (pT_{reg} cells) rather than effector T cells are activated.

tolerogenic—a barrier to the development of nonliving vaccines, which need to overcome local regulatory mechanisms. Food proteins are not digested completely in the intestine; significant amounts are absorbed into the body in an immunologically relevant form. The default response to oral administration of a protein antigen is the development of a phenomenon known as **oral tolerance**. This is a form of **peripheral tolerance** that renders the systemic and mucosal immune systems relatively unresponsive to subsequent exposures to the same antigen. It can be demonstrated experimentally in mice by feeding them a foreign protein such as ovalbumin (Fig. 12.28). When the animals are then challenged with the antigen in adjuvant via a nonmucosal route, such as injection into the skin, the normal immune response one would expect is blunted. This suppression of systemic immune responses is long lasting and is antigen specific; responses to other antigens are not affected. A similar suppression of subsequent immune responses is observed after the administration of proteins into the respiratory tract, giving rise to the general concept of **mucosal tolerance**, because the usual response to such antigens is delivered via a mucosal surface. Systemic T-cell responses can also be inhibited by feeding humans protein antigens that they have not encountered previously, although it has proven an ineffective strategy for reversing reactivity to antigens to which individuals are already sensitized, such as food allergens. Thus, although mucosal tolerance can be used to avoid inflammatory disease in experimental animal models of type 1 diabetes mellitus, arthritis, and encephalomyelitis, clinical trials in humans have been less successful and have given way to other therapies, as we will discuss in greater detail in Chapters 14 and 16.



Mice are fed either ovalbumin or a control mixture
On day 7, the mice are injected with ovalbumin plus adjuvant to stimulate an effective immune response

+++

Fig. 12.28 Tolerance to antigens can be generated experimentally by oral administration. Mice are fed for 2 weeks with 25 mg of either ovalbumin or a control protein. Seven days later, the mice are immunized subcutaneously with ovalbumin plus an adjuvant, and after 2 weeks, the serum antibodies and T-cell function are measured. Mice that were fed ovalbumin have a lower ovalbumin-specific systemic immune response than that of mice fed the control protein.

Various mechanisms are likely to account for oral tolerance to protein antigens, although the preferential generation of peripheral regulatory T (pT_{reg}) cells appears to be dominant. Antigens delivered to the GALT or draining lymph nodes generally induce antigen-specific FoxP3$^+$ T_{reg} cells at homeostasis. As we will learn, migratory dendritic cells of the intestinal mucosa are conditioned by the local cytokine environment to produce two factors that induce T_{reg} cell differentiation from naive CD4 T-cell precursors—retinoic acid and TGF-β—without producing pro-inflammatory signals, such as IL-1, IL-6, IL-23, or IL-12, which would otherwise stimulate the differentiation of effector CD4 T cells, such as T_H17 or T_H1 cells. These same pT_{reg} cell–inducing factors also induce the expression of homing molecules that direct the migration of pT_{reg} cells back to the intestinal mucosa, where they act to repress subsequent exposure to their cognate antigens. Although it is known that these same factors are also essential for the suppression of systemic immune responses to the same antigens, the mechanisms responsible for this link between the mucosal and peripheral immune systems are not yet understood. One plausible mechanism is that pT_{reg} cells that have been primed in the intestines encounter antigen peripherally as they circulate from the intestines via draining lymph into the bloodstream. Alternatively, there is evidence that orally administered antigens can be found in lymph and the bloodstream, enabling access to resident dendritic cells in peripheral lymph nodes, although this remains to be proven. Notably, unlike soluble antigens, microbial antigens generally induce tolerance that is confined to the intestine; the systemic immune system normally remains ignorant of them, which may reflect their containment by the GALT and draining lymph nodes. Importantly, at times oral tolerance induction can fail, as is believed to occur in celiac disease (discussed in detail in Section 14-17) and peanut allergies (discussed in Sections 14-10 and 14-12).

Celiac Disease Case Study

12-8 Macrophages and dendritic cells have complementary roles in the maintenance of immune tolerance in the intestines.

Both inductive and effector sites within the intestinal mucosa contain abundant macrophages and dendritic cells (DCs). Indeed, the lamina propria of the healthy intestines contains the largest population of macrophages and

conventional dendritic cells (cDCs) in the body, with the highest number residing in the small intestine. A major historical confounder in understanding the origins and function of macrophages and DCs in the intestines has been the crossover in expression of several markers between the two lineages in this tissue. Thus, the classical macrophage marker, F4/80, is expressed by some cDCs in the intestines, and many intestinal macrophages express the DC marker CD11c (Fig. 12.29). However, recent studies indicate that while both intestinal macrophages and DCs express CD11c and class II MHC, unlike most DCs in this site, intestinal macrophages generally lack expression of α_E integrin (CD103). Instead, intestinal macrophages have been found to express **FcγRI** (CD64; see Fig. 10.38) and, in the mouse, **CX3CR1**, the receptor for the chemokine CX3CL1 (fractalkine); most intestinal DCs do not. On the basis of these markers, it is clear that intestinal macrophages are dependent on colony stimulating factor 1 (CSF1; also known as M-CSF) for their development and survival; in contrast, intestinal DCs are dependent on FLT3 ligand (FLT3L). Accordingly, CD64^{+}CD11c^{+}MHC II^{+} cells are tissue-resident and display characteristic macrophage morphology, with abundant cytoplasm and intracytoplasmic vacuoles, while CD64^{-} CD11c^{+}MHC II^{+} cells are migratory and localize to the GALT and mesenteric lymph nodes in a CCR7-dependent manner to participate in T-cell priming.

In contrast to many other tissues, where macrophages seed early in life and are maintained by local turnover, intestinal macrophages continually differentiate within the intestinal lamina propria from circulating Ly6C^{hi} monocytes that are recruited there by homeostatic chemokines recognized by CCR2 (for example, CCL2, CCL8). The transition from incoming monocytes to mature macrophages takes several days, and although the mature cells typically have a tissue life span of days to weeks, some studies have shown that a minority of macrophages can persist for several months. In the intestines, macrophages are much more prevalent than cDCs and represent ~75% of all mononuclear phagocytes. They are positioned immediately under the epithelium and are highly phagocytic and microbicidal, and thus ideally suited to ingest and degrade any microbes or other particulates that penetrate the epithelial barrier. They also clear dying epithelial cells, which are found in large numbers in the intestine—an inevitable consequence of the high turnover of most IECs.

As mentioned earlier, intestinal macrophages, unlike macrophages in other parts of the body, are conditioned by the intestinal microenvironment to be

non-inflammatory; they do not produce significant quantities of inflammatory cytokines (for example, TNF-α, IL-1β, IL-6) or reactive oxygen or nitrogen species in response to phagocytosis or exposure to stimuli such as bacteria or TLR ligands. They also lack receptors for IgA, complement, and the signaling components of the IgG receptor, and they have limited antigen-presentation capacity. Because of their anti-inflammatory properties, these cells are sometimes referred to as **inflammation-anergic macrophages**. Unlike other tissue macrophages, these cells appear to be terminally differentiated and do not give rise to M1 or M2 macrophages (see Section 11-6). Like other immune cells in the gut, intestinal macrophages are conditioned by exposure to the commensal microbiota, as evidenced by decreased numbers and lower turnover of these cells in germ-free mice and mice treated with broad-spectrum antibiotics.

The terminal differentiation of intestinal macrophages from incoming monocytes is regulated by TGF-β signaling. TGF-β is abundant in the intestinal lamina propria, where it is produced in its latent form by IECs, stromal cells, T_{reg} cells, mast cells, and macrophages themselves, and binds to the extracellular matrix. Once in the mucosa, signaling via TGF-β receptor 1 (TGF-βRI) and TGF-β receptor 2 (TGF-βRII) on incoming monocytes is essential for their differentiation into intestinal macrophages. The up-regulation of genes that are characteristic of the homeostatic profile of intestinal macrophages, such as CX3CR1 and CD11c, and the down-regulation of others, such as Ly6C, is mediated by the TGF-β–TGF-βR axis. Also up-regulated by TGF-β signaling is $\alpha_v\beta_5$ integrin, which is used by intestinal macrophages to ingest apoptotic cells in a process referred to as **efferocytosis** (Latin for 'to bury'). This integrin also activates latent TGF-β, and the process of efferocytosis induces TGF-β expression by intestinal macrophages, providing a feed-forward mechanism by which macrophage uptake of apoptotic cells contributes to tissue homeostasis. In this regard, apoptotic up-regulation of the ligand for CX3CR1 (that is, CX3CL1) by apoptotic epithelial cells serves to attract tissue macrophages to ensure their prompt removal, contributing also to their positioning immediately beneath the epithelium. CX3CR1 and $\alpha_v\beta_5$ integrin also contribute to the extension of **transepithelial dendrites (TEDs)**, cellular processes that extend across the epithelium to sample the luminal contents without perturbing tight junctions and epithelial integrity, as will be discussed further in Section 12-9.

While TGF-β signaling is required for induction of the inflammation-anergic phenotype of intestinal macrophages, IL-10 signaling also contributes by down-regulating components of TLR signaling, including MyD88, TRIF, and TRAF6, as well as CD14, a component of the LPS recognition complex. Thus, despite expressing TLR-3 and TLRs 5–9, intestinal macrophages have impaired abilities to activate MyD88-dependent and -independent NFκB signaling downstream of TLR ligation. IL-10 signaling also up-regulates inhibitors of NFκB signaling. Although intestinal macrophages can express IL-10, they appear to be a minor source, as macrophage-specific deletion of IL-10 does not disrupt intestinal homeostasis. Instead, CD4 T cells, particularly $FoxP3^+$ T_{reg} cells and $FoxP3^-$ T regulatory 1 (T_R1) cells, appear to be the major source of IL-10 that restrains intestinal macrophages from assuming a pro-inflammatory function (see Section 12-10). Thus, T cell–specific deletion of IL-10 and macrophage-specific deletion of the IL-10 receptor both lead to severe intestinal inflammation. Dietary and microbiota-derived metabolites, such as the short-chain fatty acid butyrate, can also repress the expression of pro-inflammatory cytokines.

In the inflamed intestines, whether the inflammation is caused by infection or immune-mediated disease (for example, inflammatory bowel disease), the accelerated influx of monocytes from the circulation results in a large number of phagocytic cells that express high levels of CD14, CD11c, and MHC II ($CD14^{hi}CD11^{hi}$MHC II^{hi} cells) and couple TLR signaling to an inflammatory

response. These cells can produce abundant pro-inflammatory cytokines, such as TNF-α, IL-1β, IL-6, and IL-23, as well as chemokines that recruit both innate and adaptive immune cells. Monocytes recruited by inflammatory signals also demonstrate enhanced antigen processing and presentation capabilities, and they deploy the typical array of functional Fc and complement receptors. Notably, the CX3CR1^{hi} resident macrophages that persist in an inflammatory setting retain their anti-inflammatory signature, consistent with their fixed, terminal differentiation.

Dendritic cells that populate the intestinal mucosa at homeostasis share many features with those in other tissues. At homeostasis, these cells actively sample antigens transported across the epithelium, and they spend a relatively short time in the intestine before migrating into T-cell zones of the GALT or draining lymph nodes. As elsewhere, migration of dendritic cells to lymph nodes depends on the chemokine receptor CCR7 (see Fig. 9.7). It is estimated that 5–10% of the mucosal DC population emigrates to mesenteric lymph nodes every day, allowing constant delivery of antigens from the mucosa to lymph nodes. However, intestinal DCs differ from peripheral DCs in two fundamental ways: first, in the GALT, the lines between migratory and lymphoid tissue–resident DCs are somewhat blurred because of the close proximity of the antigen-sampling regions beneath the follicle-associated epithelium (FAE) to T-cell zones and the lack of afferent lymphatics; and second, at homeostasis, intestinal DCs are conditioned by the TGF-β–rich microenvironment to induce primarily noninflammatory adaptive immune responses dominated by the production of peripheral T_{reg} cells and T follicular helper (T_{FH}) cells that favor B-cell class switching to secretory IgA. These functions are critical to the induction of antigen-specific immune tolerance of food and the commensal microbiota, and they reinforce the anti-inflammatory tone of the intestines in a complementary, reinforcing feedback loop with intestinal macrophages. We will discuss further the role of DCs in maintaining homeostasis in Section 12-10.

12-9 The intestines have multiple routes for uptake and delivery of antigen to antigen-presenting cells.

A key challenge to the intestinal immune system is the task of surveying the immense intestinal surface area for the diversity of soluble, particulate, and microbial luminal antigens to which it must respond—all while maintaining an intact barrier. The intestinal mucosa must monitor what is 'out there' so that it can regulate its external and internal environments while remaining vigilant for potential threats. Accordingly, multiple mechanisms for the uptake of luminal antigens have evolved. These follow two general routes: across the specialized follicle-associated epithelium (FAE) that overlies Peyer's patches and ILFs; and across the non-FAE intestinal epithelium that overlies the lamina propria (Fig. 12.30). In both locations, antigens can be transported directly across the epithelial cells themselves (transepithelial transport, or transcytosis), between epithelial cells through regulated passages within the tight junctions (paracellular transport), or via transepithelial processes of macrophages and DCs that extend across the epithelium between IECs (phagocyte-mediated transport). Finally, antigens can be delivered across the epithelium in association with dying epithelial cells that are taken up by phagocytes. Although many luminal antigens are sampled as 'free' molecules, microbial antigens in particular are often taken up bound to secretory IgA (SIgA). Whereas antigens taken up across the non-FAE epithelium are transported to regional lymph nodes via afferent lymphatics, as is the case for other tissues, those taken up across the FAE epithelium are typically transported directly to the underlying GALT, which lacks afferent lymphatics but shares with other lymphoid tissues a similar network of reticular cells and conduits through which antigens are delivered for recognition by naive T cells (see Section 9-4).

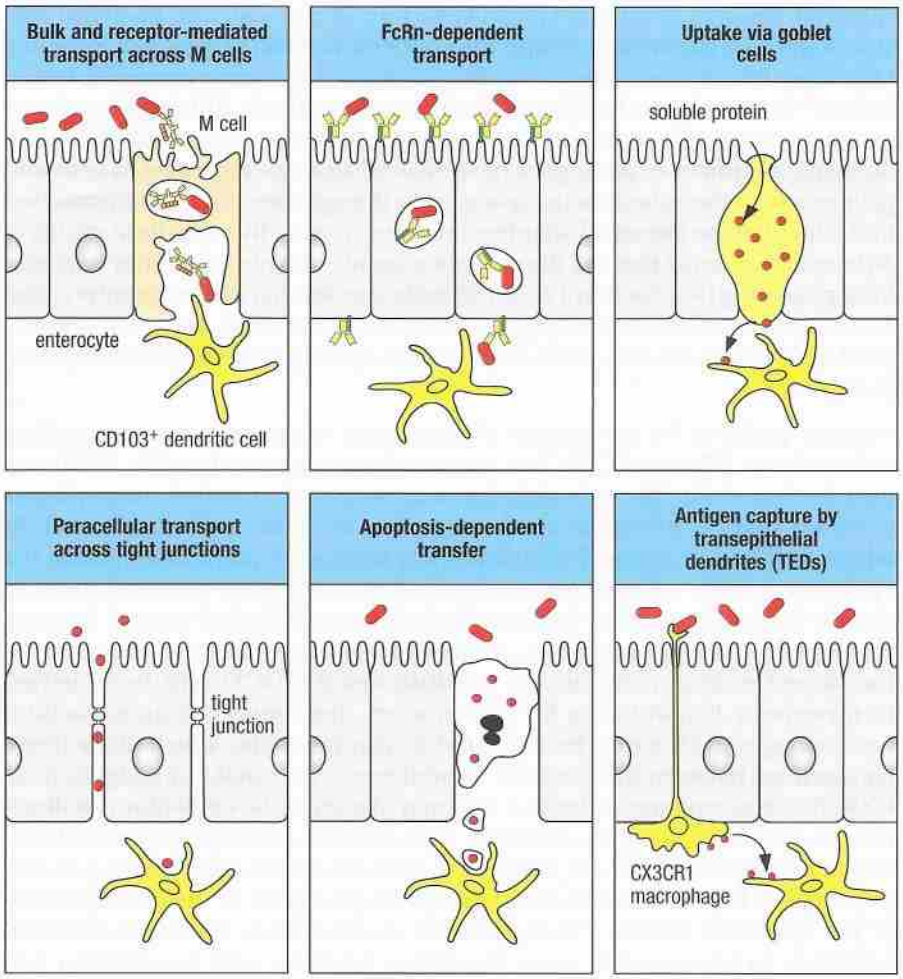

Fig. 12.30 Routes of antigen uptake in the intestines. Top row, first panel: Particulate antigens, such as bacteria, can be transported directly across M cells, either free or bound by SIgA via receptor-mediated transport. Second panel: Enterocytes can capture and internalize antigen:antibody complexes by means of the neonatal Fc receptor (FcRn) on their surface and transport them across the epithelium by transcytosis. Lamina propria dendritic cells express FcRn and other Fc receptors and capture and internalize the complexes. Third panel: During the process of exocytosis of mucin granules by goblet cells, soluble antigens can be endocytosed and transported across the goblet cell to $CD103^+$ dendritic cells in the lamina propria that dock with the secreting goblet cell. Bottom row, first panel: Small, soluble antigens can be transported across the tight junctions that seal the apical borders of adjacent enterocytes, enabling antigen uptake by a dendritic cell beneath the epithelium, a process called paracellular transport, or 'leak.' Second panel: Enterocytes infected with a pathogen can undergo apoptosis and be phagocytosed by a dendritic cell. Third panel: Mononuclear phagocytes can extend cellular processes called transepithelial dendrites (TEDs) between the cells of the epithelium without disturbing its integrity. These cells, thought to be primarily $CX3CR^+$ macrophages, may internalize antigen and pass it to neighboring conventional dendritic cells for presentation to T cells.

As noted previously, specialization of the FAE includes the absence of a glycocalyx and the presence of M (microfold) cells. M cells continually sample luminal antigens that range from macromolecules and small particulates to viruses and whole bacteria particles. This material is transported through the interior of the cell in membrane-bound vesicles to the basolateral cell membrane, where it is released. The basal cell membrane of an M cell makes close contacts with processes of dendritic cells to facilitate local antigen presentation within Peyer's patches and ILFs (see Fig. 12.30; see also Fig. 12.9). These dendritic cells are recruited to the subepithelial dome, or even into the FAE, in response to chemokines that are released constitutively by FAE epithelial cells; CCL20 and CCL9 produced by FAE cells bind to their receptors (CCR6 and CCR1, respectively) on dendritic cells. Although many antigens are taken up by macropinocytosis and micropinocytosis, intact microbes in particular can be taken up by receptor-mediated endocytosis. For a number of bacteria this may involve specific recognition of the bacterial FimH protein found in type 1 pili by a glycoprotein (GP2) on the M cell or receptors that recognize SIgA bound to the bacteria. Because antigens delivered via M cells promote SIgA responses in the GALT, the receptor-mediated uptake of SIgA-coated microbes provides a positive feedback loop for SIgA production. In addition to receptor-mediated uptake of SIgA-bound antigens by the M cell, non-M cells of both FAE and non-FAE express the **neonatal Fc receptor (FcRn)**, which binds and transcytoses IgG bidirectionally across the epithelium. Although primarily a pathway to import maternal IgG from breast milk to the newborn for passive transfer of antibodies (see Section 10-17), this mechanism can also mediate the uptake of IgG-bound antigens, as well as transport IgG from the lamina propria into the lumen, typically in the context of infections (see Section 12-20).

Although the FAE is enriched for M cells, rare M cells can also be found outside of the FAE, particularly within the epithelium of villi of the small intestine. Here they transcytose antigens to DCs in the villous lamina propria, which migrate to mesenteric lymph nodes to present antigen. Although continual sampling by M cells represents an important pathway for sensing of luminal antigens, a number of pathogens have evolved strategies to target M cells and gain access to the subepithelial space, even though they then find themselves in the heart of the intestinal adaptive immune system. These include strains of *Salmonella enterica* that are the causative agents of typhoid fever or bacterial food poisoning (see Section 12-20); *Shigella* species that cause dysentery; and *Yersinia pestis*, which causes plague. Poliovirus, reoviruses, some retroviruses (such as HIV), and prions (such as the causal agent of scrapie) follow the same entry route.

Another pathway for the uptake of particulate antigens is via transepithelial dendrites (TEDs) of CX3CR1$^+$ intestinal macrophages (see Fig. 12.30; see also Section 12-8). The subepithelial recruitment of intestinal macrophages positions them to eliminate any bacteria that cross the epithelial barrier. In addition, they can extend TEDs containing tight-junction proteins across the epithelial barrier without perturbing epithelial integrity, allowing them to capture bacteria and other antigens directly in the intestinal lumen. As these macrophages are nonmigratory, antigens taken up in this manner must be transferred to local conventional dendritic cell 2 (cDC2) cells to be ferried to mesenteric lymph nodes for presentation. The transfer of antigens from macrophages to DCs may be mediated by gap junctions, which allow direct connections between the two cells. In addition to the uptake of antigens from CX3CR1$^+$ macrophages, intestinal DCs may also enter the epithelium for direct uptake of luminal antigens. Although each of these activities has been identified at homeostasis, they are particularly evident during infection and appear to provide a key mechanism to sample pathogens prior to their compromise of the epithelial barrier. Finally, antigen derived from apoptotic epithelial cells may be processed by cross-presenting dendritic cells (see Section 6-5) for induction of immune responses against enteric (that is, intestinal) viruses, such as rotaviruses, which cause diarrheal disease because of their specialized ability to infect enterocytes.

While the pathways described above play important roles in the acquisition of particulate antigens, including microbes, other pathways appear to dominate in the uptake of soluble antigens at homeostasis; the relatively limited surface area of follicle-associated epithelium and the small number of M cells restricts the flux of antigens that can be sampled via this route, and direct TED-mediated uptake at homeostasis is limiting. Recently, it was found that in addition to their role in secreting mucins, goblet cells have an important role in the transport of soluble antigens across the epithelial barrier. This occurs via **goblet cell–associated passages (GAPs)** that conduct low-molecular-mass soluble antigens (<70 kDa) to underlying CD103$^+$ cDC2 cells in the lamina propria (see Fig. 12.29). Precisely how antigen is transferred to DCs is unclear, but it appears to be linked to the process of goblet-cell secretion; when goblet-cell mucin secretion is stimulated, there is increased antigen uptake by goblet cells. DCs that have taken up antigen by this mechanism are found to contain goblet-cell proteins, indicating that goblet-cell components are transferred to DCs along with the luminal antigens. Importantly, in mice in which goblet cells were deleted, luminal antigen delivery to lamina-propria dendritic cells was undetectable, indicating that GAPs are a major pathway for soluble-antigen delivery at homeostasis and likely play a central role in oral-tolerance induction.

Another route for the uptake of soluble antigens is via **paracellular transport**, also referred to as paracellular 'leak.' As discussed in Section 12-4, because of the network of tight junctions between adjacent IECs, the intestinal

epithelium is a selectively permeable barrier, allowing water, solutes, small molecules, and ions through, but preventing the transit of larger proteins (see Fig. 12.17). However, the permeability of tight junctions can be regulated by the differential expression of certain claudin proteins (for example, claudin-2), allowing macromolecules up to 10 kDa to traverse the epithelium. In the small intestine, paracellular transport appears to vary between villi at homeostasis, suggesting that it is actively regulated locally. Small antigens delivered via paracellular transport are not taken up efficiently by intestinal DCs. Instead, they are transported via lacteals and lymphatics to mesenteric lymph nodes, where they are delivered to resident DCs via reticular conduits (see Section 9-4). In inflammatory intestinal disease, such Crohn's disease or ulcerative colitis, increased permeability and disruption of tight junctions results in increased paracellular leak, possibly contributing to a breakdown in tolerance to antigens of the commensal microbiota.

12-10 Intestinal dendritic cells favor the induction of antigen-specific T_{reg} cells that are critical for the maintenance of mucosal immune homeostasis.

Peripheral FoxP3$^+$ T_{reg} cells are central players in intestinal immune tolerance to food and the commensal microbiota and are preferentially induced in the gut at homeostasis. Although thymic-derived regulatory T cells (tT_{reg} cells) circulate to GALT and mesenteric lymph nodes, just as they do to peripheral lymphoid tissues, the dominant T_{reg} cells in the intestinal tissues are pT_{reg} cells, which express a distinct TCR repertoire that reflects their development in response to nonself antigens taken up from the intestines, not to self antigens expressed in the thymus. These two populations can be distinguished by expression of the transcription factor helios and the surface receptor neuropilin-1 (NRP1), both of which are preferentially expressed by FoxP3$^+$ tT_{reg} cells, but not by pT_{reg} cells; hence the majority of T_{reg} cells in the intestines are typically FoxP3$^+$helios$^-$NRP1$^-$ pT_{reg} cells. Global deficits in FoxP3$^+$ T_{reg} cells, such as those seen in people or mice with mutations in the FOXP3 gene, are associated with systemic autoimmunity that includes **inflammatory bowel disease (IBD)** and food allergies (see Section 15-4). In mice deficient for a conserved intronic enhancer element in the Foxp3 gene called CNS1 (conserved nucleotide sequence 1), which controls the development of pT_{reg} cells, but not tT_{reg} cells, there is intestine-specific breakdown in tolerance that results in inflammation and an imbalance in the microbiota in the colon. Thus, intestinal immune homeostasis is primarily controlled by pT_{reg} cells responsive to antigens introduced via the gut.

As elsewhere, conventional dendritic cells (cDCs) are important in initiating and shaping immune responses in mucosal tissues. They are deployed both in intestinal lymphoid tissues (that is, GALT) and throughout the lamina propria. Both of the major subtypes of conventional dendritic cells (cDC1 and cDC2) are present in the intestine (see Fig. 12.29; see also Section 6-5 and Section 9-6). Given their dominant role in presentation of extracellular antigens, including those derived from food and commensal microbes, cDC2 cells are critical to the induction of T_{reg} cells in the gut. As mentioned earlier (see Section 12-8), the anti-inflammatory, pro-regulatory behavior of mucosal dendritic cells in the healthy gut is promoted by factors that are constitutively produced in the mucosal microenvironment. These include thymic stromal lymphopoietin (TSLP) produced by IECs; short-chain fatty acids (SCFAs), such as butyrate, which are produced by anaerobic commensal bacteria; prostaglandin E2 (PGE2) produced by stromal cells; neuropeptides, such as vasointestinal peptide (VIP), produced by local neurons; IL-10 produced by intestinal macrophages and FoxP3$^+$ T_{reg} cells; and TGF-β and retinoic acid (RA) produced

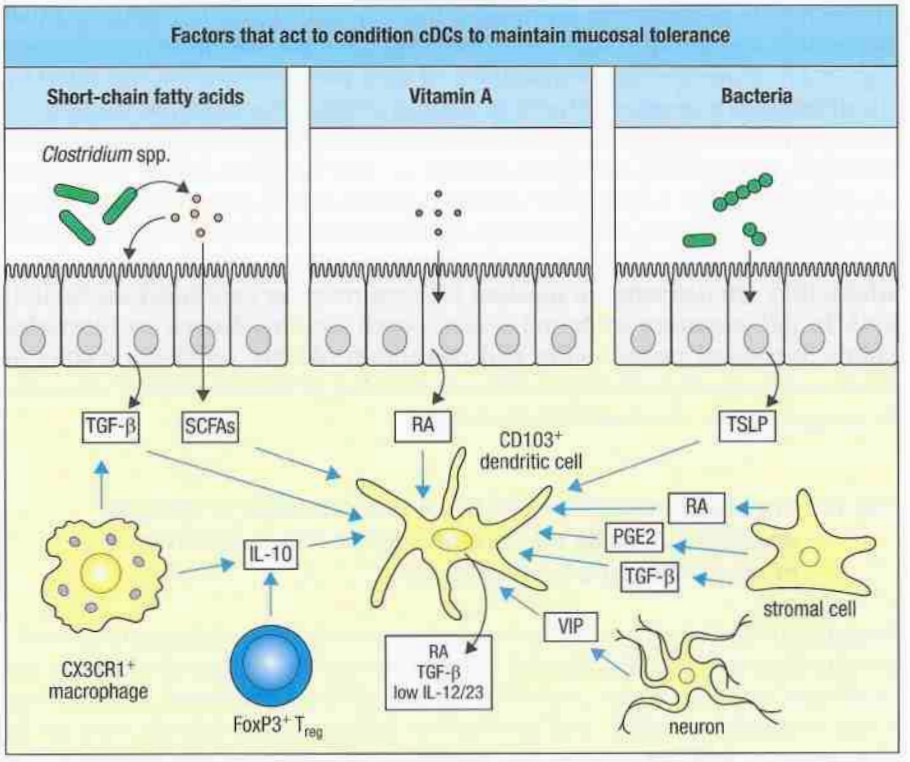

Fig. 12.31 Factors controlling the function of conventional dendritic cells in the intestinal lamina propria. The differentiation and function of dendritic cells in the intestinal lamina propria are affected by products of bacteria, epithelial cells, stromal cells, and neuronal cells, as well as dietary and microbial metabolites. Major factors that induce a pro-tolerogenic DC functional state include TGF-β, IL-10, retinoic acid, and TSLP. Circulating pre-DCs can acquire a tolerogenic phenotype in response to epithelial-cell production of retinoic acid (RA; derived from vitamin A), transforming growth factor-β (TGF-β), and thymic stromal lymphopoietin (TSLP), to active bacterial metabolites such as short-chain fatty acids (SCFAs) and niacin, as well as to specific microbial products, such as zymosan (β-glucan). Immune and nonimmune cells produce IL-10, TGF-β, prostaglandin E2 (PGE2), RA, and vasoactive intestinal peptide (VIP), which can influence cDC function.

by IECs and stromal cells (Fig. 12.31). The collective action of these factors induces the expression by intestinal DCs of RA and TGF-β, both of which are critical to the induction of FoxP3$^+$ pT$_{reg}$ cells (see Section 9-15 and Fig. 9.37).

Because vitamin A (retinol), the substrate from which RA is generated, cannot be synthesized and must be absorbed by the intestine from the diet, pT$_{reg}$ cell induction is dependent on a dietary factor. Retinol stored in the liver and delivered to the small intestine via bile provides an additional source for the local generation of retinoic acid in the intestines. Production of RA from vitamin A requires the sequential actions of enzymes expressed by intestinal DCs: alcohol dehydrogenases (ADHs) and retinal dehydrogenases (RALDHs). RA is a ligand for a nuclear receptor, retinoic acid receptor (RAR), activation of which promotes the development of pT$_{reg}$ cells while strongly repressing the differentiation of T$_H$17 cells (see Fig. 9.37). RA also induces the expression of gut-specific homing receptors, including $\alpha_4\beta_7$ and CCR9 (see Section 12-11). The induction of regulatory T cells in intestinal tissues is also dependent on TGF-β, which is produced by migratory and lymphoid tissue-resident cDC2 cells that take up antigens in the lamina propria and GALT, respectively. TGF-β also induces expression of the integrin $\alpha_E\beta_7$ (CD103) on developing T$_{reg}$ cells. The combined effects of RA and TGF-β therefore, are to induce the differentiation of FoxP3$^+$ pT$_{reg}$ cells and to direct their trafficking to the intestines.

After trafficking to the intestines, pT$_{reg}$ cells can acquire additional functional features that are important in maintaining immune homeostasis. It is thought that this transition involves further differentiative signals received when T$_{reg}$ cells enter effector sites in the intestines, such as the lamina propria. Referred to as **effector regulatory T (eT$_{reg}$) cells**, these cells are characterized by their expression of the anti-inflammatory cytokines IL-10 and TGF-β, both of which contribute to the tolerogenic nature of homeostatic intestinal cDCs in a positive feedback loop and are indispensable for restraining inflammatory responses to the commensal microbiota in the large intestine. Studies that examined the expression of FoxP3 and IL-10 in tissues throughout the body using transgenic reporter mice found that the highest frequency of IL-10–expressing cells in

	T_{reg} cells are highly enriched in the intestinal mucosa			
	$CD4^+FoxP3^-$		$CD4^+FoxP3^+$	
	$IL\text{-}10^-$	$IL\text{-}10^+$	$IL\text{-}10^-$	$IL\text{-}10^+$
Mesenteric LNs	80–90%	~1%	5–10%	~1%
Small intestine	70–80%	5–10%	5–10%	5–10%
Large intestine	60–70%	3–5%	10–15%	15–20%
Large intestine, GF	80–90%	~1%	5–10%	~1%

Fig. 12.32 T_{reg} cell subsets are major populations in the large and small intestines. Flow cytometry was used to analyze T_{reg} cell subsets in murine intestines and mesenteric lymph nodes, defined by concordant or differential expression of IL-10 and FoxP3 within the total fraction of CD4 T cells. The analysis of large intestinal cells compared those isolated from conventionally housed and germ-free (GF) mice. LNs, lymph nodes.

the body was in the intestines (Fig. 12.32), particularly in the large intestine, where it is primarily expressed by $FoxP3^+helios^-NRP1^-$ pT_{reg} cells at homeostasis. The functional importance of IL-10 expression by eT_{reg} cells has been demonstrated in studies in which selective deletion of the gene *Il10* in $FoxP3^+$ T cells resulted in spontaneous inflammation of the large intestine, or colitis. Thus, IL-10 produced by eT_{reg} cells is important for immune homeostasis in the large intestine.

Elegant experiments in the 1990s led to the now generally accepted idea that T cells with the potential to respond to commensal microbiota are present in normal animals but are usually kept in check through active repression by T_{reg} cells (Fig. 12.33). In these studies, the transfer of naive CD4 T cells into immunodeficient mice led to spontaneous IBD, or colitis, unless a separate population that included T_{reg} cells was co-transferred. The cell types that drove this disease were later shown to be microbiota-reactive T_H17 and T_H1 cells

Cells transferred	Microbiota	Disease
Unfractionated $CD4^+$ T cells	+	No
$CD4^+CD45RB^{hi}$ T cells (naive)	+	Colitis
$CD4^+CD45RB^{hi}$ T cells + $CD4^+CD45RB^{lo}$ T cells (includes T_{reg} cells)	+	No
$CD4^+CD45RB^{hi}$ T cells + IL-10–deficient $CD4^+CD45RB^{lo}$ T cells (includes T_{reg} cells)	+	Colitis
$CD4^+CD45RB^{hi}$ T cells	–	No

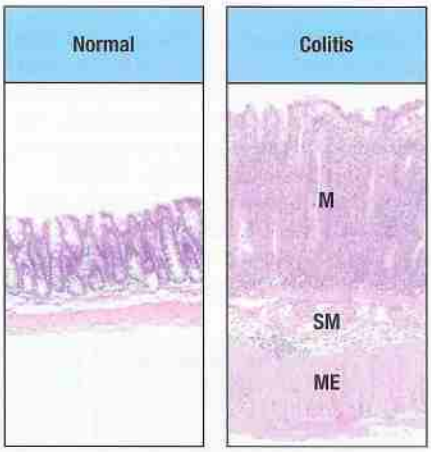

Fig. 12.33 T cells with the potential to produce inflammation in response to commensal bacteria are present in normal animals, but are controlled by regulatory T cells. Transfer of total (unfractionated) $CD4^+$ T cells from a normal mouse into an immunodeficient mouse, such as one lacking the gene *Rag1* (*Rag1*$^{-/-}$), will lead to reconstitution of the CD4 T-cell compartment. However, if naive CD4 T cells ($CD4^+CD45RB^{hi}$) are isolated from the total CD4 T-cell population and transferred, the recipient mice develop severe inflammation of the colon. This is prevented by co-transferring $CD4^+CD45RB^{lo}$ T cells that were removed during the isolation of the naive ($CD45RB^{hi}$) fraction of the total $CD4^+$ T-cell population. The $CD4^+CD45RB^{lo}$ fraction comprises nearly all of the T_{reg} cells within the CD4 T-cell population. If the $CD4^+CD45RB^{lo}$ fraction is isolated from IL-10–deficient mice, the protective effect of these cells is lost. The intestinal inflammation caused by naive $CD4^+$ T cells requires the presence of the microbiota; it does not occur in germ-free mice or in mice treated with antibiotics. These experiments demonstrate that some $CD4^+$ T cells in normal animals are capable of provoking inflammatory responses against the intestinal microbiota, but they are normally held in check by regulatory T cells. Shown in the two right panels are examples of the histopathology of the normal mouse colon (left) and the colitic colon (right), the latter demonstrating a much thickened mucosa (M) due to elongation of the crypts and dense infiltrates of inflammatory cells, as well as the expansion of the submucosa (SM) and thickening of the muscularis externa (ME).

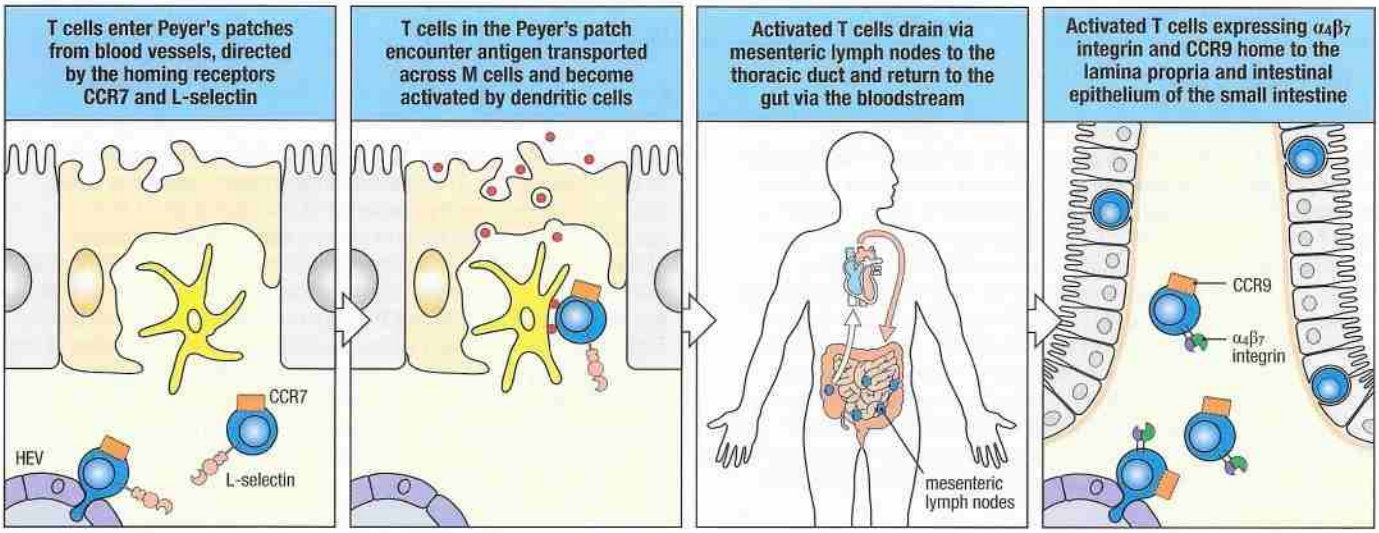
that developed from the transferred naive CD4 T cells. That the inflammatory response was directed against the intestinal microbiota was demonstrated by the absence of disease in germ-free mice. An essential requirement for IL-10 expression by T_{reg} cells in preventing disease was found, as the transfer of T_{reg} cells deficient in IL-10 failed to control the development of colitis. Similar studies have shown that T_{reg} cells deficient for TGF-β are impaired in their prevention of colitis. Accordingly, mutations in the genes *IL10RA*, *IL10RB*, *TGFBR1*, or *TGFBR2* in humans are associated with severe early-onset inflammatory bowel disease, such as Crohn's disease, presumably due, at least in part, to defects in the function of eT_{reg} cells reactive to commensal microbial antigens.

12-11 Lymphocytes primed within the mucosal immune system are directed to return to the mucosal tissue by tissue-specific adhesion molecules and chemokine receptors.

The destination of naive T cells and B cells circulating in the bloodstream is not predetermined, and like those in other peripheral lymphoid tissues, the cells destined to be primed in the GALT or mesenteric lymph nodes enter through **high endothelial venules (HEVs)** (see Fig. 9.4). As in the systemic immune system, this process is controlled largely by the chemokines **CCL21** and **CCL19**, which are released from stromal cells in these sites and bind the receptor **CCR7** on naive lymphocytes. In the Peyer's patches and ILFs, this process is assisted by the binding of the mucosal vascular addressin **MAdCAM-1** on HEVs to the **L-selectin** expressed on naive T cells. **CXCR5** responding to **CXCL13** produced in B-cell areas is also important for recruitment of naive B cells to Peyer's patches and ILFs. As in other peripheral lymphoid tissues, if the naive lymphocytes do not see their antigen, they do not down-regulate **sphingosine 1-phosphate receptor 1 (S1PR1)**, and they return to the bloodstream via the lymphatics. If they encounter antigen in the GALT or regional lymph nodes, they are imprinted by intestinal DCs to return to the intestinal lamina propria.

Although some T and B lymphocytes initially activated in Peyer's patches or ILFs may migrate directly to adjacent parts of the lamina propria, most leave via the lymphatics, pass through mesenteric lymph nodes, and eventually end up in the thoracic duct. From there they circulate in the bloodstream (Fig. 12.34) and selectively reenter the intestinal lamina propria via small blood vessels. Gut-specific homing by antigen-stimulated T and B cells is determined in large part by the expression of the integrin $\alpha_4\beta_7$, which binds



T cells enter Peyer's patches from blood vessels, directed by the homing receptors CCR7 and L-selectin
T cells in the Peyer's patch encounter antigen transported across M cells and become activated by dendritic cells
Activated T cells drain via mesenteric lymph nodes to the thoracic duct and return to the gut via the bloodstream
Activated T cells expressing α4β7 integrin and CCR9 home to the lamina propria and intestinal epithelium of the small intestine

α4β7 integrin

Fig. 12.34 Priming of naive T cells and the redistribution of effector T cells in the intestinal immune system. Naive T cells express the chemokine receptor CCR7 and L-selectin, which direct their entry into Peyer's patches and isolated lymphoid follicles (ILFs) via high endothelial venules (HEVs). In T-cell areas, they encounter antigen that has been transported into the lymphoid tissue by M cells and is presented by local dendritic cells. During activation, and under the selective control of signals from dendritic cells activated locally by TGF-β, the T cells lose L-selectin and acquire the chemokine receptor CCR9 and the integrin $\alpha_4\beta_7$. After activation, but before full differentiation, the primed T cells exit from the Peyer's patch via the draining lymphatics, passing through the mesenteric lymph node to enter the thoracic duct. The thoracic duct empties into the bloodstream, delivering the activated T cells back to the wall of the small intestine. Here T cells bearing CCR9 and $\alpha_4\beta_7$ are attracted specifically to leave the bloodstream and enter the lamina propria of the villus.

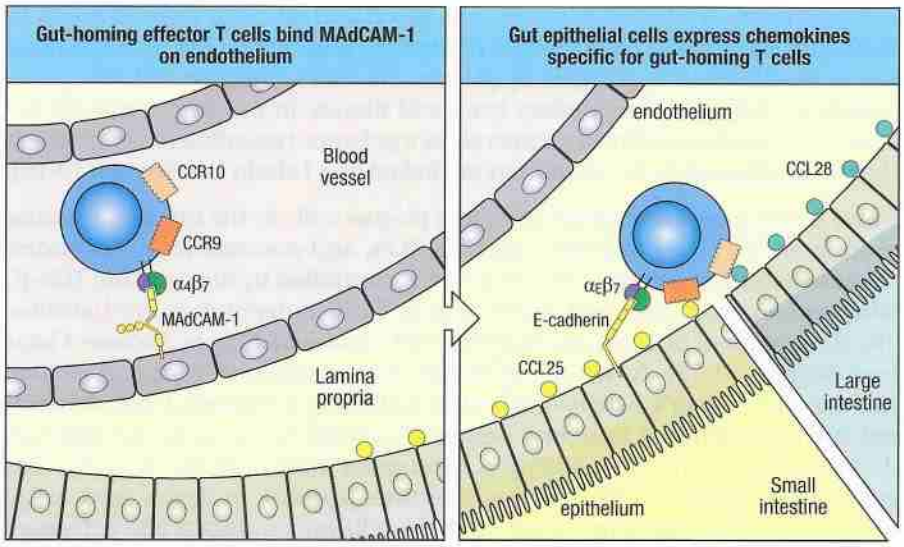

Fig. 12.35 Molecular control of intestine-specific homing of lymphocytes. Left panel: T and B lymphocytes primed by antigen in the Peyer's patches or mesenteric lymph nodes arrive as effector lymphocytes in the bloodstream supplying the intestinal wall (see Fig. 12.34). The lymphocytes express the integrin $\alpha_4\beta_7$, which binds specifically to MAdCAM-1 expressed selectively on the endothelium of blood vessels in mucosal tissues. This provides the adhesion signal needed for the emigration of cells into the intestinal lamina propria. Right panel: If primed in the GALT or lymph nodes draining the small intestine, the effector lymphocytes also express the chemokine receptor CCR9, which allows them to respond to CCL25 (yellow circles) produced by epithelial cells of the small intestine; this enhances their selective recruitment to the small intestine. Effector lymphocytes that have been primed in the GALT or lymph nodes draining the large intestine do not express CCR9 but instead express CCR10. CCR10 may respond to CCL28 (green circles) produced by colon epithelial cells to fulfill a similar function. Lymphocytes destined to enter the epithelial layer no longer express the $\alpha_4\beta_7$ integrin and instead express the $\alpha_E\beta_7$ integrin. The receptor for this is E-cadherin on intestinal epithelial cells (IECs). These interactions may help to retain lymphocytes in the epithelium once they have entered the lamina propria or the epithelium.

to MAdCAM-1 expressed on microvessels of intestinal tissues (Fig. 12.35). Homing of these lymphocytes to the small intestinal or large intestinal mucosa is further regulated by differential expression of the chemokine receptors, including CCR9 or CCR10, which respectively bind the homeostatic chemokine CCL25 (small intestine) or CCL28 (large intestine) produced by the local epithelium. The chemokine receptor–like orphan G-coupled protein receptor 15 (GCPR15) also appears to be important for trafficking of effector T cells to the large intestine, although its ligand(s) is not yet known. Notably, the epithelium of the lactating breast also expresses CCL28. In this way, SIgA-producing B lymphoblasts primed to commensal microbial antigens in the large intestine are recruited to the breast where they produce maternal SIgA, which is passively transferred to the nursing neonate.

12-12 Secretory IgA is the dominant class of antibody associated with the mucosal immune system at homeostasis.

The dominant class of antibody in the mucosal immune system is immunoglobulin A (IgA), which is produced locally by plasma cells in the lamina propria, including that of the intestines. Hundreds of thousands of IgA-producing plasma cells are present in the normal human intestine, and they produce 3–4 g of IgA each day, by far the most of any immunoglobulin class produced in the gut. This continual production of large quantities of IgA occurs in the absence of pathogenic invasion and is driven almost entirely by recognition of the commensal microbiota. The nature of IgA differs between the two main

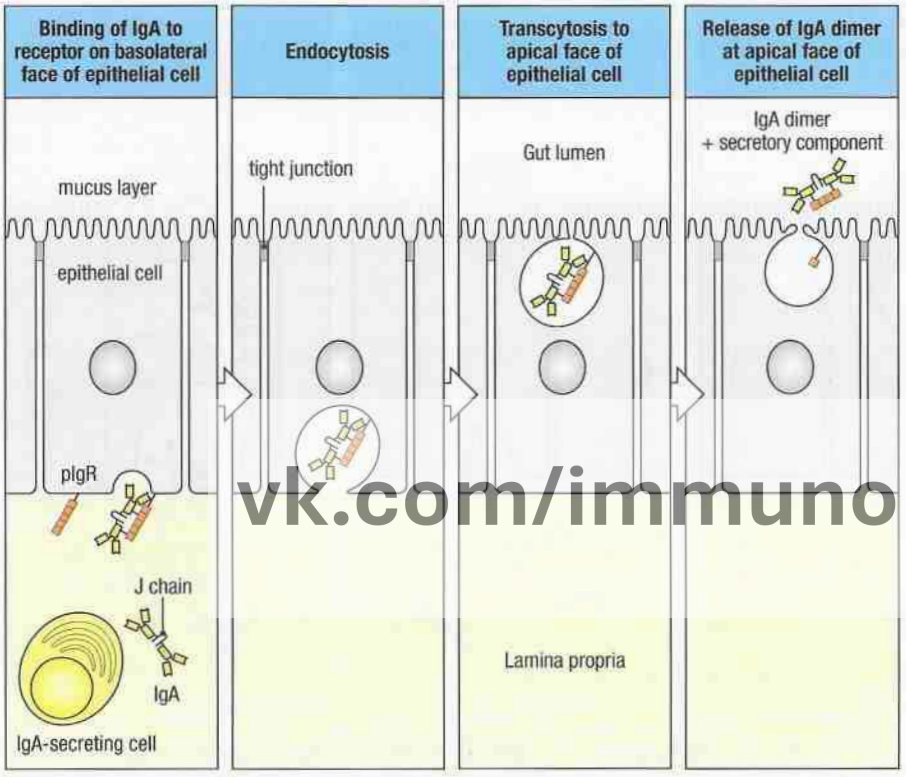
compartments in which it is found—the blood and mucosal secretions. IgA in the blood is mainly in the form of a monomer (monomeric IgA, or MIgA) that is produced in the bone marrow by plasma cells that home there following their initial development in secondary lymphoid tissues. In mucosal lymphoid tissues, IgA is produced almost exclusively as a polymer, typically a dimer in which the two immunoglobulin monomers are linked by a **J chain** (see Section 10-16).

Naive B-cell precursors of IgA-secreting plasma cells in the intestinal lamina propria are activated in Peyer's patches, ILFs, and mesenteric lymph nodes. Class switching of activated B cells to IgA is controlled by the cytokine TGF-β, whether generated via T cell–dependent or T cell–independent mechanisms. The development of T cell–independent IgA class switching is discussed later (see Section 12-13). In lymphoid tissues with developed germinal centers (for example, Peyer's patches), IgA class switching is entirely T-cell dependent and regulated by **T follicular helper (T_{FH})** cells by the same mechanisms described in Chapter 10. Notably, a substantial fraction of the T_{FH} cells that support IgA class switching in the intestines appears to derive from pT_{reg} cells. This makes regulatory sense, as these cells are producers and activators of TGF-β, and by inducing the production of SIgA to antigens they recognize, they provide a self-reinforcing positive feedback loop, due to the fact that delivery of antigens in complex with SIgA favors the generation of pT_{reg} cells. In this regard, it has been shown in mice that depletion of T_{reg} cells leads to a decline in IgA^+ plasma cells and intestinal IgA over a few days, indicating that intestinal plasma cells are relatively short-lived and that T_{reg} cells are critical for their maintenance and/or their replacement.

Unlike mice, which produce a single isotype of monomeric and dimeric IgA, humans produce two IgA isotypes, IgA1 and IgA2. The ratio of IgA1 to IgA2 varies markedly depending on the tissue, being about 10:1 in the blood and upper respiratory tract, about 3:2 in the small intestine, and 2:3 in the colon. Some common pathogens of the respiratory mucosa (such as *Haemophilus influenzae*) and the genital mucosa (such as *Neisseria gonorrhoeae*) produce proteolytic enzymes that can cleave IgA1, whereas IgA2 is cleavage-resistant. The higher proportion of plasma cells secreting IgA2 in the large intestine might result because the high density of commensal microorganisms at this site drives the production of cytokines that cause its selective class switching. The IgA isotype produced in mice is most like human IgA2.

IgA-expressing B plasmablasts produced in the GALT or regional lymph nodes express the mucosal homing integrin $\alpha_4\beta_7$ and the chemokine receptors CCR9 or CCR10, which cause them to localize to the small or large intestinal lamina propria. Once there, these cells undergo final differentiation into plasma cells that synthesize IgA dimers and secrete them into the subepithelial space (Fig. 12.36). To reach antigens in the gut lumen, the dimeric IgA must be transported across the epithelium by the **polymeric immunoglobulin receptor (pIgR)** (see Section 10-16). pIgR is expressed constitutively on the basolateral surfaces of immature epithelial cells located at the base of intestinal crypts where it binds dimeric IgA. pIgR transports the dimeric IgA to the luminal surface of the epithelium, where it is released by proteolytic cleavage of the extracellular domain of the receptor. Part of the cleaved pIgR remains associated with IgA and is known as **secretory component (SC)**. The resulting antibody is protected from proteolytic cleavage and is referred to as secretory IgA (SIgA) (see Section 10-16). The same pathway is used to transport pentameric IgM across the intestinal epithelium—so-called secretory IgM (SIgM)—which appears to play an important role in the colonization of the intestines by the commensal microbiota early in life.

In some animals there is a second route of IgA secretion into the intestine—the **hepatobiliary route**. Dimeric IgA that has not bound pIgR is taken up into venules in the lamina propria, which drain intestinal blood to the liver via the portal vein (see Fig. 12.7). In the liver, the portal vein delivers the dimeric IgA



vk.com/immuno

Fig. 12.36 Transcytosis of IgA antibody across epithelia is mediated by the polymeric Ig receptor (pIgR), a specialized transport protein. Most IgA antibody is synthesized in plasma cells lying just beneath epithelial basement membranes of the gut, the respiratory epithelia, the tear and salivary glands, and the lactating mammary gland. The IgA dimer, linked by a J chain, diffuses across the basement membrane and is bound by the pIgR on the basolateral surface of the epithelial cell. The bound complex undergoes transcytosis, by which it is transported in a vesicle across the cell to the apical surface. There the pIgR is cleaved, leaving the extracellular IgA-binding component bound to the IgA molecule as the so-called secretory component. Although not shown, carbohydrate on the secretory component binds to mucins in mucus and holds the IgA at the epithelial surface. The residual part of pIgR that remains cell-associated is nonfunctional and is internalized and degraded. IgA is transported across epithelia in this way into the lumina of several organs that are in contact with the external environment. Pentameric IgM, which is also linked by a J chain, is similarly transported across mucosal epithelia by pIgR and released in association with the secretory component.

to sinusoids that are lined by a fenestrated endothelium containing 'holes' that allow the antibodies direct access to underlying hepatocytes, which express pIgR on their surface. IgA is taken up into the hepatocytes and transported by transcytosis into an adjacent bile duct. In this way, secretory IgA can be delivered back to the duodenum via the common bile duct. This hepatobiliary route allows dimeric IgA to eliminate antigens that have invaded the lamina propria and have been bound there by IgA. Although highly efficient in rats and other rodents, this route does not seem to be of great significance in humans and other primates, in whom hepatocytes do not express pIgR.

IgA secreted into the gut lumen binds to the layer of mucus coating the epithelial surface via carbohydrate determinants in secretory component. There it prevents invasion by pathogenic organisms and also has a crucial role in maintaining the homeostatic balance between the host and the commensal microbiota. IgA does this in a number of ways (Fig. 12.37). First, it inhibits microbial adherence to the epithelium, its ability to bind bacteria being assisted by the unusually wide and flexible angle between the Fab pieces of the IgA molecule, particularly the IgA1 isotype, allowing very efficient bivalent binding to large antigens such as bacteria. Secretory IgA also aggregates bacteria such that they are less able to penetrate the network of mucins in the mucus. Secretory IgA can also neutralize microbial toxins or enzymes.

In addition to its activities in the lumen, IgA can neutralize bacterial lipopolysaccharide and viruses it encounters within endosomes inside epithelial cells, as well as across the epithelial barrier in the lamina propria after bacteria and viruses have penetrated there. The resulting IgA:antigen complexes are then reexported into the gut lumen. From there they are excreted from the body. Complexes containing dimeric IgA formed in the lamina propria can also be excreted via the hepatobiliary route described earlier. In addition to enabling the elimination of antigens, the formation of IgA:antigen complexes can enhance the uptake of luminal antigen by M cells and local dendritic cells, via binding of carbohydrate residues on IgA to lectin receptors such as Dectin-1

Fig. 12.37 Mucosal IgA has several functions in epithelial surfaces. First panel: IgA adsorbs on the layer of mucus covering the epithelium, where, in addition to aggregating commensal bacteria (not shown), it can neutralize pathogens and their toxins, preventing their access to tissues and inhibiting their functions. Second panel: Pathogens and toxins internalized by the epithelial cell can meet and be neutralized by IgA in endosomes. Third panel: Toxins or pathogens that have reached the lamina propria encounter pathogen-specific IgA there, and the resulting complexes are reexported into the lumen across the epithelial cell as the dimeric IgA is secreted. Fourth panel: Antigen bound to secretory IgA in the lumen can bind via carbohydrate residues on the Fc portion of IgA to Dectin-1 on M cells in Peyer's patches and be transported to underlying dendritic cells.

and DC-SIGN, respectively. In addition to these antigen-specific effects, secretory IgA can restrict the entry of bacteria in a nonspecific manner, because the high carbohydrate content of the Fc part of the IgA heavy chain allows it to act as a decoy for receptors that bacteria use to bind carbohydrates on the epithelial surface. Importantly, SIgA has little capacity to activate the classical pathway of complement or to act as an opsonin, and so does not induce inflammation. Uptake of IgA:antigen complexes by dendritic cells also induces these cells to produce anti-inflammatory IL-10. Together these properties mean that IgA can limit the penetration of microbes into the mucosa without risking inflammatory damage to these fragile tissues, something that would be potentially harmful in the intestine. For the same reasons, secretory IgA fosters the beneficial symbiosis between the host and its commensal microbiota.

12-13 T cell–independent processes can contribute to IgA production in some species.

A significant proportion of intestinal SIgA is derived from T cell–independent B-cell activation and class switching. This is clearly true in mice, and probably similar in humans, although experimental support for the latter is more limited. T cell–independent B-cell activation depends on activation of the innate immune system by the products of commensal microbes and results from the direct interaction of B cells with intestinal cDCs and follicular dendritic cells in isolated lymphoid follicles. Most of this SIgA production seems to involve lymphocytes of the B-1 subset (see Section 8-10), which arise from precursor B cells in the peritoneal cavity and migrate to the intestinal wall in response to microbial constituents such as lipopolysaccharide (LPS). Once in the mucosa, TGF-β–dependent class switching to IgA occurs under the influence of local factors, including IL-6, retinoic acid, and BAFF and APRIL (see Fig. 10.6), which bind to TACI on B cells, substituting for signals otherwise supplied by CD4 helper T cells (see Section 10-1). Intestinal epithelial cells produce BAFF and APRIL, while local macrophages, DCs, and eosinophils may contribute by producing APRIL, IL-6, and TGF-β.

The IgA antibodies produced in these T cell–independent responses are generally of more limited diversity and lower affinity, with little evidence of

somatic hypermutation. They are nevertheless an important source of 'natural' antibodies directed at commensal bacteria and may play a particularly important role in modulating the developing intestinal microbiota in neonates prior to establishment of more mature T- and B-cell responses. With progressive maturation of the immune system during the first years of life, there is a shift to a greater fraction of SIgA contributed by T-dependent B-cell activation and class switching; hence, a greater proportion of SIgA has undergone somatic hypermutation with increasing age. T-independent SIgA production in the intestines may offer a glimpse into the evolutionary history of specific antibody responses in the mucosa, and it appears to serve as a 'backup' for the generation of SIgA when T cell–dependent IgA production is compromised, as it is in AIDS or in individuals with an inherited deficiency of CD40.

12-14 IgA deficiency is relatively common in humans but may be compensated for by secretory IgM.

Selective deficiency of IgA production is one of the most common inherited, or primary, immune deficiencies in humans, occurring in about 1 in 500 to 700 Caucasians. (It is somewhat rarer in other ethnic groups.) The most frequent genetic mutation that has been identified in this condition is in the TACI receptor for BAFF. A slightly higher incidence of respiratory infections, atopy (a tendency for allergic reactions to harmless environmental antigens), and autoimmune disease has been reported in older people with IgA deficiency. However, most individuals with IgA deficiency are not overly susceptible to infections. The dispensability of IgA probably reflects the ability of IgM to replace IgA as the predominant antibody in secretions, and increased numbers of IgM-producing plasma cells are indeed found in the intestinal mucosa of IgA-deficient people. Because IgM is a J chain–linked polymer, IgM produced in the gut mucosa is bound efficiently by the pIgR and is transported across epithelial cells into the gut lumen as secretory IgM. The importance of this backup mechanism has been shown in knockout mice. Animals lacking IgA alone have a normal phenotype, but those lacking the pIgR are susceptible to mucosal infections. They also show increased penetration of commensal bacteria into tissues and a consequent systemic immune response to these bacteria. Genetic absence of the pIgR has never been reported in humans, suggesting that such a defect is lethal.

12-15 Large numbers of antigen-experienced T cells are present in the intestinal lamina propria even in the absence of disease.

Most of the T cells in the healthy lamina propria have been activated by dendritic cells and express markers of effector or memory T cells. Just as for T_{reg} cells and B cells, the largest deployment of effector T cells at homeostasis is in the intestines. The T-cell population of the lamina propria has a ratio of CD4 to CD8 T cells of 3:1 or more, similar to that in systemic lymphoid tissues. In industrialized countries, where intestinal helminth infections are less common, the major effector T-cell subsets resident in the gut express cytokines characteristic of T_H17 and T_H1 cells. And like T_{reg} cells and B cells, the development of these effector subsets is largely dependent on the dominant component of the microbiota—bacteria. T_H17 cells in particular, in their role as responders to extracellular antigens, are particularly abundant, due in part to their developmental ties to pT_{reg} cells with which they share a requirement for the abundant intestinal cytokine, TGF-β (see Section 9-14). Their large number likely reflects the constant state of immune recognition of the microbiota and other environmental antigens that takes place in the intestine. At least some T_H17 cells in the lamina propria appear to be resident memory (T_{RM}) cells, although the proportion varies depending on the antigenic exposure history. Cytokines produced by intestinal T_H17 cells are important components

of intestinal homeostasis and defense. IL-17 is needed for full expression of the polymeric immunoglobulin receptor involved in secretion of IgA into the lumen, while IL-22 stimulates intestinal epithelial cells to produce antimicrobial peptides that help maintain epithelial barrier integrity. Effector CD8 T cells are also present in the normal lamina propria and are capable of both cytokine production and cytotoxic activity when a protective immune response to a pathogen is required.

Whether at steady state, in response to infection, or in the context of chronic inflammation induced by inflammatory bowel disease (IBD), the intestine contains, in addition to effectors that express IL-17, cells that express IFN-γ, or both IL-17 and IFN-γ. Although a fraction of these T cells is generated in response to the microbiota and are therefore presumed to be specific for antigens of the commensal flora, their developmental origins and functions remain incompletely defined. Notably, however, in contrast to T_H1 and T_H2 cells, T_H17 cells retain the capacity for divergent cytokine expression profiles and function after their commitment to the T_H17 pathway and can give rise to IL-17$^+$IFN-γ$^+$ effectors, as well as IL-17$^-$IFN-γ$^+$ effectors that resemble classical T_H1 cells, so-called T_H17/T_H1 cells (see Section 11-14 and Fig. 11.21). This has been demonstrated for both human and mouse T_H17 cells and has raised the possibility that many of the IFN-γ–producing 'T_H1' cells in the intestine arise from the T_H17 pathway. While the relative contributions of T_H17 and T_H17/T_H1 cells to host defense or inflammatory disease remain to be elucidated, IFN-γ–producing cells are required for disease pathogenesis in at least some mouse models of IBD. Although these T_H17/T_H1 cells share many features of classical T_H1 cells, gene-expression analyses indicate important differences that are likely to have implications for immune disease mediated by these cells. This suggests generic categorization of IFN-γ–producing CD4 T cells as 'T_H1' cells is an oversimplification, and so further studies aimed at dissecting the contributions of branches of the T_H17 pathway to immune protection or pathogenesis will be important.

In any other situation, the presence of such large numbers of differentiated effector T cells would suggest the presence of a pathogen and likely would lead to inflammation. The fact that it does not so do in the healthy lamina propria is because the generation of T_H1, T_H17, and cytotoxic T cells is balanced by the presence of substantial numbers of IL-10–producing T cells. In the large intestine, these are almost entirely FoxP3$^+$ T_{reg} cells, whereas in the small intestine, FoxP3$^+$ T_{reg} cells and FoxP3$^-$ CD4 T cells (T_R1) produce IL-10 and are likely involved in preventing unrestrained effector T cell–driven inflammation, as occurs in IBD.

12-16 Priming of lymphocytes in one mucosal tissue may induce protective immunity at other mucosal surfaces.

Not all parts of the mucosal immune system use the same tissue-specific chemokines, allowing localized compartmentalization of lymphocyte recirculation within the system. Thus, effector T and B cells primed in lymphoid organs draining the small intestine (mesenteric lymph nodes and Peyer's patches) are most likely to return to the small intestine; similarly, those primed in the respiratory tract migrate most efficiently back to the respiratory mucosa. This programming of tissue homing is useful in returning antigen-specific effector cells to the mucosal organ in which they will be most effective in fighting an infection or controlling immune responses against foreign proteins and commensals. Nevertheless, some lymphocytes that have been primed in the GALT, for example, can also circulate as effector cells to other mucosal tissues such as the respiratory tract, urogenital tract, and lactating breast. This overlap between mucosal recirculation routes gave rise to the idea of a **common mucosal immune system**, which is distinct from other parts of the immune system. Although this is now understood to be an oversimplification,

it does have important implications for vaccine development, because it may enable immunization by one mucosal route to be used to protect against infection at another mucosal surface. An important example of this is the induction of SIgA antibody production in the lactating breast by natural infection or vaccination of mucosal surfaces such as the intestine. As we have seen, this is because the vasculature of the lactating breast expresses MAdCAM-1 and chemokines recognized by CCR10 (see Section 12-11). This "cross-talk" is a crucial means of generating protective immunity that can be transmitted to nursing infants by passive transfer of the antibodies in maternal milk. A further example has been shown in experimental animals, in which nasal immunization has a special ability to prime immune responses in the urogenital tract against HIV. The mechanisms behind this are currently unknown.

Summary.

A fundamental challenge of the intestinal immune system is the maintenance of tolerance in the face of considerable nonpathogenic antigenic challenges, both microbial and nonmicrobial. Multiple mechanisms contribute to this, but central to immune homeostasis in the intestines is the delivery of antigens under conditions that favor the differentiation of pT_{reg} cells and SIgA-producing plasma cells—adaptive immune cells that both reinforce non-inflammatory responses to their inductive antigens. This is achieved by the creation of a microenvironment rich in anti-inflammatory cytokines, principal among which are TGF-β, which is produced by IECs and stromal cells, and IL-10, which is produced primarily by pT_{reg} cells themselves. Among other local factors important to intestinal immune homeostasis is retinoic acid (RA), which is produced from vitamin A by IECs and stromal cells, as well as cDCs that are conditioned in the intestines. TGF-β has potent actions on macrophages and cDCs, but also has direct effects on developing T cells and B cells to favor pT_{reg} cell differentiation and IgA class-switching, respectively, as does RA. IL-10 potently suppresses the production of pro-inflammatory cytokines by intestinal macrophages, playing a nonredundant role in maintaining the anti-inflammatory tone of the intestinal mucosa. The critical role of pT_{reg} cells and IL-10 has been demonstrated in murine studies wherein deletion of either results in spontaneous intestinal inflammation. SIgA promotes intestinal homeostasis as a non-complement-fixing antibody isotype that promotes pro-tolerogenic delivery of antigens to which it binds.

Many of the same factors that contribute to tolerogenic adaptive immunity in the intestines also promote homing of lymphocytes to effector sites in the intestinal mucosa. Thus, TGF-β and RA both contribute to the expression of integrins (for example, $\alpha_4\beta_7$) and chemokine receptors (for example, CCR9 and CCR10) that direct lymphocytes to the intestines, ensuring that pT_{reg} cells and IgA plasmablasts are directed to the site where they can reinforce tolerance to the antigens that induced their differentiation. Importantly, expression of the mucosal addressin (MadCAM-1) and chemokines that can attract gut-primed B cells by the lactating breast provides an important mechanism for delivery of maternal SIgA reactive to the mother's microbiota to her newborn, providing a mechanism to transmit immune tolerance to her offspring.

The intestinal immune response in host defense and immune-mediated disease.

Although major functions of the intestinal immune response are the control of interactions with the commensal microbiota and barrier surveillance and repair at homeostasis, host defense against a variety of infectious agents is

also a critical function. Despite the array of innate immune mechanisms in the gut and stiff competition from the indigenous microbiota, the gut is nevertheless a frequent site of infection by a wide variety of pathogenic organisms. These include many viruses; enteric bacteria such as enteropathogenic *E. coli*, *Vibrio*, *Salmonella*, and *Shigella* species, and *Listeria monocytogenes*; protozoans such as *Entamoeba histolytica*; multicellular helminth parasites such as tapeworms and pinworms; and fungi. These pathogens cause disease in different ways, and, as elsewhere in the body, the key to generating protective immunity is the activation of appropriate aspects of the innate and adaptive immune systems.

As in other tissues, the intestines must be able to generate a spectrum of immune responses tailored to individual pathogens, as discussed in the last chapter. Not surprisingly, many microbes have evolved means of adapting to and subverting these host responses. To ensure an adequate response to pathogens, the mucosal immune system needs to be able to recognize and respond to any foreign antigen, but it must not produce the same effector response to harmless antigens (from food or commensals). A major role of the intestinal immune system is to balance these competing demands. As we have highlighted previously, both innate and adaptive responses to intestinal infection are initiated through, and integrated with, the intestinal epithelium. In the last chapter, we highlighted features of type 2 immunity in the intestines (see Section 11-10). In this part of the chapter, we will consider several types of enteric bacterial infections to highlight some of the different strategies taken by pathogens to penetrate the intestinal defenses, along with mechanisms available to resist these pathogens. In the final part of the chapter, we will consider viral infections of the respiratory tract and fungal infection of the skin to highlight features of barrier defense against these types of pathogens.

12-17 Enteric pathogens elicit 'danger signals' by activating pattern-recognition receptors that are sequestered in the intestinal epithelium.

Central to the response of innate and adaptive immune cells in the intestinal tissues is the assessment of relative threat of those microbes that interact with and traverse the epithelial barrier. As we have seen, at homeostasis there is continual, albeit low-level transcytosis of commensal microbes. However, because these microbes enter in an orderly fashion, transported in large part across M cells, their recognition generally favors the induction of tolerance. Moreover, the large majority of commensal bacteria pose little risk to the host because they are strict anaerobes that cannot persist outside of the low-oxygen environment of the intestinal lumen, especially in the large intestine, where most reside. Although the surface epithelium of the intestines is relatively hypoxic—due to high oxygen consumption induced by the metabolism of short-chain fatty acids produced by commensal anaerobes—the more aerobic environment of host tissues, including the deeper lamina propria, prevents the growth of these anaerobes. However, a small but persistent fraction of the intestinal microbiota includes facultative anaerobes, particularly Enterobacteriaceae family members from the phylum Proteobacteria, which can thrive outside the intestinal lumen and retain the potential for serious disease should they traverse the epithelium in substantial numbers and disseminate as opportunistic pathogens. Similarly, most bacterial pathogens are facultative anaerobes that can thrive outside the gut lumen. The sensing of these organisms by the intestinal mucosa is therefore of paramount importance to host defense.

A central mechanism for discriminating friend from foe at the intestinal barrier is, as in most tissues, the activation of pattern-recognition receptors (PRRs), such as Toll-like receptors (TLRs). However, because TLRs that sense bacteria are down-modulated in the intestines to accommodate to the

commensal microbiota, there are special adaptations of the intestinal epithelium that allow bugs to reach the border, but not cross it, except via M cells that direct them directly to the GALT. Central to this balancing act is the partitioning of PRRs within the polarized epithelium. Thus, while some receptors that sense microbes at the apical surface of IECs are down-modulated, these same receptors are retained within intracellular vacuoles, as well as in the IEC cytosol and at basolateral surfaces, such that penetration of microbes into or across the epithelial barrier elicits pro-inflammatory responses, ignited by signals from the epithelium itself (Fig. 12.38). TLRs in intracellular vacuoles or at the basolateral surface of IECs detect intracellular pathogens or extracellular pathogens and their products that have been internalized by endocytosis or have penetrated the epithelium. Moreover, IECs express a variety of cytosolic sensors, as described in Chapter 3, which are activated when microorganisms or their products enter the cytoplasm. These include the **nucleotide-binding and oligomerization domain (NOD)** proteins NOD1 and NOD2, as well as cGAS and STING, among others (see Sections 3-9 and 3-10; Figs. 3.18 and 3.19). NOD1 recognizes a diaminopimelic acid–containing peptide that is found only in the cell walls of Gram-negative bacteria. NOD2 recognizes a muramyl

Bacteria in cytoplasm or escaping from phagosome are taken into forming autophagosome and destroyed after fusion with lysosome

Fig. 12.38 Epithelial cells have a primary role in innate defense against pathogens. TLRs are present in intracellular vesicles or on the basolateral or apical surfaces of epithelial cells, where they recognize different components of invading bacteria. Cytoplasmic NOD1 and NOD2 detect cell-wall peptides from bacteria. TLRs and NODs activate NFκB (see Fig. 3.19), inducing epithelial cells to produce CXCL8, CXCL1 (GROα), CCL1, and CCL2, which attract neutrophils and macrophages, and CCL20, which attracts dendritic cells. Many types of cell damage can activate an inflammasome (see Section 3-11), which in turn activates pro-caspase 1 and produces IL-18. Bacteria that invade the epithelial-cell cytoplasm or escape into the cytosol from phagosomes can induce autophagy. The organisms become ubiquitinated, leading to the recruitment of adaptor proteins that attract the phagophore, forming an autophagosome. Fusion with lysosomes then leads to destruction of the cargo within the autophagosome. NOD2 can also trigger autophagosome formation by binding directly to adaptor proteins, including the Crohn's disease–associated molecule ATG16L1.

dipeptide found in the peptidoglycans of most bacteria, as well as structures in certain viruses and mycobacteria. Epithelial cells defective in NOD2 are less resistant to infection by intracellular bacteria. Mice lacking NOD2 also show increased translocation of bacteria across the epithelium. A defect in recognition of the commensal microbiota by NOD2 also seems to be important in some cases of Crohn's disease, as up to 15% of Caucasian individuals carry a mutation in the NOD2 gene that renders the NOD2 protein nonfunctional.

Crohn's Disease

Ligation of TLRs or NOD proteins in IECs stimulates the production of cytokines, such as IL-18, and the production of chemokines. It can also modulate the production of antimicrobial peptides, mucins, and tight junctions, whether through direct actions or by indirect actions of cytokines induced by local immune cells that act, in turn, on the epithelium. Epithelial cells also express members of the intracellular **NOD-like receptor (NLR)** family, including NLRC4 and NLRP6, which can form **inflammasomes** (see Fig. 12.38). As described in Section 3-11, the formation of an inflammasome leads to activation of caspase 1, which cleaves pro-IL-18 to produce the active cytokine (see Fig. 3.20). While the cell targets activated by IL-18 (for example, macrophages) contribute to epithelial defense against bacterial invasion by promoting barrier integrity, these cells can cause tissue damage if activated for long periods, as in IBD.

One mechanism recently recognized as important for epithelial defense against infection is **autophagy**, which we discussed in Section 6-6 in regard to its relationship to antigen processing. In this process, a crescent-shaped double-membrane fragment in the cytoplasm, called the **isolation membrane**, or **phagophore**, engulfs various cytoplasmic contents to form a complete vesicle, the **autophagosome**, which fuses with lysosomes to degrade the contents (see Fig. 12.38). When autophagy is disrupted, bacteria cannot be contained effectively, and epithelial cells become stressed. This can lead to increased penetration of bacteria into the body and to NFκB-mediated inflammation. Autophagy is promoted by the NOD1 and NOD2 intracellular bacterial sensors. As with NOD2, mutations in the autophagy-related genes *ATG16L1* and *IRGM1* are associated with susceptibility to Crohn's disease in humans.

12-18 Pathogens induce inflammatory adaptive immune responses when innate defenses have been breached.

If pathogens gain access to the subepithelial space, they interact with innate immune cells in the underlying tissue. Although resident macrophages are inflammation-anergic at homeostasis (see Section 12-8), and therefore resistant to activation of pro-inflammatory responses, in the context of pro-inflammatory signals from the epithelium and products from pathogens themselves, these cells can become activated to release pro-inflammatory cytokines and chemokines. This response, in turn, results in the rapid recruitment of monocytes from the circulating blood, which are not inflammation-anergic, and amplifies the pro-inflammatory cascade in a feed-forward manner. Together with the cascade of inflammatory mediators released by epithelial cells, this process dramatically alters the environment of the mucosa and changes the behavior of local antigen-presenting cells, including dendritic cells.

As described in Section 9-8, activated dendritic cells will traffic to local T-cell zones and express high levels of co-stimulatory molecules, as well as polarizing cytokines such as IL-6, IL-23, IL-12, or IL-4, which promote development of the appropriate subset of effector T cells. Dendritic cells activated in Peyer's patches migrate to the T cell–dependent areas of the patch, whereas dendritic cells that encounter antigen in the lamina propria migrate to the mesenteric lymph node. The effector T cells activated in these ways acquire gut-homing molecules (see Section 12-11), ensuring that they return to the gut wall to encounter the invading organisms. Similarly, SIgA-producing B

lymphocytes are generated in Peyer's patches and mesenteric lymph nodes, giving rise to plasma cells that accumulate in the lamina propria. IgA secretion into the lumen is enhanced in response to infection because pIgR expression is enhanced by TLR ligands and pro-inflammatory cytokines. In a number of infections, B cells undergo class switching to IgG, generating intestinal plasma cells that produce complement-fixing IgG isotypes that enhance the eradication of the invading microbes, as we discuss later in Section 12-20.

The activated myeloid cells found in the inflamed mucosa may also contribute to amplifying and sustaining the functions of effector T and B cells that arrive in the mucosa. For example, IL-1 and IL-23 produced by recently arrived monocytes appear to be important for the survival and function of local T_H17 cells. Pro-inflammatory myeloid cells also produce mediators such as IL-6, TNF-α, and nitric oxide, which help drive IgA switching and secondary expansion of mucosal B cells.

12-19 Effector T-cell responses in the intestine protect the function of the epithelium.

Once activated, the effector T cells that accumulate in the intestine behave much like their counterparts elsewhere in the body, producing cytokines and generating cytolytic activity as appropriate to the pathogen. What is different is that a major aim of the protective immune response in the intestine is tailored to preserving the integrity and function of the epithelial barrier. This is achieved in a number of ways, depending on the nature of the pathogen.

In viral infections, CD8 cytotoxic T cells among intraepithelial lymphocytes kill infected epithelial cells (see Fig. 12.25), triggering their replacement by uninfected cells derived from the rapidly dividing stem cells in the crypts. A similar process can occur during other forms of protective immune responses, with cytokines from CD4 effector T cells directly stimulating stem cells in the colonic crypts to accelerate epithelial-cell generation and modulate the developmental trajectory of IECs toward either the secretory pathway (for example, in response to helminths) or the absorptive pathway (for example, in response to extracellular bacteria). This forces the replacement of infected cells and generates a moving target for organisms that are attempting to attach to the surface of the epithelium. It also expands the types of cells best suited to combat particular types of pathogens.

As an example, the production of IL-13 by ILC2 cells and T_H2 cells during parasitic infections increases the number of goblet cells and enhances their production of mucus, and also expands the number of tuft cells that contribute to a positive feedback loop by producing IL-25, which enhances production of IL-13 from ILC2 cells and T_H2 cells. Conversely, IL-22 produced by T_H17 cells contributes to defense against extracellular bacteria and fungi by promoting a shift in the type of mucin produced by goblet cells, promoting the cell death and sloughing of infected IECs and stimulating the production of antimicrobial peptides by Paneth cells and other IECs, as we discuss in the next section. Finally, these mediators and others can enhance the peristaltic action of the intestine and its outward secretion of fluid, washing out pathogens within the lumen of the intestine. Together these processes aim to generate a hostile and unstable environment for the pathogen, reducing its ability to invade and damage the epithelial barrier.

12-20 Noninvasive and invasive enteric bacterial pathogens use different strategies to colonize the intestines.

Bacterial pathogens elicit different host defenses contingent on their pattern of intestinal infection. Some bacterial pathogens are invasive; that is, they

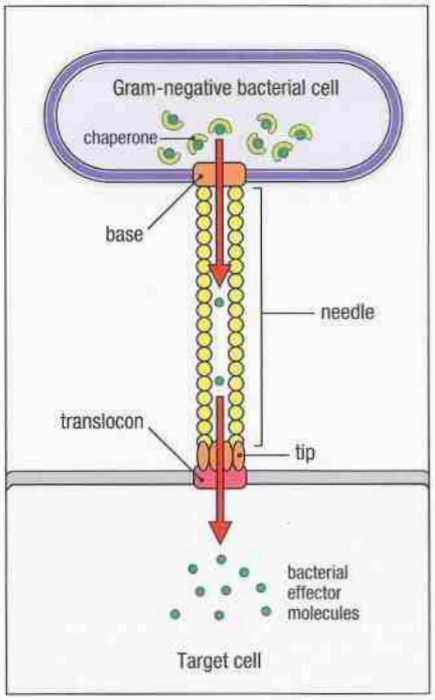

Fig. 12.39 Pathogenic bacteria use specialized secretion systems to inject effector molecules into host cells. A number of pathogenic Gram-negative bacteria use a complex, needle-like protein assembly—a type III or IV secretion system, or injectisome—to inject virulence proteins into target cells to compromise host defenses and establish infection. These 'nanoinjectors' are assembled from more than 20 proteins and are composed of a base that spans the two bacterial membranes, a needle that is anchored in the base and is formed by the polymerization of repeating α-helical subunits, and a tip complex that serves as a docking structure for the translocon, which penetrates the host-cell membrane to allow bacterial effector proteins to pass into the host cell.

typically penetrate the intestinal epithelial barrier and are able to disseminate beyond the mucosa. Other bacterial pathogens are noninvasive and neither traverse the intestinal epithelium nor disseminate. Enteric bacterial pathogens can also differ in the region of the intestinal tract they colonize. In any case, in order for enteropathogens to gain access to the host, they must first adhere to the epithelium, whether or not they subsequently traverse it. In the small intestine, which lacks the thick, two-layer mucus defense present in the large intestine, the opportunity for directly engaging the epithelium is greater, and, in the case of the proximal small intestine or follicle-associated epithelium overlying Peyer's patches and ILFs, there is scant mucus to prevent it. Indeed, as we shall see, like bacterial constituents of the commensal microbiota, several enteric pathogens specifically target M cells as an entry point to cross the epithelium. Thus, the epithelium can serve as both barrier and gateway for enteropathogens.

Enteropathogenic bacteria have evolved a variety of strategies for colonization and/or invasion of the intestinal epithelium, most of which are organism-specific. The bacterial molecules that mediate these properties are typically encoded by a cluster of genes called a pathogenicity island, which is either present on an extrachromosomal plasmid or integrated into the bacterial genome flanked by genetic mobility elements, enabling transfer between bacteria. The factors encoded within these elements that confer pathogenicity are referred to as virulence factors. Although each pathogen has developed distinctive ways to colonize the intestine, the expression of molecules that promote their attachment to, and/or internalization by, intestinal epithelial cells is a common feature. These include fimbriae (that is, specialized pili) and/or adhesins that bind host-membrane molecules. Many Gram-negative bacteria also assemble a needle-like protein structure, or **injectisome**, such as a type III secretion system (T3SS) or a type IV secretion system (T4SS) (Fig. 12.39), through which a wide spectrum of bacterial proteins, or effectors, is injected into host cells, including receptors for enhanced binding of the bacterium. In addition to their role in bacterial adhesion, these bacterial effectors can also target cellular pathways in IECs to modulate host-cell signaling pathways to facilitate pathogen replication and spread. However, as discussed earlier (see Section 12-17), these bacterial effectors can also activate intracellular pattern-recognition receptors that initiate host immunity. Some bacteria also use injectisomes, particularly type VI secretion systems (T6SSs), to deliver effectors to other bacteria and kill them in a type of interbacterial warfare that allows the pathogen to outcompete commensals.

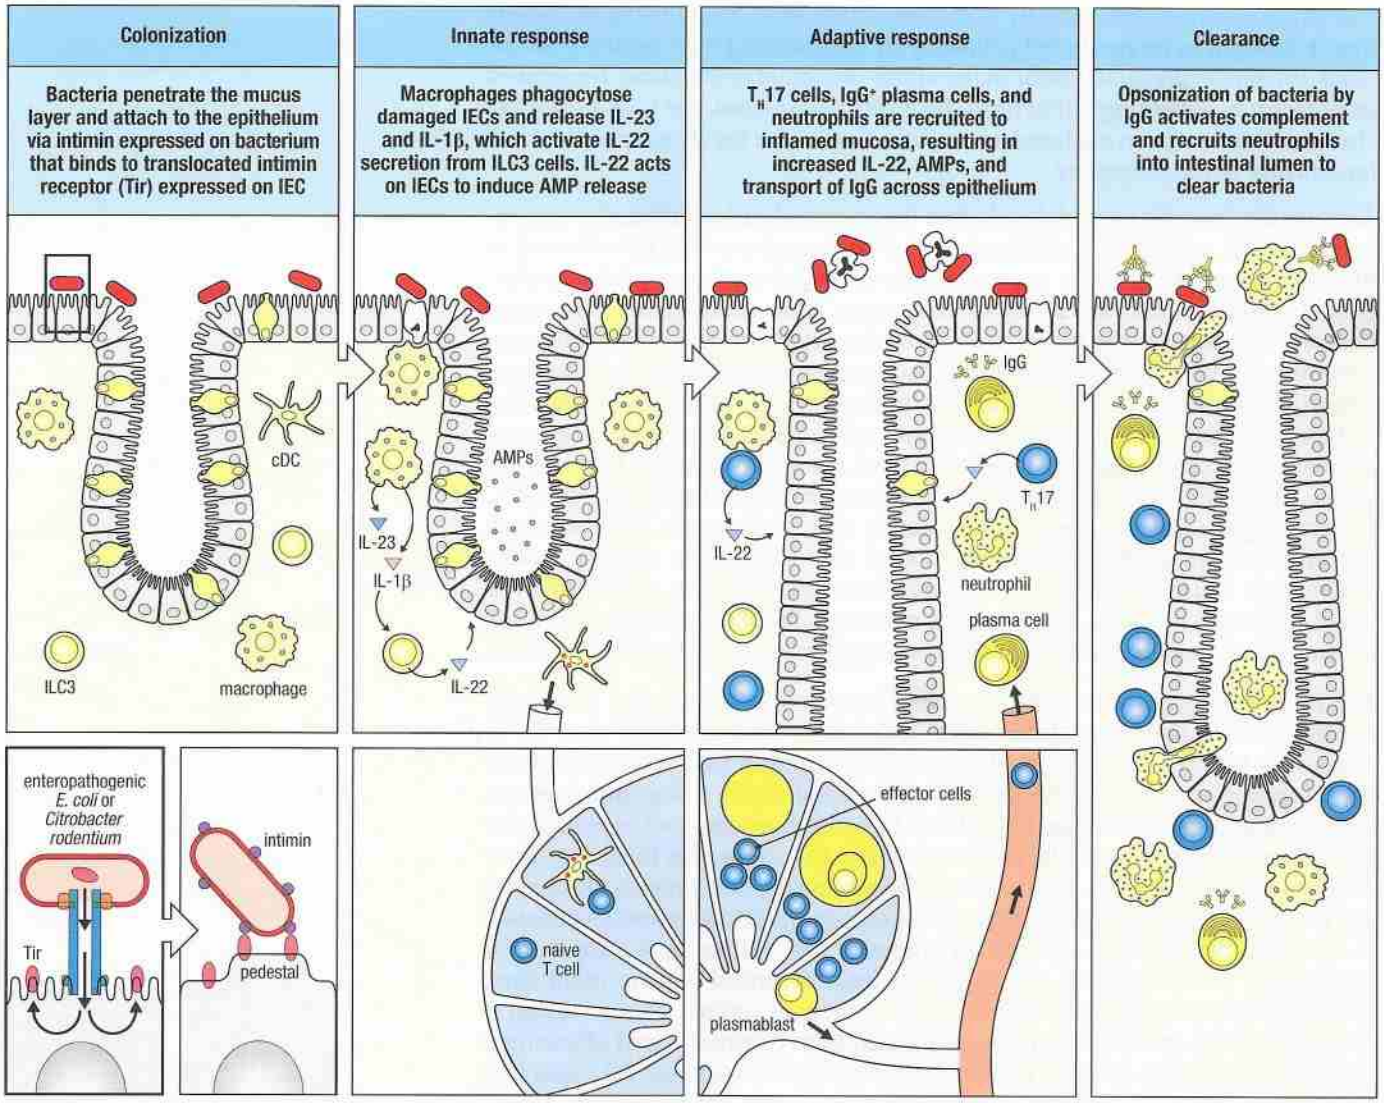
Here we consider two noninvasive bacterial pathogens that attach to the intestinal epithelium, but do not invade. *Vibrio cholerae*, a Gram-negative, flagellum-expressing (motile) bacterium, is the causative agent of cholera, a prominent diarrheal disease that affects more than 2 million people and causes more than 75,000 deaths annually worldwide, particularly in underdeveloped regions with poor sanitation. Although most strains of *V. cholerae* are nonpathogenic free-living aquatic bacteria, pathogenic strains express at least two virulence factors that result in human disease: cholera toxin (CT) and the adhesin toxin-coregulating pilus (TCP). Both are required for virulence; TCP mediates initial attachment of *V. cholerae* to IECs of the small intestine, and CT mediates the pathogenic effect of cholera. Cholera toxin is a multi-subunit exotoxin composed of a pentameric binding subunit (CTB) and a monomeric active subunit (CTA). CTB binds to the cell-surface ganglioside GM1, which is widely expressed. The binding of CTB to the surface of an IEC stimulates endocytosis of the toxin and cleavage of CTB from the CTA subunit. The CTA subunit is delivered into the host cell where it activates adenylate cyclase, resulting in accumulation of intracellular cyclic AMP (cAMP). This stimulates the robust secretion of chloride ions and blocks the uptake of sodium chloide, causing a massive efflux of water. The resulting efflux of water and electrolytes results in severe diarrhea and dehydration that can be lethal, particularly for infants

and small children. Infection by *V. cholerae* stimulates long-lasting immunity that is thought to be mediated primarily by neutralizing SIgA antibodies that block the bacteria's attachment to the small-intestinal epithelium. Because of its potency in delivering antigens to the intestinal mucosa, the CTB subunit of cholera toxin has been explored as a mucosal adjuvant for antigens linked to it for delivery to the intestines.

Another noninvasive bacterial pathogen that causes diarrheal disease is enteropathogenic *E. coli* (EPEC). Although *E. coli* strains are normal constituents of the commensal microbiota, enteropathogenic *E. coli* strains contain a pathogenicity island called the locus of enterocyte effacement (LEE), so-named because it comprises the genes responsible for attaching and effacing lesions, a feature of EPEC characterized by tight adherence of the bacterium to enterocytes that results in characteristic destruction of microvilli (**Fig. 12.40**). The LEE pathogenicity island encodes multiple virulence factors, including components of a T3SS, which is used to deliver bacterial effectors into enterocytes. LEE also encodes two genes required for the attachment of EPEC to enterocytes: intimin and a translocated intimin receptor (Tir) to which intimin binds to establish firm adhesion to the cell surface of IECs. Unlike *V. cholerae*, which stimulates remarkably little inflammation in the involved small-intestinal mucosa, EPEC, which colonizes the large intestine, induces colonic inflammation (colitis) that resolves only when the infection is cleared.

The immune response to EPEC has been modeled in mice using the highly related rodent pathogen, *Citrobacter rodentium*. Host defense against *C. rodentium* infection is dominated by a type 3 response that is initiated when the bacterium penetrates the mucus layer in the distal colon and interacts with colonic enterocytes (see Fig. 12.40). *C. rodentium* does not express a flagellum and is thus nonmotile, so how it is able to traverse the thick, two-layer colonic mucus barrier is unknown. However, during the process of traversing the mucus layers, the bacterium assembles its T3SS from proteins encoded in the LEE, allowing it to dock to an epithelial cell. Adhesion is stabilized by injection of the Tir protein, which inserts into the apical plasma membrane of the IEC where it can bind intimin on the bacterial surface. This adhesion is strengthened by creation of a pedestal formed from disruption and effacement of host-cell microvilli by other bacterial effectors injected into the IEC, enabling a broad area of contact between pedestal and bacterium—hence the term 'attaching and effacing' bacterial pathogen. Detection of bacterial effectors injected into the cytosol of the IECs is thought to initiate the IEC's programmed death, resulting in the phagocytosis of dying bacteria-laden cells by subepithelial $CX3CR1^+$ macrophages and cDC2 cells. TEDs projected across the infected epithelium by these phagocytes may also contribute by direct uptake of the pathogen. The local production of IL-1β and IL-23 by activated mononuclear phagocytes activates ILC3s within the mucosa, which, in turn, release type 3 cytokines, including IL-17 and IL-22, as described in Chapter 11 (see Section 11-3). The induction of IL-22 by ILC3 cells is particularly important to the innate immune response to *C. rodentium*, as mice deficient for either IL-22 or IL-23 rapidly succumb to infection prior to induction of an adaptive immune response. However, the adaptive response is also indispensable for host protection, as mice deficient for CD4 T cells or B cells succumb to infection, albeit later, after the earlier innate phase of the response.

The adaptive immune response against *C. rodentium* is dependent on the development of pathogen-specific T_H17 cells that produce IL-22, which are recruited to the lamina propria of the infected segment of the large intestine and are required to fully amplify the protection of the epithelium initiated by ILC3 cells. Indeed, as the host response progresses, CD4 T cells become the major source of IL-22. The adaptive response also contributes *Citrobacter*-specific IgG antibodies, which are transported across the epithelium to bind the bacterium in the intestinal lumen. This IgG, which is dependent on FcRn



Colonization
Bacteria penetrate the mucus layer and attach to the epithelium via intimin expressed on bacterium that binds to translocated intimin receptor (Tir) expressed on IEC
Innate response
Macrophages phagocytose damaged IECs and release IL-23 and IL-1β, which activate IL-22 secretion from ILC3 cells. IL-22 acts on IECs to induce AMP release
Adaptive response
T_H17 cells, IgG+ plasma cells, and neutrophils are recruited to inflamed mucosa, resulting in increased IL-22, AMPs, and transport of IgG across epithelium
Clearance
Opsonization of bacteria by IgG activates complement and recruits neutrophils into intestinal lumen to clear bacteria

Fig. 12.40 Innate and adaptive phases of the host response to attaching and effacing enteropathogenic bacteria. Certain Gram-negative human enteric pathogens, such as pathogenic strains of *E. coli*, are typically noninvasive, but they cause intestinal inflammation by their colonization of the intestinal epithelium. This infection is modeled in mice by *Citrobacter rodentium*, which is very similar to enteropathogenic *E. coli*. These bacteria can penetrate the inner mucus layer and attach to the superficial surface of epithelial cells in the colon, thereby inducing a type 3 immune response (first upper panel). During attachment to an IEC, the bacterium uses a type III secretion system (T3SS; see Fig. 13.39) to inject bacterial effector molecules into the epithelial cell, including the translocated intimin receptor (Tir), to which the bacterial surface protein intimin binds to establish firm attachment (insets, first two lower panels). In the process, the attached bacterium causes loss (effacement) of microvilli on the IEC, hence the term 'attaching and effacing' bacteria. Recognition of the attached bacteria by epithelial cells and epithelial-cell pyroptosis results in the release of chemokines and cytokines that recruit mononuclear phagocytes, which take up infected IECs and bacteria. The ensuing release of IL-23 and IL-1β causes the activation of ILC3 cells to release IL-22, which acts on the intestinal epithelium to induce protective responses, including the release of antimicrobial peptides (AMPs) and the recruitment of neutrophils, which restrain bacterial growth (second upper panel). Trafficking of bacterial antigen–laden dendritic cells to draining lymph nodes induces the development of T_H17 cells and bacteria-specific IgG-producing plasmablasts, which migrate to the inflamed colon via the bloodstream (second two lower panels). In the colon, they further amplify the protective response via the release of greater amounts of IL-22 (T_H17 cells) and IgG antibodies, which are transported across the epithelium by the neonatal Fc receptor (FcRn; not shown) (third upper panel). Inflammatory cytokines stimulate increased cell turnover in the crypts, resulting in increased depth of crypts (crypt hyperplasia), as well as the emptying of goblet cells and their decreased differentiation (so-called goblet cell 'hypoplasia'). Secreted IgG binds to bacteria, fixing complement and recruiting neutrophils into the intestinal lumen where they destroy the bacteria, resolving the infection (fourth panel).

for transepithelial transport from the lamina propria into the lumen, opsonizes bacteria and leads to their clearance by neutrophils recruited to the infection site by CCR2-activating chemokines and complement fragments (see Fig. 12.40). In normal mice, the infection is completely cleared within 3–4 weeks, and IgG-dependent protective immunity is generated.

ANIMATION 11.2

In contrast to noninvasive bacterial pathogens, invasive bacteria can penetrate the intestinal epithelium to cause local injury or disseminate from the intestinal mucosa to cause systemic disease. Examples include *Listeria, Shigella,* and *Salmonella* spp., among others. Although we have previously considered *Listeria monocytogenes* in the context of systemic immunity (see Chapter 11), it is normally transmitted via the intestinal tract. *L. monocytogenes* is a foodborne, aerobic, Gram-positive rod, an intracellular pathogen that has evolved mechanisms to escape killing within phagocytes (see Section 11-6). It uses the virulence factor internalin A to initially establish a foothold within IECs of the small intestine. Internalin A binds to E-cadherin, which is normally expressed beneath tight junctions and therefore inaccessible to the bacterium. However, E-cadherin becomes luminally accessible around goblet cells during their exocytosis of mucins, and *L. monocytogenes* is then able to bind and be internalized into endocytic vesicles. *L. monocytogenes* may take advantage of the goblet cell–associated passage (GAP) pathway to be transcytosed to the basolateral surface of the epithelium, from which it can spread to other epithelial cells and to macrophages. Another *L. monocytogenes* virulence factor, **listeriolysin O (LLO)**, is a pore-forming toxin that allows *L. monocytogenes* to escape phagolysosomes within macrophages to enter the cytosol, where it avoids intracellular killing and replicates. Once in macrophages, *L. monocytogenes* can be transported out of the gut to systemic tissues, where it can spread cell-to-cell without exposure to the extracellular environment (see Section 13-22), rendering antibody responses ineffectual. Cell-to-cell transmission is achieved by *L. monocytogenes*–induced polymerization of actin filaments within the host-cell cytoplasm that propel the bacterium to the cell membrane, where it forms protrusions into neighboring cells that can be internalized, and from which the bacterium can again escape, initiating another cycle of cell-to-cell dissemination. The host response to *L. monocytogenes*, an obligate intracellular pathogen, bridges type 1 and cytotoxic immunity (see Section 11-6).

Shigella dysenteriae is a nonmotile, Gram-negative rod that causes shigellosis, or bacillary dysentery, which is transmitted via the fecal–oral route. Shigellosis is a major enteric infection in developing countries, where it causes as many as 150 million cases and 100,000 deaths each year. Like *Listeria, Shigella* spp. are intracellular pathogens that have evolved mechanisms for escape from phagolysosomes and use a similar actin-mediated propulsion to spread cell-to-cell and evade host immunity. However, *Shigella* uses the M cell for transport across the intestinal epithelium of the ileum and colon (Fig. 12.41), where it is delivered to subepithelial dome macrophages, which it is able to infect and

Fig. 12.41 *Shigella flexneri* infects intestinal epithelial cells to cause bacillary dysentery. *Shigella flexneri* binds to M cells and is translocated beneath the gut epithelium (first panel). The bacteria infect intestinal epithelial cells from their basal surface and are released into the cytoplasm (second panel). Muramyl tripeptides containing diaminopimelic acid in the cell walls of shigellae bind to and oligomerize the protein NOD1. Oligomerized NOD1 binds the serine/threonine kinase RIPK2 and activates the NFκB pathway (see Fig. 3.19), leading to the transcription of genes for chemokines and cytokines (third panel). Activated epithelial cells release the chemokine CXCL8, which acts as a neutrophil chemoattractant (fourth panel). IκB, inhibitor of κB; IKK, IκB kinase.

kill. The release of the bacterium from macrophages allows it to spread locally to intestinal epithelial cells via their basolateral surfaces. By activating intracellular sensors of IECs such as NOD1 as it migrates from cell to cell, *Shigella* stimulates a robust innate immune response that, along with direct bacterial damage, causes extensive damage to the epithelium. *Shigella* also releases Shiga toxin, an exotoxin that injures local endothelial cells, resulting in bloody diarrhea; it can also affect the microvasculature in other organs, such as the kidney, to produce hemolytic uremic syndrome (HUS), so named for its intravascular destruction of red blood cells (hemolysis) and damage to kidney function (uremia). Although the more virulent *Shigella* spp. such as *Shigella dysenteriae* can cause considerable local injury of the intestinal mucosa, they do not typically disseminate beyond the intestines. As for *L. monocytogenes*, eradication of *Shigella* is dependent on type 1 and cytotoxic immunity; antibody responses are poorly induced and nonprotective.

Like *Shigella*, *Salmonella enterica* serovar Typhi, the causative agent of typhoid fever in humans, targets the M cells of Peyer's patches to traverse the intestinal epithelium, although it is also able to directly invade other enterocytes and can be taken up by TEDs of subepithelial mononuclear phagocytes (**Fig. 12.42**). *Salmonella enterica* serovar Typhi is a food-borne, Gram-negative, rod-shaped facultative anaerobe that infects only humans. It is equipped with multiple flagella and is highly motile. *Salmonella* uses both type III and type VI secretion systems to cause disease. Expression of the T6SS is induced first to destroy

Fig. 12.42 *Salmonella enterica* serovar Typhimurium is an important cause of food poisoning and penetrates the epithelial layer in three ways. *Salmonella enterica* serovar Typhimurium adheres to and enters M cells, which it then kills by causing apoptosis (top left panel). It then can infect macrophages and gut epithelial cells. TLR-5 expressed by the epithelial basal membrane can bind *Salmonella* flagellin, activating the NFκB pathway. After uptake by macrophages in the lamina propria, invasive *Salmonella* induces caspase 1 activation, promoting production of IL-1β and IL-18. CXCL8 is also produced by the infected macrophages, and together these mediators recruit and activate neutrophils (lower left panel). Salmonellae can also invade gut epithelial cells directly by adhering to the luminal epithelial surface via fine threadlike protrusions called fimbriae (top middle panel). The cell processes extended between epithelial cells by mononuclear phagocytes may be infected by salmonellae in the lumen and thus effectively breach the epithelial layer (top right panel). Dendritic cells in the lamina propria may take up antigen from infected macrophages and carry those antigens to the draining mesenteric lymph node to prime the adaptive immune response (lower right panel). If containment processes in the lymph node fail, salmonellae can invade beyond the intestine and its lymphoid tissues and enter the bloodstream to cause systemic infection.

commensal bacteria to clear a niche for infection. This is down-regulated as the T3SS is expressed. As for EPEC, the T3SS is important in the attachment of the bacterium to host cells, although *Salmonella* can also enter IECs after attachment. As we learned in Chapter 11 (see Section 11-14), *Salmonella* are facultative intracellular pathogens that can shift from an extracellular lifestyle to an intracellular lifestyle as they try to evade first a type 3 and then a type 1 host immune response, respectively. By adapting to survival within migratory dendritic cells, *Salmonella* can be transported with their phagocyte host to regional lymph nodes and, if not contained there, can disseminate widely.

12-21 Dysregulated immune responses to commensal bacteria provoke intestinal disease.

Because of their antigenic memory and longevity, effector CD4 T cells are a liability when inappropriately directed against self antigens or, in the case of the microbiota, the 'extended' self that includes antigens of the commensal microbiota. Indeed, in view of the enormous number of antigens encoded in the collective genome (microbiome) of the intestinal microbiota, it is remarkable that dysregulated effector responses against the microbiota are the exception. When they do occur, the result is inflammatory bowel disease (IBD), including Crohn's disease (CD) and **ulcerative colitis (UC)**. Although these two types of IBD have distinct clinical and histopathologic features, both are characterized by aberrant immune responses to antigens of the intestinal microbiota. In all experimental models of IBD, the intestinal damage depends on the presence of commensal bacteria; it can be prevented by administration of broad-spectrum antibiotics and does not occur in germ-free animals. As in autoimmunity directed against host self antigens (see Chapter 15), dysregulated CD4 T-cell responses to antigens of the microbiota lead to chronic, typically relapsing and remitting disease that reflects the immune system's inability to eliminate the antigens that drive the abnormal response.

Many genes that are associated with susceptibility to Crohn's disease in humans encode proteins that regulate innate immunity. When these regulatory processes fail, systemic immune responses are generated against antigens from commensal bacterial, such as **flagellin**, the monomer that polymerizes to form bacterial flagella. Studies of both mouse models and humans with CD reveal a remarkably similar reactivity to specific flagellin epitopes expressed by *Clostridium* spp. that appear to be immunodominant despite their minor representation within the commensal flora. Why these commensals are common targets in a large subset of individuals with CD—but not UC—is unknown, but it likely reflects unique properties that place them in specific geographic niches in the microbiota and/or in intimate contact with the immune system, where their expression of flagella, which is atypical for commensal bacteria, makes them unusually proficient at inducing effector responses rather than regulatory responses.

In view of their prominent role in adaptive immune responses to the intestinal microbiota and propensity for generating inflammation promoted by both IL-17 and IFN-γ, it is not surprising that T_H17 cells have emerged as leading contributors to IBD pathogenesis. Prior to the discovery of T_H17, CD and UC were viewed in the context of T_H1- and T_H2-centric mechanisms, respectively, but increasingly, data from genome-wide association studies (GWASs) implicate the contributions of the T_H17 pathway in both disorders. Indeed, it is fitting that IL-23, discovery of which revolutionized views on the immunopathogenesis of autoimmunity and led to discovery of T_H17 cells, was the first cytokine linked to IBD by GWASs, as variants of its receptor (IL-23R) have been found to confer both protection and susceptibility to CD and UC. As the number of GWASs and next-generation sequencing studies has proliferated, so too has the number of genes linked to the T_H17 pathway in IBD (see Section

15-14). This has been supplemented by genes of innate and adaptive immune pathways that are integrated with, and control, T_H17 responses, spanning the gamut from epithelial barrier integrity maintenance and restitution to microbial sensing to immunomodulatory cytokines.

Summary.

Despite robust mechanisms that favor immune tolerance at homeostasis, as a major portal for the entry of pathogens the intestinal mucosa must be able to respond rapidly to all classes of pathogens. Thus, cytotoxic, type 1, type 2, or type 3 responses are each efficiently induced in response to enteric pathogens. How this is achieved in the face of a dominant tolerogenic tone is not completely understood, but a major contributor is the generation of pro-inflammatory signals generated by the intestinal epithelium upon sensing pathogen invasion. Polarization of the epithelium into apical (lumen-facing) and basolateral (internal tissue–facing) surfaces by the tight-junctional apparatus allows distribution of pattern-recognition receptors into endosomal/cytosolic and basolateral compartments where they sense microbes that have violated epithelial integrity but remain relatively insensate with respect to microbes in the mucus layer or lumen.

For invasive pathogens that directly violate the integrity of the intestinal epithelium, they must first transit or avoid the mucus barrier. A number of pathogens have evolved mechanisms that direct them to target mucosal sites that are relatively mucus-free, such as the small-intestinal villi or the follicle-associated epithelium and M cells of Peyer's patches and ILFs. Others have evolved mechanisms, which are not fully understood, by which they can penetrate the mucus layers to gain access to epithelial cells. Whatever the mechanism, the result is the production by the activated epithelium of pro-inflammatory signals that override the tolerogenic tone of the homeostatic mucosa to activate local ILCs and recruit circulating monocytes and granulocytes that further amplify inflammatory signals and promote adaptive immune effector responses.

Immunity at other barrier tissues.

Like the intestines, other barrier tissues present a considerable surface area for interaction with the external environment. Indeed, infections of the respiratory tract and skin are among the most common, and respiratory infections cause more deaths than do any other type of infection (see Fig. 12.4). While the innate and adaptive immune cells that participate in barrier immunity in these tissues are similar, there are anatomic differences in the organs and the epithelia that invest them that deserve special consideration. Moreover, the unique physiological functions of these tissues present special challenges for the immune system. Here, we briefly examine features of the respiratory tract and skin that bear on these challenges.

12-22 Anatomy and mucosal immunity of the airways.

Although there are many similarities in mucosal immunity of the gastrointestinal and respiratory tracts, there are also important differences that reflect their unique anatomy and physiological functions. The primary function of the respiratory tract is gas exchange—the intake of oxygen and release of CO_2. Because life is not supported by even a brief interruption in this function, the lungs, where gas exchange occurs, are continually exposed to 5–10 liters of air per minute at rest. The respiratory tract is divided into upper and

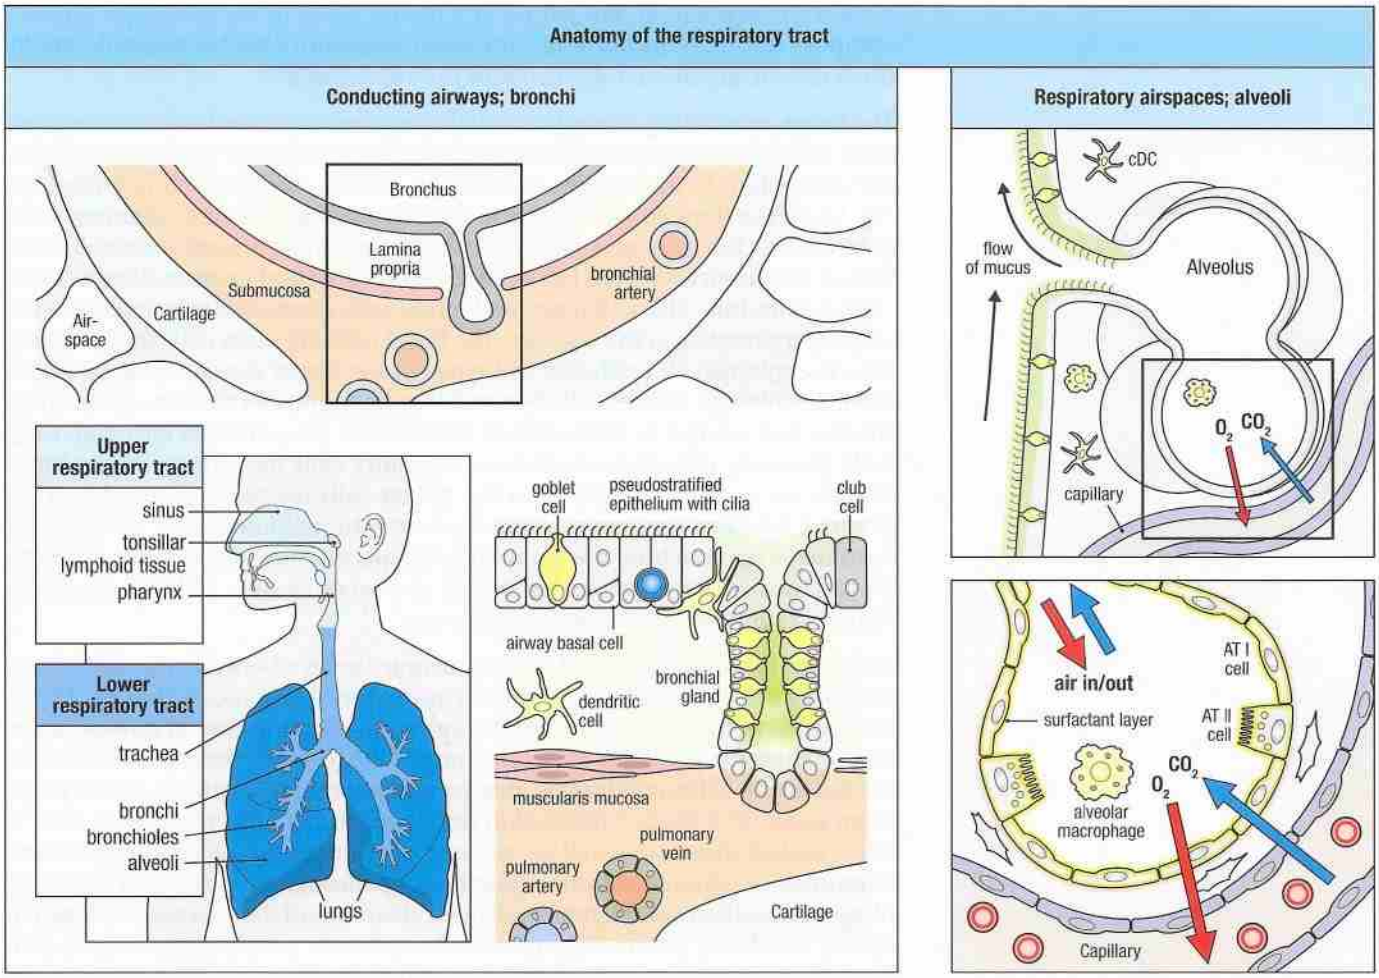

Fig. 12.43 Anatomy of the respiratory tract. The respiratory tract includes the nasal passages and sinuses, the pharynx, and the trachea, which branches into bronchi that divide further into smaller and smaller bronchioles (inset, left panel). These end in small clusters of air sacs, called alveoli, where gas exchange occurs. The large and small conducting airways in the chest cavity (trachea, bronchi, and bronchioles) are lined by a pseudostratified epithelium, which rests on a basement membrane underlaid by the lamina propria (left panel). The respiratory epithelium in the conducting airways includes goblet cells, club cells, and the more numerous respiratory epithelial cells, which have cilia on their apical surface that beat rhythmically to propel the mucus layer toward the pharynx where it can be expectorated or swallowed. The mucus is produced by goblet cells in the epithelium and in bronchial glands within the mucosa, which also produce antimicrobial peptides, similarly to crypts of the intestinal tract. Immune cells are present within the epithelium and lamina propria of the conducting airways. Under normal conditions, the airways are sterile below the larynx, and no organized lymphoid tissues are present within the mucosa. However, there are extensive lymphatics that drain to regional lymph nodes (bronchial and mediastinal lymph nodes), and the upper airways contain nasal-associated lymphoid tissue (NALT) and tonsillar tissues. The respiratory epithelium progressively thins to a single layer of columnar cells with fewer goblet cells in the smallest airways. The terminal bronchioles and alveoli lack goblet cells and are not covered by mucus. Alveoli are lined by two types of epithelium (right panel): type I alveolar cells (AT I), a very thin, squamous epithelium that covers most of the alveolar surface and is adapted for gas exchange; and type II alveolar cells (AT II), cuboidal cells that produce surfactant, which reduces the surface tension of the alveolar lining to prevent the airspaces from collapsing. A specialized macrophage, the alveolar macrophage, resides in the alveolus and is responsible for clearing any inhaled particles or pathogens.

lower segments, separated by the vocal cords of the larynx (Fig. 12.43). Like the intestines, the upper respiratory tract—including the nose and nasal sinuses, pharynx, and larynx above the vocal cords—is populated by a commensal microbiota that develops after birth. Unlike the intestines, which harbor a preponderance of anaerobes, particularly in the large intestine, a greater contribution by facultative anaerobes is found in the upper respiratory tract. The lower respiratory tract includes the conducting airways—the larynx below the vocal cords, trachea, and branching bronchi and bronchioles—through which air is conducted in inspiration and expiration, as well as the respiratory airspaces, including alveoli, in which gas exchange between the inspired air and blood

occurs. Collectively, all the pulmonary tissues distal to the two major bronchi compose the lungs. Importantly, the lower respiratory tract is normally sterile; there is no resident microbiota below the vocal cords.

The larger conducting airways are lined by a pseudostratified columnar epithelium, which becomes progressively thinner and transitions to a simple columnar epithelium in the smaller conducting airways (terminal bronchioles; see Fig. 12.2). The dominant cell types in these airways are ciliated columnar cells, goblet cells, club cells, and airway basal cells. In addition, there are small numbers of respiratory tuft cells (also called brush cells) and neuroendocrine cells. Goblet cells, tuft cells, and neuroendocrine cells serve similar functions in the respiratory tract as in the GI tract. The basal cells are stem cells that differentiate to replenish all epithelial cell types in the larger airways (that is, above the bronchioles). Goblet cells become less numerous as the airways become smaller and are lost in the terminal bronchioles (the smallest airways). **Club cells** (formerly called Clara cells) are secretory cells that appear in the bronchioles, increasing in number as the goblet cells decrease in number. They produce a serous product that lubricates the bronchiole as the mucus layer terminates approaching the respiratory airspaces. They also produce antimicrobial factors (for example, lysozyme) and serve as stem cells for repopulation of the epithelium of the distal airways.

As in the intestines, the wall of conducting airways beneath the epithelium includes the lamina propria, muscularis mucosa, and submucosa (see Fig. 12.43). In contrast to the GI tract, where the outer wall is composed of muscle layers that produce the peristaltic waves that propel the luminal contents downstream, the outer wall of the conducting airways is supported by cartilage, which keeps them open. In a further distinction from the GI tract, the respiratory tract is blind-ended; that is, inspired air and any particulates or microbes that it contains must be eliminated by transport back up through the airways or locally by phagocytic cells. A central mechanism for clearance of the airways is the **mucociliary escalator**, a term that refers to the constant propulsion of mucus produced by goblet cells (and, in the larger conducting airways, bronchial glands) up and out of the respiratory tract by the constant unidirectional beating of cilia of the ciliated columnar cells. This constant clearance mechanism is enhanced by coughing and sneezing, which can propel air, particulates, and inhaled microbes from the airways at speeds up to 100 miles per hour.

The alveoli are lined by two epithelial cell types: type I and type II alveolar cells (AT I and AT II cells) (see Fig. 12.43). Most of the surface area of the alveoli is lined by the AT I cells, which are simple squamous cells that facilitate gas exchange with surrounding alveolar capillaries. AT II cells are more cuboidal and produce a surfactant composed of a variety of phospholipids and glycoproteins that reduces the surface tension of the alveolus to facilitate reinflation after exhalation. Although more numerous than AT I cells, AT II cells cover far less surface area due to their smaller footprint on the alveolar basement membrane. Within alveoli are **alveolar macrophages**, which reside in the alveolar lumen, where they act to scavenge small particulates that are deposited there, including microbes. Like macrophages at other mucosal sites, alveolar macrophages are anti-inflammatory at homeostasis, as gas exchange is highly sensitive to thickening of the space between the alveolar lumen and surrounding capillaries (the alveolo-capillary membrane). This is due to the production of TGF-β by alveolar epithelial cells, which is activated and 'presented' to alveolar macrophages by $\alpha_v\beta_6$ integrin expressed on the surface of AT I cells. The turnover of alveolar macrophage populations is very slow at steady state, and renewal is largely dependent on local cell division. However, as for tissue-resident macrophages in the airways and the gut, renewal of alveolar macrophages during inflammatory processes occurs via incoming monocytes.

As in the GI tract, the respiratory airways are populated by a complement of innate and adaptive immune cells that are found within the lamina propria

and the epithelium itself. These cells include conventional dendritic cells (cDCs), plasmacytoid DCs (pDCs), resident CX3CR1$^+$ macrophages, ILCs, T cells, and antibody-secreting plasma cells. Notably, the antibody isotypes that predominate in the upper and lower respiratory tract differ: in the upper respiratory tract, SIgA dominates, whereas in the lower respiratory tract, IgG is dominant, transported across the epithelium by pIgR and FcRn, respectively. This difference likely reflects the presence of a commensal microbiota in the upper respiratory tract, but not in the lower tract. As in the intestines, most intraepithelial T cells, including both conventional and nonconventional T cells, express CD8, whereas CD4 T cells dominate in the lamina propria. Also, the mucus layer contains SIgA and antimicrobial peptides that restrain invasion by microbes. Moreover, airway macrophages and dendritic cells (DCs) are located immediately beneath and within the airway epithelium and can extend cellular projections (transepithelial dendrites, or TEDs) into the airway lumen as they do within the gut.

However, unlike the intestinal mucosa, the respiratory mucosa of adults does not typically contain lymphoid tissues. While isolated lymphoid follicles can be found within the walls of the larger airways in childhood (bronchus-associated lymphoid tissue, or BALT), these are lacking in adults. Thus, the induction of adaptive immune responses in the adult respiratory tract, as in nonmucosal tissues, is initially mediated by draining lymph nodes (hilar, parabronchial, and mediastinal lymph nodes). Effector T and B cells primed in these sites return to the lung effector sites, such as lamina propria and the respiratory epithelium. As in the intestines, at homeostasis the immunologic 'tone' of these inductive sites in the upper airways favors the generation of FoxP3$^+$ T_{reg} cells and SIgA-expressing plasma cells, due to similar mechanisms (retinoic acid and TGF-β) that trigger the generation of cDC2 cells that promote these tolerogenic mechanisms. However, in response to infections, BALT can be induced rapidly in the lower airways. After BALT is established, it generates B-cell areas containing germinal centers and T-cell areas around high endothelial venules that are organized similarly to other MALT—including an overlying FAE and M cells—and supports the induction of adaptive immune responses as in other mucosal tissues.

12-23 Respiratory immunity to inhaled pathogens; respiratory viruses.

The extensive surface area (~70 m^2 in adult humans), high rate of continual air exchange with the environment (~10,000 liters per day), and absence of a competing microbiota in the lower airways make the respiratory tract a major portal for the entry of infectious agents. At all barrier sites, the types of microbial exposure shape the types of disease, and, in the respiratory tract, pathogens generally enter suspended in air as particulates. This favors infections by organisms that can be transmitted in small droplets or as free particles—particularly bacteria and viruses.

The efficiency of the airways in removing particulates is size-dependent. The larger the particle, the less likely it is to be deposited in the smaller airways and alveoli. Larger particles are blocked by hairs in the nostrils, and particles with an aerodynamic diameter greater than 10 μm (roughly the size of an activated T cell) are cleared by the upper airways, especially when inhaled through the nose. This is due to the extensive mucus-coated 'baffles' formed by the turbinate bones, which project into the nasal passages and nasal sinuses and provide a large surface mucosal surface that helps to trap particulates that flow over them. In the lower respiratory tract, particulates and microbes entrapped by mucus in the conducting airways are directed by cilia toward the back of the throat, where they can be expectorated or swallowed. Most particles that do pass to the conducting airways are efficiently removed from the air by the highly branching nature of the tracheobronchial tree; with more than 20 generations of branches, the likelihood is great that even smaller particulates (1–5 μm) will

Major respiratory viral pathogens					
Viruses	Genome	Receptors	Cellular tropism		Disease
			Primary	Secondary	
Influenza virus	(–) ssRNA	Sialylated glycan	Epithelial cells	DCs, macrophages, fibroblasts	Influenza epidemics and pandemics
Respiratory syncytial virus (RSV)	(–) ssRNA	GAG	Epithelial cells	Macrophages, T cells	Infant 'colds'
Adenovirus	dsDNA	CAR	Epithelial cells	Fibroblasts	Bronchitis, croup, viral pneumonia
Rhinovirus	(+) ssRNA	ICAM-1	Epithelial cells	Macrophages	Upper respiratory infections, sinusitis
Coronavirus	(+) ssRNA	APN, ACE2, DPP4	Epithelial cells	Type I alveolar epithelial cells	Common cold Severe acute respiratory syndrome (SARS-CoV, SARS-CoV-2, MERS)
Coxsackie virus	(+) ssRNA	CARs	Epithelial, vascular endothelial cells	–	Sore throat, upper respiratory infections
Paramyxovirus (Parainfluenza)	(–) ssRNA	Gangliosides, sialylated glycoproteins	Epithelial cells	–	Parainfluenza

Fig. 12.44 Major respiratory viral pathogens. See text for details. Abbreviations: APN, aminopeptidase N; ACE2, angiotensin-converting enzyme 2; CAR, Coxsackie–adenovirus receptor; DPP4, dipeptidyl peptidase 4; GAG, glycosaminoglycan; ICAM-1, intracellular adhesion molecule-1.

be trapped in the mucus blanket and removed. However, those microbes that express receptors that allow their attachment to the respiratory epithelial cells (RECs) can establish a foothold if they penetrate the mucus layer—especially those that are delivered deeper into the airways and thus have a longer distance to travel to be cleared by the mucociliary escalator. Finally, particles less than ~1 μm in size (roughly the size of a bacterium) can be delivered to the terminal respiratory airways and alveoli, which are devoid of a mucus coating. In this instance, the last line of defense is alveolar macrophages, which are efficient at disposing of inhaled bacteria, but less able to eliminate viruses.

Common respiratory pathogens include a variety of viruses (Fig. 12.44). While some of these cause relatively mild, self-limiting upper respiratory infections (for example, rhinovirus), others frequently cause more serious lower respiratory infections (for example, respiratory syncytial virus, parainfluenza). Here we consider influenza and coronavirus, two classes of viral pathogens that cause disease that can be mild or life-threatening, depending on the particular strain. Both are RNA viruses, meaning that the viral genome is encoded by RNA, not DNA, and therefore must be replicated by RNA polymerases, which have a greater error rate than DNA polymerase (see Section 13-25). As a consequence, the mutation rate for these viruses is greater than for DNA viruses. The alteration of viral proteins—and thus of viral antigens that are the targets of immune recognition—resulting from these proofreading mutations is referred to as **antigenic drift** (Fig. 12.45). Moreover, because the influenza RNA genome is segmented, and the virus's two major surface proteins—**hemagglutinin** and **neuraminidase**—are encoded on different segments, new viral strains can be generated by reassortment of the linear genetic elements encoding these two proteins when more than one strain of influenza infects the same cell. Consequently, prior B- and T-cell immunity generated from exposure to one strain of the virus may not be protective against the newly generated strain. The rapid changes in viral antigens caused by these reassortments of viral gene segments is referred to as **antigenic shift**. Similar assortment of viral nucleoproteins may also affect shifts in host recognition by T cells. Accordingly, influenza is prone to develop pandemics because prior herd immunity may not be protective against these new strains.

Antigenic shift
Antigenic shift occurs when RNA segments are exchanged between viral strains in a secondary host
No cross-protective immunity to virus expressing a novel hemagglutinin

Fig. 12.45 Two types of variation allow repeated infection with type A influenza virus. Neutralizing antibody that mediates protective immunity is directed at the viral surface protein hemagglutinin (H), which is responsible for viral binding to and entry into cells. Antigenic drift (left panels) involves the emergence of point mutants with altered binding sites for protective antibodies on the hemagglutinin. The new virus can grow in a host that is immune to the previous strain of virus, but as T cells and some antibodies can still recognize epitopes that have not been altered, the new variants cause only mild disease in previously infected individuals. Antigenic shift (right panels) is a rare event involving the reassortment of the segmented RNA viral genomes of two different influenza viruses, probably in a bird or a pig. These antigen-shifted viruses have large changes in their hemagglutinin, and therefore T cells and antibodies produced in earlier infections are not protective. These shifted strains cause severe infection that spreads widely, causing the influenza pandemics that occur every 10–50 years. There are eight RNA molecules in each viral genome, but for simplicity only three are shown.

Individual strains of influenza are identified by type and the combination of hemagglutinin (H) and neuraminidase (N) variants. There are three major types of influenza that infect humans (A, B, C), two of which, types A and B, are responsible for most seasonal human disease. In general, type B strains cause less virulent infections; type A strains are the only viruses known to cause flu pandemics. At least 18 type A hemagglutinin and 11 neuraminidase subtypes have been identified to date, resulting in more than a hundred influenza A subtypes, which are identified by their combination of H and N usage [for example, influenza A (H3N2)]. Seasonal influenza viruses cause 3–5 million serious infections and up to a half million or more deaths worldwide each year. The outbreaks typically occur in the winter, when people are clustered indoors, facilitating spread from person to person. Influenza viruses also infect other species (for example, birds, pigs), which can be a source of further antigenic shifts due to **zoonotic** infections; that is, the transmission of a related infectious agent from other animals to humans. When this occurs, the existing immunity within humans can be ineffective, resulting in particularly lethal pandemics. A prime example is the swine flu pandemic of 1918, which was caused by an influenza A (H1NI) strain and caused an estimated 40 million deaths worldwide.

The attachment of influenza virus to the respiratory epithelium is mediated by the viral hemagglutinin surface molecule, which recognizes sialic acid residues on host-cell surface glycoproteins. Because of the broad expression of sialic acid on the cells of many tissues, the **cellular tropism**, or ability of the virus to infect specific host-cell types, is broad. Therefore, the route of delivery of influenza, typically in microdroplets inhaled via the airways, determines its localization to the respiratory tract more than its targeting to a particular cell type in the respiratory tract. And because the virus can infect cells outside

the respiratory system, it can undergo systemic spread, accounting for the extrapulmonary symptoms that frequently accompany disease. The binding of hemagglutinin to host cells stimulates virion uptake into endocytic vesicles, in which the virus fuses with the endosomal membrane to gain entry to the host-cell cytoplasm, where viral replication is initiated. Viral neuraminidase does not contribute to the entry, replication, or budding of the virus, but appears to be important in the release of new virions from the infected cell surface and removal of sialic acid residues on viral surface proteins to prevent aggregation of virions. As for other viruses that invade via the respiratory tract, RECs are a primary target of both infection and propagation of influenza virus.

The detection of, and initial innate immune response against, influenza virus occurs in RECs, but also involves airway macrophages and DCs, including pDCs. Collectively, these innate immune sensor cells express a complete complement of pattern-recognition receptors (PRRs), including TLR-3, TLR-7, TLR-8, RIG-I, and NLRP3, each of which has been shown to contribute to the innate response to influenza. TLR-3 (dsRNA), TLR-7 (ssRNA), and, in humans, TLR-8 (ssRNA) detect viral RNA within endosomes, whereas RIG-I and NLRP3 detect virus within the cytosol of infected cells. This triggers the release of pro-inflammatory cytokines and type I and type III interferons (Fig. 12.46; and see Fig. 13.25). Engagement of receptors for these cytokines on epithelial cells

Fig. 12.46 The immune response to respiratory viruses. Virus infection of respiratory epithelial cells (RECs) is first detected by cytosolic and/or endosomal pattern-recognition receptors (PRRs) in the infected epithelial cells (not shown). Recognition of the invading virus by the PRRs leads sensor cells to produce type I interferons (IFN-αβ) and type III interferon (IFN-λ), as well as pro-inflammatory cytokines, such as IL-18, and chemokines, such as CC-chemokine ligand 2 (CCL2; not shown) (left panel). Viral recognition by plasmacytoid dendritic cells in the mucosa also stimulates the release of type I interferons, which acts on epithelial cells and local mononuclear phagocytes to amplify their production of inflammatory mediators, including TNF-α. These soluble mediators promote the recruitment of monocytes and activate type 1 and type 2 conventional dendritic cells, which ingest viral particles and deliver antigen to draining lymph nodes where they release IL-12 and induce T_H1 and CTL responses, as well as B-cell responses to induce the development of IgG-producing antibodies (middle panel). Migration of CTLs, T_H1 cells, and plasmablasts from draining lymph nodes to the infected respiratory mucosa results in lysis of virally infected cells and the prevention of cell-to-cell spread of virus through antibody-mediated blockade of viral attachment (right panel).

and other cell types present in the lungs (for example, pDCs, γδ T cells, and NK cells) induces intracellular resistance mechanisms to viral replication and also amplifies the initial innate response and contributes to the release of chemokines that promote the recruitment of circulating inflammatory cells, such as pro-inflammatory monocytes and neutrophils. These signals also activate resident cells in the airways that can kill infected epithelial cells, such as NK cells and intraepithelial lymphocytes, as well as initiate the adaptive immune response. The uptake of dying RECs by cDC1 cells is important for the induction of an influenza-specific cytotoxic T lymphocyte (CTL) response, which is coordinated with a T helper type 1 response induced either by the same cDC1 cells or by cDC2 cells on which type I interferons have acted. This results in the recruitment of CTLs and T_H1 cells to the respiratory mucosa where they act to eliminate infected cells and amplify the IFN response by releasing type II interferon (IFN-γ), which also enhances local antigen presentation of viral antigens. There is also production of IgG-producing plasmablasts that traffic to the respiratory mucosa where they mature and produce antibodies that target the elimination of free virus by phagocytes.

Antibody responses to the influenza virus surface glycoproteins, particularly those directed against hemagglutinin, also block viral attachment and are therefore neutralizing, conferring protection against cell-to-cell transmission of the influenza virus during active infection, as well as preventing viral reinfection after recovery from initial infection. Antigenic sites on the head domain of hemagglutinin that contribute to binding of the virus to the sialic acid residues on host cells are the dominant target of the neutralizing antibody response and are immunodominant compared to other viral B-cell epitopes; they block the interactions of hemagglutinin with host-cell sialic acid residues, thereby preventing viral attachment and entry into RECs. The importance of antibodies in protection against influenza infection was discovered in the 1930s, when it was found that the transfer of serum from infected individuals was protective. The relatively rapid mutation of the gene encoding hemagglutinin results in antigenic drift, which is a principal reason that influenza virus vaccines have to be updated yearly. This is also true for new pandemic viruses that result from antigenic shift, for which antigenically matched vaccines have to be produced. This is despite the fact that antibody responses against influenza virus are typically robust and long lasting.

In view of the importance of the antibody response to protection against influenza, it is evident that B-cell help mediated by T_{FH} cells is central to a protective host response. Cytotoxic T cells (CTLs) are also required for optimal clearance of influenza virus. The CTL response targets antigenic components of the influenza viral core, or nucleocapsid, that include nucleoprotein (NP), membrane protein M1, and the viral polymerases, which, because of their conserved function to viral replication are less tolerant of antigenic drift. Thus, in contrast to the antibody response, the CTL response is more conserved across different influenza virus strains and subtypes. This may mitigate against the severity of disease caused by new viral strains in individuals who have been infected by influenza previously. Because current vaccines use killed virus, which provokes good antibody responses but not CTL responses, there is interest in developing better vaccines that also provide cross-protective immunity by eliciting robust CTL memory responses.

Another RNA virus family that can elicit mild or severe respiratory disease is the Coronaviridae, or coronaviruses, literally, 'crown' viruses, so named because of the appearance of their surface glycoproteins when viewed by electron microscopy (Fig. 12.47). Coronaviruses have the largest genomes of known RNA viruses (~25 to 32 kb; roughly twice the size of the influenza virus genome) and cause disease ranging from the common cold to life-threatening **severe acute respiratory syndrome,** or **SARS**. There are two major subfamilies of coronavirus, Torovirinae and Coronavirinae, the latter of which includes the *Alphacoronavirus* and *Betacoronavirus* genera that typically infect only

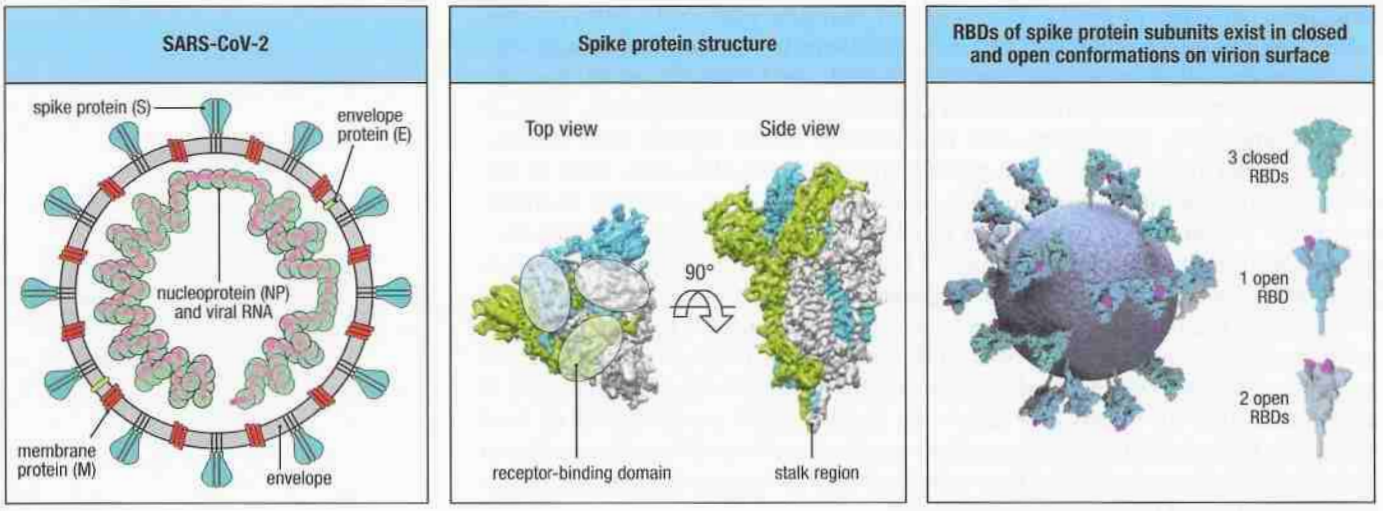

Fig. 12.47 Structure of the SARS-CoV-2 virion, the cause of the COVID-19 SARS pandemic. SARS-CoV-2, the causative agent of the COVID-19 SARS pandemic, is an enveloped plus-stranded RNA virus with a large nucleoprotein (NP)-encapsidated genome (left panel). The virion is roughly spherical and measures about 100 nm in diameter. The viral lipid membrane includes three transmembrane proteins: the spike protein (S), which is a trimer of identical subunits, and two smaller proteins, a membrane protein (M) and an envelope protein (E). The structure of the spike protein solved by cryo-electron microscopy (cryo-EM) is shown in the middle panel. In its closed conformation (shown), the receptor-binding domains (RBDs) of each subunit are folded down on the apical surface of the S-protein trimer, preventing binding to the cellular receptor targeted by the virus—angiotensin-converting enzyme 2 (ACE2). ACE2 is an ectoenzyme that is expressed by cells lining the airways of the lungs, as well as by other cells in the body, such as certain endothelial cells that line blood vessels. Although not highlighted here, each S-protein subunit is composed of two fragments—an S1 fragment that contains the RBD and an S2 fragment that contains the fusion domain—that are generated by proteolytic cleavage during virion assembly. The RBDs and the stalk region, at the S-protein base, are identified. The RBDs of each subunit of the S protein can open spontaneously to permit binding to ACE2, as modeled in the right panel. At any point in time, most S proteins expose none of the RBDs in open conformation (3 closed RBDs), with fewer numbers of S proteins exposing one (1 open RBD) or two (2 open RBDs) binding domains (highlighted in purple). Note that the stalk region at the base of the S protein is highly flexible, allowing the head of the protein to tilt freely on the virion surface. Binding of the S protein to ACE2 on a target cell results in cleavage of the S2 fragment by a host-cell surface serine protease (for example, transmembrane serine protease 2, or TMPRSS2), which is thought to trigger to dissociation of the S1 fragment and refolding of the S2 fragment into a conformation that mediates fusion of the viral membrane with the host-cell membrane, resulting in virion uptake by the host cell.

mammals and are causes of human disease. Strains of both alphacoronaviruses and betacoronaviruses can cause the common cold. Less common strains of betacoronaviruses cause SARS, of which there have been three major outbreaks to date: SARS coronavirus (SARS-CoV; 2002–2004); Middle East respiratory syndrome coronavirus (MERS-CoV; 2012–2015); and most recently, SARS-CoV-2 (late 2019–present). The viral syndrome caused by SARS-CoV-2 has been referred to as **coronavirus disease-2019,** or **COVID-19**, reflecting its date of emergence.

Just as for influenza, the factors that determine the virulence of different strains of coronavirus are not well understood, although the emergence of zoonotic infections against which there is little preexisting immunity appears contributory. Although not proven, bats appear to be the likely source of each of the coronavirus strains that have caused the outbreaks responsible for SARS-CoV, MERS-CoV, and SARS-CoV-2. Whereas MERS-CoV originated in the Middle East and has remained largely endemic to the Arabian Peninsula where endemic infection of camels serves as a reservoir for transmission to humans, both SARS-CoV and SARS-CoV-2 originated in China and may have been amplified in, and been transmitted to, humans by intermediate hosts yet to be identified.

Although the scope of the initial SARS-CoV outbreak (~8000 cases and ~800 deaths worldwide) has now been dramatically eclipsed by SARS-CoV-2 (at least 175 million cases and over 3 million deaths worldwide to date), both of these pathogens, and all other strains of coronavirus, are primarily transmitted

via respiratory spread. While MERS-CoV has diverged and uses the host ectoenzyme dipeptidyl peptidase 4 (DPP4) for virion attachment, SARS-CoV and SARS-CoV-2 use **angiotensin-converting enzyme 2 (ACE2)**, an ectoenzyme that is preferentially expressed on the apical surface of airway epithelial cells. Attachment of these viruses to DPP4 or ACE2 is mediated by the **coronavirus spike protein (S)**, a homotrimeric envelope protein that is the dominant protein expressed on the virus surface—the one responsible for the 'crown' motif for which the virus is named (see Fig. 12.47). The S protein has two fragments that are separated by a protease cleavage site: the S1 region contains the receptor-binding domain (RBD), and the S2 region mediates membrane fusion.

Binding of the S protein to the host cell stimulates its uptake into endosomes, wherein its cleavage by host proteases exposes the S2 fragment that causes viral membrane fusion with the endosomal membrane, triggering release of the viral genome into the host-cell cytosol. At least for SARS-CoV-2, the spike protein can bind ACE2 of multiple mammalian species, including bats, cats, civet cats, swine, ferrets, nonhuman primates, and possibly dogs, in addition to humans. Pangolins, which are scale-covered, ant-eating mammals that are a protected species that is traded illegally in Asia and elsewhere, have been implicated as an intermediate host in some studies. The distribution of the ACE2 viral receptor to epithelial cells of alveoli (in addition to those of the airways), like that of sialic acid residues targeted by influenza virus, may contribute to the severe respiratory syndromes that strains of each of these types of virus can cause by direct injury to the alveoli. In a further parallel with influenza virus, ACE2 is expressed by other epithelial cells of the body, including the epithelium of the intestines, which can be the primary site of infection if the virus is ingested rather than inhaled in respiratory droplets or a secondary site of involvement after spread from the lungs. ACE2 is also expressed by endothelial cells and may mediate infection of blood vessels.

In contrast to influenza, the coronavirus genome is not segmented, but rather is a single continuous positive-sense RNA strand (see Fig. 12.44), such that the virus may undergo antigenic drift but not antigenic shift. There is insufficient information at present as to the rate of antigenic drift in SARS-CoV-2. However, early evidence indicates that the virus has mutated several times during the current pandemic, producing several substrains that are more infectious than the parent strain. Indeed, it has been found that much of the antigenic drift observed in coronaviruses is focused on the RBD of the S1 fragment of the spike protein, which mediates attachment to the ACE2 host-cell receptor. Because the RBD of each monomer of the spike protein is an extended loop that projects from its surface and is not critical for its structural integrity, mutations in RBDs can occur rapidly without threat to virion integrity and function. In the case of SARS-CoV-2, the affinity of the RBD for ACE2 is substantially higher than that of SARS-CoV, suggesting a mechanism for its more efficient spread and rapid emergence as a pandemic. Thus, somewhat similar to influenza, the virus may be able to alter the antigenic targets of the host antibody response to evade blockade of virion uptake. In the case of SARS-CoV-2 this may be particularly selected for in bats, which represent ~20% of all mammalian species and live in dense populations that facilitate rapid selection of new strain variants that can sustain propagation within the host community.

Although there is limited information at present on details of the host immune response to SARS-CoV-2, there is reason to believe that the host response shares many features with the response to influenza, in which both neutralizing antibodies and CTLs play central roles (see Fig. 12.46). Neutralizing antibodies against SARS-CoV and MERS-CoV have been characterized from survivors of these infections, and some cross-protective antibodies against SARS-CoV-2 have been identified in individuals previously infected by SARS-CoV. Indeed, there is some indication that prior exposure to less pathogenic strains of betacoronaviruses that cause the common cold and also use ACE2

as a host receptor can afford at least partial protection against SARS-CoV-2. Although some reports have suggested that protective antibody responses to SARS-CoV-2 may, for unknown reasons, be short-lived, experience from SARS-CoV and MERS-CoV indicates that at least some neutralizing antibodies persist for many years, raising the possibility that the vaccines that have recently been implemented for SARS-CoV-2 may provide long-lived protection. Especially in view of the global health crisis caused by SARS-CoV-2, the potential for vaccines that induce neutralizing antibody responses against multiple variants of the RBD are an area of active investigation, although greater conservation of non-RBD components of the virus that are targeted by CTLs may also hold promise (see Chapter 16).

12-24 Cutaneous immunity.

Our focus so far has been on the immune responses at mucosal surfaces of the intestines and respiratory tract. Although not a mucosal tissue, the skin is nevertheless a highly important barrier. Unlike the intestinal and respiratory tracts, the skin develops from ectoderm rather than endoderm, and though smaller in total surface area than these mucosal tissues, it is the largest organ of the body by weight. Although the skin contributes to the generation of essential metabolites, including active vitamin D, and plays a major role in regulating body temperature and sensing the external environment, its main function is protective. Thus, in contrast to the GI and respiratory tracts, where physiological functions necessitate a thin epithelium that facilitates exchange with the external environment, the skin forms a tight but not impermeable seal that is ideal for providing protection against physical damage (for example, lacerations and radiative and chemical threats), microbial incursion, and water loss. However, despite structural differences between skin and other barrier tissues, many of the immune-cell populations present in skin are similar to those in other barrier tissues as are the host-protective strategies, although there are some unique features of skin immunity that we will highlight here.

The skin consists of the outer epidermis and the inner dermis (**Fig. 12.48**; and see Fig. 12.2), which are in many ways analogous in function to the epithelium and lamina propria, respectively, of mucosal tissues. However, unlike the single-cell epithelium of the intestines or the pseudostratified epithelium of the respiratory tract, the epithelium of the skin lacks goblet cells and, therefore, mucus. Similarly, the skin lacks standing inductive lymphoid tissues, such as the Peyer's patches and ILFs of the intestinal tract, and given that SIgA is a specialized adaptation of mucosal tissues, it is absent in skin. Rather, the first line of defense of the skin is the continually proliferating keratinocytes—so named because of their high content of keratin, a highly cross-linked fibrous protein that is a major structural component of epidermal cells as well as hair and nails. Keratinocytes differentiate as they mature toward the skin surface to create an outer, densely keratinized and cross-linked matrix of anucleated, dead squamous cells, which are continually sloughed and replaced. This outermost layer, or stratum, of the epidermis is the stratum corneum, which is composed of dead keratinocytes sealed by extracellular lipids, which prevents fluid loss and acts as a relatively impenetrable barrier. The stratum corneum is replaced about every 10 days. The other layers of the skin include (from outside, in) the stratum granulosum and stratum spinosum, which are populated by immune cells, and the stratum basale, which is attached to the basement membrane and acts as a reservoir for renewal of the superficial layers of keratinocytes. Another epithelial cell type is the melanocyte, which produces pigment granules that are transferred to developing keratinocytes; melanocyte pigment absorbs UV irradiation to protect skin cells from solar damage. The underlying dermal tissue consists of fibroblasts within a connective matrix that supports hair follicles, some glands, and nerve endings and has a rich supply of

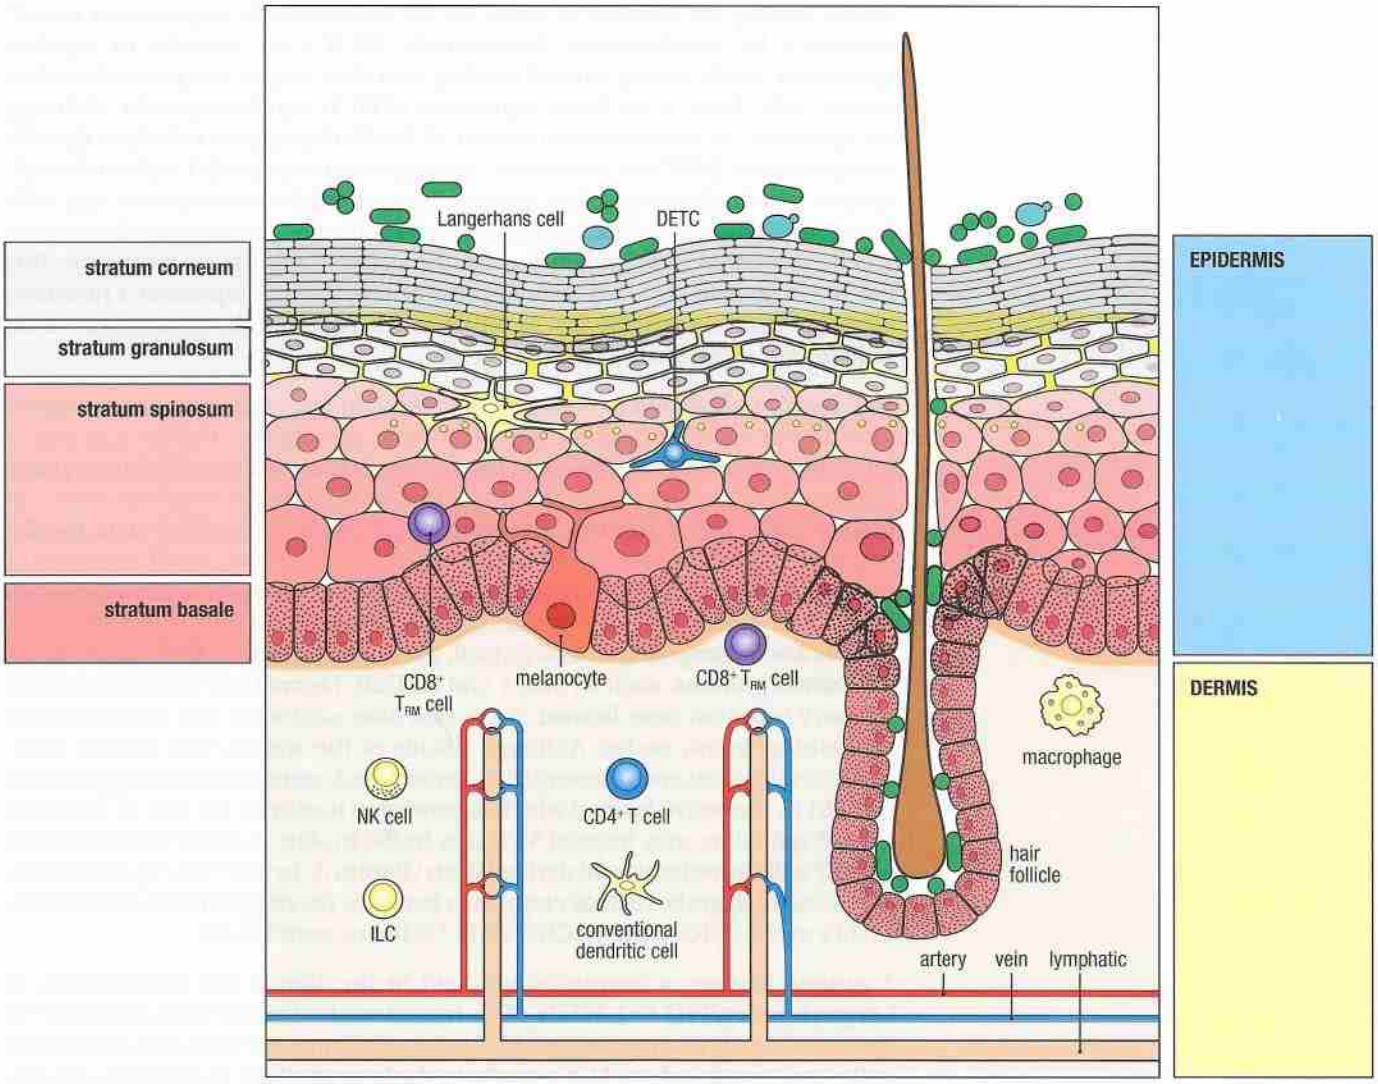

Fig. 12.48 Immune components of barrier function in skin. The skin is composed of two major compartments—the epidermis and the dermis—which are separated by a basement membrane. The outermost layer is the epidermis, which is composed of layers of increasingly differentiated keratinocytes that can be subdivided into four layers, or strata—the stratum corneum, stratum granulosum, stratum spinosum, and stratum basale. The cellular composition of the epidermis is dominated by keratinocytes, which account for ~90% of all cells in the epidermal compartment. Other epithelial cell types include the hair follicle epithelium and melanocytes, which produce pigment that is transferred to developing keratinocytes to protect from UV irradiation from the sun. Other cells that reside in the human epidermis are Langerhans cells and CD8⁺ TCRαβ tissue-resident memory T (T_{RM}) cells. The murine epidermis also contains dendritic epidermal T cells (DETCs), which are natural intraepithelial lymphocytes (nIELs) that express TCRγδ and populate the epidermis near the time of birth and are absent in human epidermis. Owing to the presence of blood and lymphatic vessels, through which circulating lymphocytes are trafficked to and from the skin, the cellular composition of the dermal compartment is more diverse than that of the epidermis. Dermis-residing immune cells include dermal dendritic cells, γδ T cells, αβ T cells, innate lymphoid cells (ILCs), mast cells, macrophages, B cells, and natural killer (NK) cells. The dermis also provides structural support for the skin and, as such, consists of fibroblasts and connective tissue.

lymphatic and blood vessels. This vascularization enables the extravasation of circulating immune cells mostly to the dermis but also to the epidermis.

Keratinocytes account for ~90% of the cells in the epidermis, although this percentage varies from site to site, depending on skin thickness. Included among the remaining cells are epidermal immune cells, primarily Langerhans cells and T cells. In mice, intraepidermal T cells are dominated by a γδ T-cell subset termed dendritic epidermal T cells (DETCs), which are unconventional T cells with a restricted antigenic specificity ($V\gamma3^+V\delta1^+$). They populate the skin from the thymus before birth (see Section 8-XX), and they remain there as long-lived resident T cells. DETC precursors up-regulate expression of CCR10

before exiting the thymus to home to the epidermis in response to CCL27 expressed by keratinocytes. Functionally, DETCs are thought to regulate epidermal repair during wound healing, and they may act as innate immune sensor cells. There is no direct equivalent of DETCs in human skin, although the epidermis of humans does contain γδ T cells that appear to be functionally comparable to DETCs in the mouse. Both species contain αβ T cells in the epidermis, which, akin to the shift from unconventional to conventional T_{RM} cells in the intestinal epithelium with age (see Section 12-5), tend to replace the γδ T cells throughout life, depending on the history of antigenic exposure. This has led to speculation that skin γδ cells present at birth represent a primitive adaptive immune system that is replaced by αβ T_{RM} cells contingent on an individual's exposure to skin pathogens.

The dermis is enriched in collagen and elastic fibers, which provide the structural framework for vascular and lymphatic vessels that deliver circulating immune cells to and from the skin. Immune cells that reside in the dermis under steady-state conditions are similar to those in the lamina propria of mucosal tissues: cDCs, tissue-resident macrophages, ILCs, γδ T cells, αβ T cells, B cells, macrophages, and natural killer (NK) cells. There are also small numbers of innate effector cells, such as mast cells. Dermal γδ T cells are considerably more diverse than their epidermal counterparts, and although their activating ligands are incompletely characterized, they appear to be mainly restricted by host stress proteins, such as MICA and NKG2B. Dermal αβ T cells are largely memory cells that have homed to the skin after activation and differentiation in draining lymph nodes. Although details of the signals that imprint skin-trafficking features are not completely understood, some evidence suggests that vitamin D, the active form of which is generated locally in the skin in response to UVB radiation, may imprint T cells to traffic to skin, as in the programming of gut T cells by retinoic acid derived from vitamin A. In any case, up-regulation of E-selectin ligands, such as cutaneous lymphocyte antigen (CLA; see Section 11-14), and CXCR3, CCR4, CCR8, and CCR10 are contributory.

A unique feature of immunity induced in the skin is the contribution of **Langerhans cells (LCs)**. While cDCs from dermis elicit the activation of CD4 and CD8 T cells in draining lymph nodes, cDCs are not typically positioned in the epidermis, where LCs constitute the largest single population of antigen-presenting cells in the entire skin. Like tissue-resident macrophages in mucosal tissues, LCs are derived from monocytic, not dendritic, cell precursors and are a long-lived, self-renewing population that populates the epidermis before birth. Langerhans cells are particularly enriched in the stratum spinosum of the epidermis. Like resident macrophages at mucosal sites, LCs constantly extend and retract dendrites between keratinocytes while maintaining barrier integrity by establishing tight junctions with adjacent keratinocytes. However, unlike mucosa-resident macrophages, LCs are migratory upon activation by inflammatory signals received from keratinocytes (for example, IL-1β and TNF-α) and traffic to draining lymph nodes where they can activate naive T cells. LCs may directly present antigen, but they can also transfer antigens transported from the epidermis to resident lymphoid DCs.

Although there is evidence supporting a role for LCs in the initiation of a variety of adaptive immune responses (for example, type 1 and type 3), LCs have limited ability to phagocytose bacteria and are particularly important in antiviral immunity in the skin. Nevertheless, cutaneous infection models with the type 3 pathogens *Candida albicans* or *Staphylococcus aureus* have demonstrated clear roles for LCs in priming protective CD4 T-cell responses. Moreover, activation of LCs in response to ionizing radiation has been shown to prime skin-tropic T_{reg} cells. In humans, but not mice, LCs also express high levels of the invariant MHC-like molecule CD1a and appear particularly adapted to present lipid antigens to T cells. Thus, LCs appear especially adapted to activate

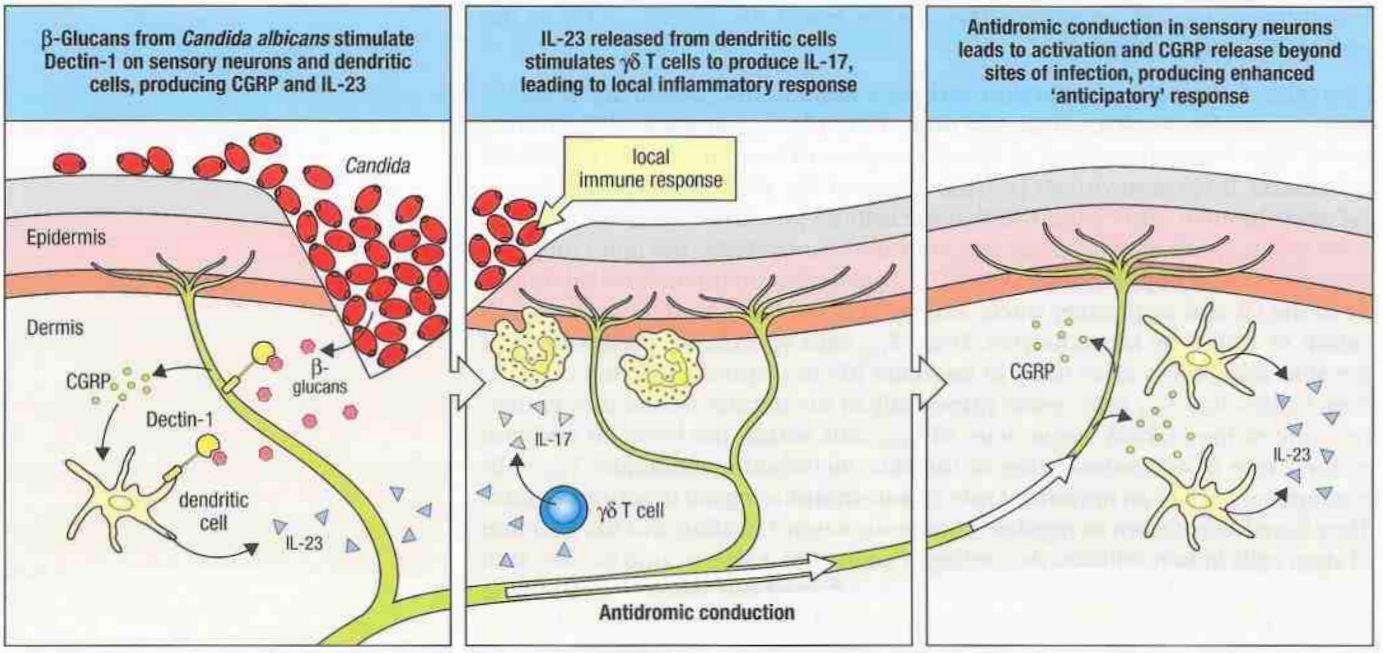
immunity to topical sensitizers that do not reach the dermis, such as the poison ivy lipid urushiol.

Like other barrier tissues, the skin harbors a resident microbiota that is established soon after birth and plays an important role in shaping local immunity in the skin. Across the ~2 m^2 of the skin surface of humans resides a diversity of bacteria, fungi, and viruses (see Fig. 12.5 and Fig. 12.48). Like the commensal microbiota in other sites, the skin microbiota provides colonization resistance to limit pathogen invasion and promote homeostasis. The latter includes the induction of populations of $FoxP3^+$ T_{reg} cells that maintain local tolerance. As in the GI and respiratory tracts, this reflects the local production and activation of TGF-β by keratinocytes. Thus, T_{reg} cells specific for components of the skin microbiota arise early in neonatal life in response to skin colonization. Cutaneous T_{reg} cells reside principally in the dermis, where they constitute one of the highest frequencies of T_{reg} cells within the body. In addition to their role in accommodating to the skin microbiota, cutaneous T_{reg} cells also appear to play an important role in non-immunological functions in skin. They have been shown to regulate cutaneous wound healing and the function of stem cells in hair follicles. Accordingly, soon after a skin wound occurs, skin T_{reg} cells accumulate in large numbers at the affected site, where they limit the effector T-cell response and promote epidermal regeneration via production of ligands of the epidermal growth factor receptor pathway. A large fraction of T_{reg} cells in skin is found near hair follicles, which serve as a major habitat for skin-resident microbes. T_{reg} cell responses in that niche may contribute to the development of hair follicles soon after birth and may promote the resident commensal microbes to thwart occupation of the niche by pathogens.

Shifts in composition of the skin microbiota, or dysbiosis, have been documented in many skin inflammatory disorders and are likely cofactors in the etiology of many immune skin disorders. For example, atopic dermatitis, a chronic inflammatory disorder of the skin, has long been associated with colonization of the skin by *Staphylococcus aureus*. Similarly, enrichment in *Streptococcus* spp. was observed in skin lesions of psoriasis. Defined microorganisms or microbial communities could potentially contribute to the initiation or amplification of skin pathologies through several mechanisms. Local expansion of defined members of the skin microbiota with enhanced inflammatory potential could alter tissue homeostasis. For example, *S. aureus* isolates that release δ-toxin trigger local allergic responses as the δ-toxin induces degranulation of dermal mast cells, which in turn promotes both innate and adaptive type 2 immune responses. *S. aureus* α-toxin can also promote IL-17 production from human CD4 T cells, a property that could be explained by the ability of this toxin to induce IL-1β production by monocytes. The skin milieu and defined factors such as vitamin B_{12} can have a profound effect on the metabolism of the skin microbiota and thus the prevention or promotion of colonization by pathogens. Additional studies will be needed to better understand the role of shifts in the skin microbiota in promoting immune-mediated disease in skin.

12-25 The sensory nervous system communicates with the immune system to enhance defense against infections in the skin.

In this section, we will describe a recently recognized mechanism that enhances the immune barrier of the skin. This involves neuroimmune interactions between the peripheral nervous system and dendritic cells in the epidermis that act to activate immune defenses not only at the direct site of infection but also at neighboring skin regions that are innervated by these neurons (Fig. 12.49). This mechanism involves c-fiber sensory neurons, which are unmyelinated small-diameter neurons that carry sensory information, often in the form of pain, to indicate damage. Such neurons are called nociceptive neurons (from the Latin *nocere*, 'to do harm'). Among these neurons is a



β-Glucans from *Candida albicans* stimulate Dectin-1 on sensory neurons and dendritic cells, producing CGRP and IL-23
IL-23 released from dendritic cells stimulates γδ T cells to produce IL-17, leading to local inflammatory response
Antidromic conduction in sensory neurons leads to activation and CGRP release beyond sites of infection, producing enhanced 'anticipatory' response

Fig. 12.49 Communication between nociceptive sensory neurons and dermal dendritic cells enhances the strength of immune responses. Left panel: When the skin barrier is breached through damage, environmental organisms, such as *Candida albicans*, can establish a local infection. This organism can be recognized directly by cells in the skin through the detection of β-glucans by the lectin receptor Dectin-1, which is expressed by dendritic cells and by TRPV1$^+$ sensory neurons. Activation of these neurons leads to their release of calcitonin gene–related peptide (CGRP), which acts on dermal dendritic cells to enhance their IL-23 production. Middle panel: Dermal dendritic cells are frequently located close to the axons of sensory neurons. CGRP released by these neurons enhances the IL-23 produced by dermal DCs, which in turn acts on various T-cell populations, including local dermal γδ T cells, to produce IL-17 family cytokines that promote local antifungal defense. Right panel: Activation of a sensory neuron by local infection also can stimulate action potentials that conduct information toward the neuronal cell body and, at branches, can conduct information by antidromic activation back toward the terminals of the sensory neuron in noninfected regions of skin. This provides for enhanced type 3 responses in anticipation of further infectious spread.

subtype expressing the transient receptor potential cation channel subfamily V member 1 (TRPV1), which is a receptor for capsaicin, the molecule in chili peppers that induces its burning sensation. Further, some TRPV1$^+$ neurons also express the sodium ion channel $Na_V1.8$, and it is this subset that seems to be important in this neuroimmune pathway.

The role of the nervous system in cutaneous defense against pathogens was recognized in an experimental system of skin inflammation induced by cutaneous administration of imiquimod (IMQ), a small compound that activates TLR-7. Normally, IMQ administration to skin produces an inflammatory response that is dependent on the production of IL-23 by dermal dendritic cells. This IL-23 can activate the production of IL-17 from local T cells, predominantly dermal γδ T cells, and leads to measurable skin thickening in regions such as the ear. As we introduced in Section 9-14, extracellular bacteria and fungi, common microbes encountered by the skin, typically induce type 3 responses, in which IL-17 family cytokines help recruit neutrophils and other cells that are effective in eliminating these types of organisms. When sensory neurons expressing TRPV1 were eliminated prior to treatment with IMQ by the administration of resiniferatoxin (RTX), a toxin and extremely strong agonist of TRPV1, it was discovered that IMQ no longer induced inflammation in treated skin. However, the administration of IL-23 to skin treated with IMQ restored its ability to induce inflammation. Further, the majority of dermal dendritic cells were located close to TRPV1$^+$ sensory fibers. These findings suggested that TRPV1 sensory neurons somehow regulated the ability of dermal dendritic cells to produce IL-23.

These findings were later extended to the setting of skin infection by the environmental fungus *Candida albicans*, which typically induces a type 3 response

involving IL-23 and IL-17 production. Recognition of *C. albicans* is mediated, at least in part, by **Dectin-1**, a C-type lectin family member (CLEC7A) that recognizes polysaccharides known as β-glucans, which are derived from the cell walls of bacteria and fungi, and even plants. In addition to its expression by dendritic cells, Dectin-1 also appears to be expressed by dermal keratinocytes and TRPV1$^+$ sensory neurons (see Fig. 12.49), suggesting that each of these cells might recognize β-glucans released by the cell walls of *C. albicans*. Indeed, it was found that infection by *C. albicans* activated neurons to release calcitonin gene-related peptide (CGRP), which acts to facilitate IL-23 production by dermal dendritic cells by an unknown mechanism. A second component of neuronal sensing of *C. albicans* seems to involve the purinoreceptor P2X3, which recognizes extracellular ATP. ATP can be released from keratinocytes activated by Dectin-1 signaling in response to β-glucans made by *C. albicans*. Additionally, some evidence suggests that some strains of *Candida* may directly release significant amounts of ATP. In either case, the combination of signaling by Dectin-1 and P2X3 leads to release of CGRP, promoting enhanced IL-23 from dermal dendritic cells, thus enhancing type 3 immunity in the vicinity of these cells.

Besides promoting IL-23 production by dendritic cells locally at the site of infection, the activation of TRPV1$^+$ neurons by *C. albicans* also has an important secondary benefit. Because sensory neurons extend branches into an entire region of skin, the activation of one branch of a sensory neuron can lead to active nerve conduction through its entire sensory field, which can enhance immune activation to areas of skin outside the initial site of infection. This effect was discovered in clever experiments that used optogenetics in which a channelrhodopsin, a light receptor activated by blue light, was selectively expressed in TRPV1$^+$ neurons of mice. Activation of neurons in a small region by shining a small focus of light onto a small patch of skin was observed to result in enhanced responses to *C. albicans* not only in the region activated by light, but also in adjacent regions of uninfected skin. This expansion of the area in which immunity is heightened occurs by conduction of nerve potential throughout the area served by the sensory neurons. This form of conduction is called antidromic nerve conduction, meaning that a nerve signal passes from the peripheral site of stimulation, first toward a neuronal cell body, but then into other local regions at the sites of axonal branching (see Fig. 12.49). In this way, the communication between sensory neurons and immune cells can provide an anticipatory response at sites not yet infected. Although this is still an active area of research, the anticipatory response is likely due to the release of CGRP by neurons induced by this antidromic conduction at distant sites independently of Dectin-1 signaling.

Summary.

Among barrier tissues, the respiratory tract is unique in that its major surface geography—the lower respiratory tract—is normally sterile; it is devoid of a commensal microbiota, reflecting the requirement for close contact between the airspaces and the blood to accomplish its major physiological function of gas exchange. Much of the protection from pathogens—and from commensals inhaled from the upper respiratory tract—lies in the unusual anatomy of the respiratory tract, which is highly efficient at trapping inhaled particulates of varying sizes and transporting them out of the airspaces via the mucociliary escalator. As in the gut, a tolerogenic tone is strongly favored in the respiratory tract to prevent the dire consequences attendant to overexuberant inflammation in the airways and airspaces, compromise of which can be rapidly fatal. These consequences, coupled with the relative ease of airborne spread of respiratory pathogens, accounts for the fact that respiratory infections are the greatest cause of death among all mucosal infections. This is painfully evident in the COVID-19 pandemic that has recently gripped the world and

has emphatically exposed the need for better vaccine strategies that prevent, rather than treat, airborne infections.

The skin differs from other barrier sites in the keratinized epithelium of its epidermis, reflecting its exposure to the greatest physical injury among barrier tissues and its role in minimizing water loss. The epidermis also represents a formidable barrier to pathogen entry, unless it is physically damaged (for example, by cuts or burns) or penetrated by other organisms (for example, insects that transmit microbial pathogens). Unlike many mucosal tissues, such as the intestines, which harbor lymphoid tissues that are in direct contact with the epithelium and its local microbiota, the skin does not normally contain local lymphoid tissues; adaptive immunity in the skin is initiated in draining lymph nodes. Unique to the skin is its population by a specialized resident macrophage, the Langerhans cell, which appears to be important in delivering antigens acquired in the epidermis to lymph nodes. Intraepidermal lymphoid cells, including conventional T_{RM} cells and unconventional γδ T cells, likely play important roles in immune defense, but the unconventional γδ T cells, including DETCs in mice, also have an important role in injury repair—representing an important immune function in supporting barrier function in a tissue so exposed to physical injury. The skin is also among the most important sensory organs of the body, literally the main interface with the outside world. Recent discoveries highlight the remarkable interplay of the neural and immune networks in skin that appear to enhance local immunity.

Summary to Chapter 12.

The barrier immune system is an extensive and diverse apparatus that has a crucial role in health, not just by protecting physiologically vital organs but also by helping to regulate the immunological tone to preserve immunological tolerance to nonthreatening antigens. Because of their extensive exposure to the external environment, the skin and mucosal surfaces of the body are at greatest risk of infection and possess unique, site-specific characteristics that distinguish their immune mechanisms from nonbarrier tissues. These include, but are not limited to: the immediate juxtaposition of mucosal epithelium and lymphoid tissue; immune regulation of mucus production that characterizes mucosal tissues; specialized antigen uptake mechanisms; a standing population of activated/memory lymphocytes and innate lymphoid cells (ILCs) even in the absence of infection; a diverse population of conventional and unconventional T cells resident within epithelia; the production of dimeric secretory IgA as the predominant antibody in mucosal tissues; and the down-regulation of immune responses to innocuous antigens such as food antigens and commensal microorganisms. Many of the most remarkable advances in immunobiology are being made in studies of barrier immunity, where there is a growing understanding both of the complexity of the role of innate and adaptive immune cells in supporting the mutualism between the host and the commensal microbiota and of the import of neuroimmune interactions that likely reflect the central role of barrier tissues in sensing, responding to, and protecting the host from the outside world.

Discussion Questions

12.1 Describe the different pathways by which antigens are taken up in the intestines.

12.2 Describe the processes that normally promote non-inflammatory immunity against antigens of the commensal microbiota in the intestines.

12.3 What factors contribute to the trafficking of T cells primed in the GALT to the intestinal mucosa?

12.4 Discuss how dendritic cells in intestinal tissues differ from their counterparts in other tissues, and describe how their functions are adapted to the local challenges faced by the immune system in the gut.

12.5 Describe the unique anatomic features of the respiratory tract that contribute to the lack of a commensal microbiota in the lungs.

12.6 An unusual aspect of the intestine is the close interaction between epithelial cells and cells of the immune system. Outline how these interactions help shape immune responses to the different kinds of antigens encountered by the gut.

Failures of Host Defense Mechanisms

13

IN THIS CHAPTER

Immunodeficiency diseases.

Evasion and subversion of immune defenses.

Acquired immune deficiency syndrome.

In the normal course of an infection, the infectious agent first triggers an innate immune response. The foreign antigens of the infectious agent, enhanced by signals from innate immune cells, then induce an adaptive immune response that ultimately clears the infection and establishes a state of protective immunity. This does not always happen, however. In this chapter we examine circumstances in which there are failures of host defense, whether due to immune defects in an abnormal host, as occurs in immunodeficiency, or to the evasion or subversion of immune defenses in normal hosts by pathogens. Finally, we will consider the special case in which the immune defenses of a normal host are impaired by one infectious agent that leads to more generalized susceptibility to infection, as occurs in the acquired immune deficiency syndrome (AIDS) caused by the human immunodeficiency virus (HIV).

In the first part of the chapter, we examine **primary (or inherited) immunodeficiency**, in which host defense fails because of an inherited defect in a gene (or genes) that results in the elimination or impaired function of one or more components of the immune system, leading to heightened susceptibility to infection with particular classes of pathogens. Immunodeficiency diseases caused by defects in T- or B-lymphocyte development, phagocyte function, and complement components have all been discovered. In the second part of the chapter, we briefly consider mechanisms by which pathogens evade or subvert specific components of the immune response to avoid elimination, so-called **immune evasion**. In the last part of the chapter, we consider how infection by HIV subverts the immune system and can lead to AIDS, an example of **secondary (or acquired) immunodeficiency**. The study of circumstances and mechanisms by which the immune system can fail has already contributed greatly to our understanding of host defense mechanisms and is providing insight into new methods of controlling or preventing infectious diseases, including AIDS.

Immunodeficiency diseases.

Immunodeficiencies occur when one or more components of the immune system are impaired; immunodeficiencies are classified as primary (inherited, or congenital) or secondary (acquired). Primary immunodeficiencies (PIDs), or inborn errors of immunity, are caused by the inheritance of damaging variants in any of a large number of genes that are involved in or control immune responses. They affect the development of immune cells, their function, or both. Clinical features of these disorders are highly variable, although a common feature is recurrent and often overwhelming infections in very young children. As will be discussed, many of the infectious agents that come to clinical attention in these individuals do not typically cause disease in those with a normal immune system and are referred to as **opportunistic pathogens**, while other infectious agents also cause disease in normal individuals but occur more frequently and with greater severity in those with impaired immunity.

Secondary immunodeficiencies are not inherited, rather they are acquired as a consequence of other diseases—including infectious diseases themselves, medical interventions that impair the immune response, or environmental factors such as nutritional deficiency. They are far more common than primary immunodeficiencies. Some forms of immunodeficiency principally affect immune regulatory pathways. Defects of this type can lead to allergy, abnormal proliferation of lymphocytes, autoimmunity, and certain types of cancer, and will be discussed in other chapters. Here, we will mainly focus on those immunodeficiencies that predispose to infection.

Primary immunodeficiencies can be classified on the basis of the components of the immune system involved. However, because of the integration of many aspects of immune defense, defects in one component of the immune system can affect the function of others. Therefore, primary defects in innate immunity can lead to defects in adaptive immunity, and vice versa. Nevertheless, it is instructive to consider immune defects in the context of the major types of immunity affected, as these can lead to distinct patterns of infection and clinical disease. By examining which infectious diseases accompany a particular immunodeficiency, we gain insights into components of the immune system that are important in the response to particular agents. The inherited immunodeficiencies also reveal how interactions between different immune cell types contribute to the immune response and to the development of T and B lymphocytes. Finally, these inherited diseases can lead us to the defective gene, often revealing new information about the molecular basis of immune processes and providing the necessary information for diagnosis, genetic counseling, and also the possibility of gene therapy for cure.

13-1 Primary immunodeficiency diseases are caused by inherited gene variants that typically cause recurrent infections early in life.

Before the advent of antibiotics, most individuals with inherited immune defects died in infancy or early childhood because of their susceptibility to particular classes of pathogens. Such cases were not easily identified because many normal infants also died of infection. In the modern era, individuals with immune deficiency first come to clinical attention through a history of recurrent infection, often by the same or similar pathogens. The type of infection hints at which part of the immune system is deficient—and often highlights the interlinked functions of different components of the innate and adaptive immune systems. Recurrent infection by **pyogenic, or pus-forming, bacteria** suggests a defect in antibody, complement, or phagocyte function. This reflects

the fact that the normal pathway of host defense against such bacteria is the binding of antibody followed by the fixation of complement, which allows the opsonized bacteria to be taken up by phagocytic cells and killed. Breaking any of the links in this chain of events can cause a similar immunodeficient state. Alternatively, a history of persistent fungal skin infection, such as cutaneous candidiasis, or recurrent viral infections suggests a defect in host defense mediated by specific functions of T lymphocytes, whereas global T-cell dysfunction impairs both B-cell responses and aspects of innate immunity, giving rise to broad defects in host defense.

Since the beginning of the 21st century, the identification of new primary immunodeficiencies (PIDs) has accelerated, reflecting the relative ease in identifying dysfunctional gene variants since completion of the first draft of the human genome in 2001 and the increasing affordability of human genome sequencing, as well as new information on the function of immune genes that has been developed from mouse studies. More than 350 primary immunodeficiencies have now been described, involving almost 2% of the ~20,000 genes encoded in the human genome. These disorders are typically **monogenic disorders**—the result of a single damaging gene variant—and can be autosomal recessive, autosomal dominant, or X-linked. Disease caused by decreased expression or function of a gene product, whether resulting in complete (**amorphic**) or partial (**hypomorphic**) loss-of-function (LOF) variants, are far more common than diseases caused by gain-of-function (GOF, or **hypermorphic**) variants. And most PIDs are the result of recessive gene variants, whether caused by mutations in genes on autosomes or the X chromosome. As males have only one X chromosome, all males who inherit an X chromosome carrying an affected gene will have disease. In contrast, female carriers with only one affected X chromosome are typically healthy.

Gene targeting in mice (see Appendix I, Section A-36) has created many immunodeficient states that continue to add to our knowledge of the contribution of individual gene products to normal immune function. Nevertheless, human immunodeficiency diseases remain the best source of insight into the normal pathways of defense against infectious diseases and immune regulation. Immunodeficiencies also teach us about the redundancy of defense mechanisms against infectious disease. By chance, the first person to be reported with a hereditary deficiency of complement (C2 deficiency) was an immunologist who showed no evidence of immune compromise. This teaches us that there are multiple protective immune mechanisms against infection, such that a defect in one component of immunity might be compensated for by other components. Thus, although there is abundant evidence that complement deficiency increases susceptibility to pyogenic infection, not every human with complement deficiency suffers from recurrent infections.

Nine general categories of PIDs are now recognized (Fig. 13.1) and are grouped on the basis of the major immune cell type or pathway affected. None is very common (IgA deficiency, the most common, affects ~1 in 500 Caucasians), and some are extremely rare (single cases or family identified). Examples of these diseases are described in subsequent sections on the basis of the causal defects and their impact on innate and adaptive immunity.

13-2 Defects in T-cell development can result in severe combined immune deficiencies.

The pathways leading to the development of circulating naive T cells and B cells are summarized in Fig. 13.2. Individuals with defects in T-cell development are highly susceptible to a broad range of infectious agents, demonstrating the central role of T-cell differentiation and maturation in adaptive immune

Major category	Example	Gene defect	Inheritance	Cells affected	Immune defect	Antibody levels	Common infections/ other features
Combined immunodeficiencies (CIDs) limited to the immune system	γ_c deficiency	*IL2RG*	XL	T cells, NK cells	Deficient T-cell and NK-cell development	Low	General susceptibility to opportunistic and standard pathogens
	RAG-1 or RAG-2 deficiency	*RAG1; RAG2*	AR	T cells, B cells	Deficient T- and B-cell development	Low	General susceptibility to opportunistic and standard pathogens
CIDs with defects in tissues outside the immune system	FOXN1 deficiency; Nude phenotype	*FOXN1*	AR	Thymic epithelium, T cells	Deficient T-cell development	Decreased	General susceptibility to opportunistic and standard pathogens
	Job syndrome	*STAT3*	AD	T_H17 and T_{FH} cells	Defective T_H17 and T_{FH} cell development	High IgE	Extracellular bacteria, mucocutaneous candidiasis, bone development abnormalities
Antibody deficiencies	Bruton's X-linked agammaglobulinemia (XLA)	*BTK*	XL	B cells	Absent mature B cells	Low	Pyogenic bacteria and enteroviruses
	AID deficiency	*AICDA*	AR	B cells	Defective Ig class-switching and somatic hypermutation	IgG and IgA low; IgM increased	Bacterial infections, enlarged germinal centers
	Selective IgA deficiency	*Unknown*	?	B cells	Deficient clas-switched IgA B cells	Low–absent IgA; other isotypes	Typically asymptomatic
Immune dysregulation	Perforin deficiency	*PRF1*	AR	CTLs and NK cells	Impaired CTL and NK-cell cytotoxicity	Normal	Fever, hepatosplenomegaly
	IL-10 deficiency	*IL10*	AR	Multiple	No IL-10	Normal	Inflammatory bowel disease (IBD)
Phagocyte defects	Elastase deficiency	*SCN1*	AD	Neutrophils	Neutrophil deficiency	Normal	Severe bacterial infections; myelodysplasia/leukemia
	GATA2 deficiency	*GATA2*	AD	Monocytes and DCs	Monocyte and DC deficiency	Normal	Susceptibility to mycobacteria, HPV, histoplasmosis; myelodysplasia/leukemia
Innate immunity defects	IL-12p40 deficiency	*IL12B*	AR	DCs, monocytes, and macrophages	IFN-γ secretion	Normal	Mycobacterial and *Salmonella* infections
	IFN-γ receptor 1 deficiency	*IFNGR1*	AR/AD	Multiple	IFN-γ signaling	Normal	Mycobacterial and *Salmonella* infections
Autoinflammatory disorders	Muckle–Wells syndrome	*NLRP3*	AD (GOF)	Neutrophils and monocytes	Inflammasome hyperactivity	Normal	Recurrent fever, urticaria
Complement deficiencies	C1q deficiency	*C1QA*	AR	Apoptotic cells	Deficient activation of classical complement pathway	Normal	Infections by encapsulated bacteria (e.g., *Streptococcus pneumoniae*, *Klebsiella pneumoniae*), immune- complex disease (e.g., SLE)
	MASP deficiency	*MASP2*	AR	None	Deficient activation of lectin complement pathway	Normal	Pyogenic bacteria, autoimmunity
Phenocopies of inborn errors of immunity	APECED syndrome	*AIRE*	AR	T cells	Impaired negative selection of T cells	Normal, with autoantibodies	Chronic mucocutaneous candidiasis, multiple endocrinopathies

Fig. 13.1 Human immunodeficiency syndromes. Examples of categories, specific gene defects, inheritance patterns, consequences for the immune system, and resulting disease susceptibilities are listed for some common and some rare human immunodeficiency syndromes. Severe combined immune deficiency (SCID) can be due to many different defects, as summarized in Fig. 13.2 and described in the text. AD, autosomal dominant; APECED, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy; AR, autosomal recessive; GOF, gain-of-function; XL, X-linked.

responses to virtually all microbes. Because such individuals make neither T cell–dependent antibody responses nor cell-mediated immune responses, and thus cannot develop immunological memory, they are said to suffer from **severe combined immune deficiency (SCID)**.

X-linked Severe Combined Immunodeficiency

X-linked SCID (XSCID) is the most frequent form of SCID and is caused by mutations in the gene *IL2RG* on the X chromosome, which encodes the

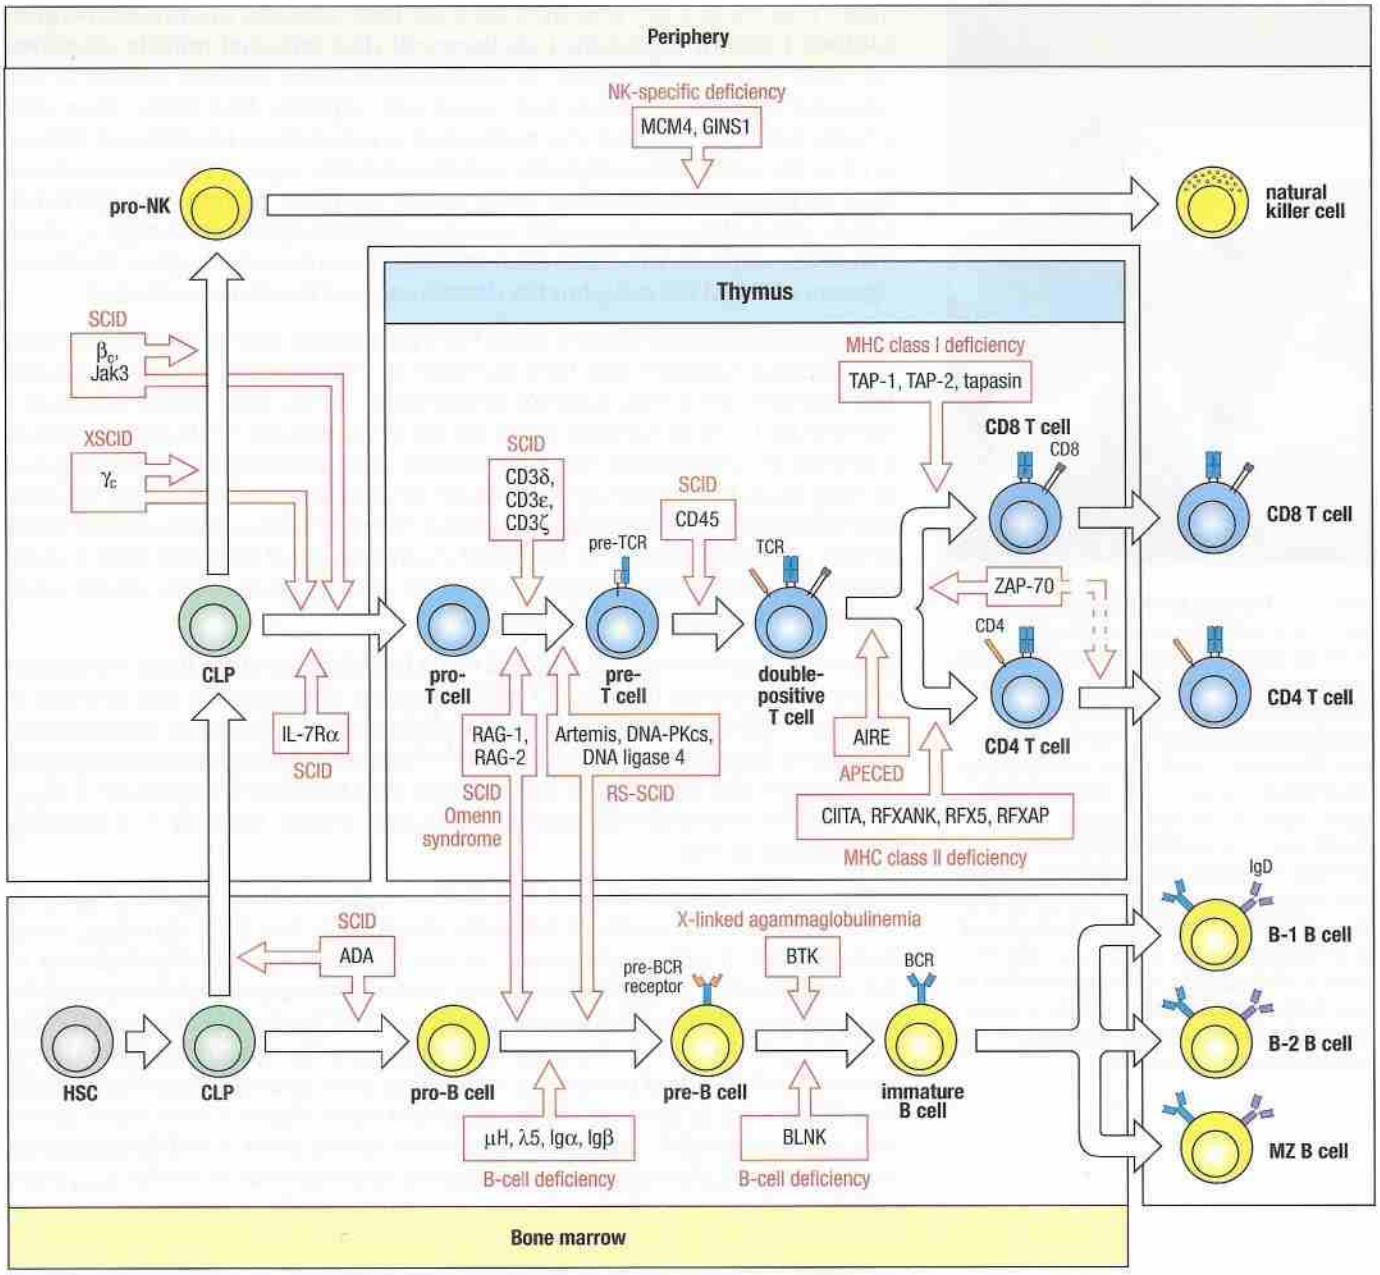

Fig. 13.2 Defects in T-cell and B-cell development that cause immunodeficiency. The pathways leading to development of circulating naive T cells and B cells are shown. Mutations in genes that cause human immunodeficiency diseases are indicated in red boxes. These include mutations in genes that encode T cell–intrinsic or B cell–intrinsic proteins (for example, γ_c, CD3λ, BTK), as well as mutations in genes that encode proteins expressed on the thymic epithelium (for example, TAP-1 or CIITA), defects that impair thymic development and thus T-cell development. BCR, B-cell receptor; CLP, common lymphoid progenitor; HSC, hematopoietic stem cell; MZ B cell, marginal zone B cell; pre-BCR, pre-B-cell receptor; pre-TCR, pre-T-cell receptor; RS-SCID, radiation-sensitive SCID; SCID, severe combined immune deficiency; TCR, T-cell receptor; XSCID, X-linked SCID.

interleukin-2 receptor (IL-2R) common gamma chain (γ_c). γ_c is required in all receptors of the IL-2 cytokine family (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). Individuals with XSCID thus have defects in signaling of all IL-2-family cytokines and, owing to the defects in IL-7 and IL-15, T cells and NK cells fail to develop normally (see Fig. 13.2). B-cell numbers, on the other hand, are normal, but due to the absence of T-cell help, their function is not. Individuals with XSCID are overwhelmingly male; in females who are carriers of the mutation, T-cell and NK-cell progenitors in which X-inactivation has preserved the wild-type *IL2RG* allele progress through development to establish a normal mature immune repertoire. XSCID is known as the 'bubble boy disease' after David

Fig. 13.3 The boy in the bubble. David Vetter was a well-known patient with X-linked SCID who raised public awareness of immunodeficiency diseases. He spent nearly the entirety of his life in specially fabricated plastic barriers to protect him from the threat of pathogens, giving rise to the moniker 'the boy in the bubble.' This photo, taken at his family's home, shows David, age 7, at his first introduction to Dr. William Shearer, a pediatric immunologist who would be a principal in David's care for the remainder of his life. In the background is Dr. Buford Nichols, another member of David's medical team. David succumbed at age 12 to complications of a bone marrow transplant. Photo courtesy of David's mother, Carol Ann Demaret.

Vetter (Fig. 13.3), a boy who lived for more than a decade in a protective, **gnotobiotic** ('known organisms') environment that excluded outside microbes. He died from complications of lymphoproliferative disease caused by the causative agent of infectious mononucleosis—Epstein–Barr virus—soon after a bone marrow transplant was performed to reconstitute his immune system. A clinically and immunologically indistinguishable type of SCID is associated with an inactivating mutation in the kinase Jak3 (see Sections 8-1 and 8-14), which physically associates with γ_c and transduces signaling through γ_c-chain cytokine receptors. This autosomal recessive mutation also impairs the development of T and NK cells, but the development of B cells is unaffected.

Other immunodeficiencies in mice have pinpointed more precisely the roles of individual cytokines and their receptors in T-cell and NK-cell development. For example, mice with targeted mutations in the β_c gene (*IL2RB*) defined a key role for IL-15 as a growth factor for the development of NK cells, as well as a role for this cytokine in T-cell maturation and trafficking. Mice with targeted mutations in IL-15 itself or the α chain of its receptor also have no NK cells and relatively normal T-cell development, but they show a more specific T-cell defect, primarily limited to impaired maintenance of memory CD8 T cells. This is in contrast to deficiencies of MCM4 or GINS1 in humans, which result in a selective deficiency of NK cells.

Although gene variants in *IL2RA* that result in deficiency of the third component of the IL-2 receptor [IL-2Rα (CD25)] impair the development and function of effector T cells (see Section 9-10) and result in immune deficiency and increased infections, these aspects are overshadowed by multi-organ autoimmune disease. The latter is due to defective development and function of regulatory T (T_{reg}) cells, which constitutively express IL-2Rα and require ongoing IL-2 signaling (see Section 15-15).

Humans with a deficiency of the IL-7 receptor α chain (IL-7Rα) have no T cells but normal levels of NK cells, illustrating that IL-7 signaling, while essential for T-cell development, is not essential for the development of NK cells (see Fig. 13.2). Notably, mice with a gene-targeted deficiency of the IL-7 receptor share with humans a deficiency of T cells, but also lack B cells, which is not the case in humans. This illustrates the species-specific role of certain cytokines and provides a cautionary note against extrapolating findings from mice to humans. In humans and mice whose T cells show defective production of IL-2 after receptor stimulation, most T-cell development itself is normal, although there is impaired development of FoxP3$^+$ T_{reg} cells, which predisposes to immune regulatory abnormalities and autoimmunity (see Chapter 15). The more limited effects of individual cytokine signaling defects are in contrast to the global defects in T- and NK-cell development in individuals with XSCID.

As in all serious T-cell deficiencies, individuals with XSCID do not make effective antibody responses to most antigens, although their B cells seem normal. Most, but not all, naive IgM-positive B cells from female carriers of XSCID have inactivated the defective X chromosome rather than the normal one, showing that B-cell development is affected by, but is not wholly dependent on, the γ_c chain. Mature memory B cells that have undergone class switching have inactivated the defective X chromosome almost without exception. This might reflect the fact that the γ_c chain is also part of the receptor for IL-21, signaling through which is important for the maturation of class-switched B cells (see Section 10-1).

13-3 SCID can also be due to defects in the purine salvage pathway.

Adenosine Deaminase Deficiency

Variants of autosomal recessive SCID that arise from defects in enzymes of the salvage pathway of purine synthesis include **adenosine deaminase (ADA) deficiency** and **purine nucleotide phosphorylase (PNP) deficiency**

(Fig. 13.4; and see Fig. 13.2). ADA catalyzes the conversion of adenosine and deoxyadenosine to inosine and deoxyinosine, respectively, and its deficiency results in the accumulation of deoxyadenosine and its precursor, *S*-adenosylhomocysteine, which are toxic to developing T and B cells. PNP catalyzes the conversion of inosine and guanosine to hypoxanthine and guanine, respectively. PNP deficiency, which is a rarer form of SCID, also causes the accumulation of toxic precursors but affects developing T cells more severely than B cells. In both diseases, the development of **lymphopenia**, or decreased numbers of lymphocytes, is progressive after birth, resulting in profound lymphopenia within the first few years of life. Because both enzymes are housekeeping proteins expressed by many cell types, the immune deficiency associated with each of these inherited defects is part of a broader clinical syndrome.

13-4 Defects in antigen receptor gene rearrangement can result in SCID.

Another group of autosomally inherited defects leading to SCID is caused by failures of DNA rearrangement that prevent successful generation of T- and B-cell antigen receptors during lymphocyte development. Mutations in either the *RAG1* or *RAG2* gene that result in nonfunctional proteins cause arrest of lymphocyte development because of absence of positive selection at the pro- to pre-T cell and pro- to pre-B-cell transitions due to a failure of V(D)J recombination. This results in a complete lack of both T cells and B cells in affected individuals. Because the effects of RAG deficiencies are limited to lymphocytes that undergo antigen receptor gene rearrangement, NK-cell development is not impaired.

Some children with hypomorphic mutations in either *RAG1* or *RAG2* can make a small amount of functional RAG protein, allowing limited V(D)J recombination. This group includes individuals with a distinctive and severe disease called **Omenn syndrome**, which, in addition to increasing susceptibility to multiple opportunistic infections, has clinical features very similar to graft-versus-host disease (GVHD) wherein the individual's T cells mount a response against his or her own tissues. This is characterized clinically by rashes, eosinophilia, diarrhea, and enlargement of the lymph nodes (see Section 15-25). An explanation for this phenotype is that low levels of *RAG* activity result in limited T-cell receptor gene recombination. Interestingly, no B cells are found, suggesting that B cells have more stringent requirements for *RAG* activity. Because of the limited number of successfully rearranged T-cell receptors, the repertoire of T cells is highly restricted in individuals with Omenn syndrome, and there is activation and clonal expansion of the limited number of specificities present. The clinical features strongly suggest that these peripheral T cells are autoreactive and are responsible for the graft-versus-host phenotype.

A subset of individuals with autosomal recessive SCID are characterized by an abnormal sensitivity to ionizing radiation. They produce very few mature B and T cells because of the failure of DNA rearrangement in their developing lymphocytes; only rare VJ or VDJ joints are seen, and most of these are abnormal. This type of SCID is due to defects in ubiquitous DNA repair proteins involved in repairing DNA double-strand breaks, which are generated not only during antigen receptor gene rearrangement (see Section 5-4) but also by ionizing radiation. Owing to the increased radiosensitivity in these individuals, this class of SCID is called **radiation-sensitive SCID (RS-SCID)** to distinguish it from SCID due to lymphocyte-specific defects. Defects in the genes for Artemis, DNA protein kinase catalytic subunit (DNA-PKcs), or DNA ligase 4 cause RS-SCID (see Fig. 13.2). Because defects in repair of DNA breaks increase the risk of translocations during cell division that can lead to

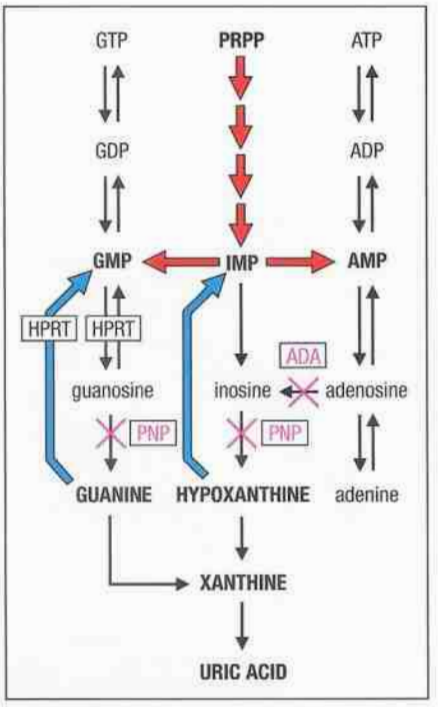

Fig. 13.4 Inherited defects in the purine salvage pathway cause SCID. Outline of purine *de novo* synthesis, salvage, and degradation. The principal precursors, intermediates, and products are boldface. Red arrows indicate synthesis, and blue arrows indicate salvage. Black arrows indicate the conversion of nucleotides to nucleosides and bases, and the conversion of nucleosides to nucleotides. More than 90% of purines are recovered from the salvage pathway rather than being generated from *de novo* synthesis. Inherited deficiencies of adenosine deaminase (ADA) or purine nucleotide phosphorylase (PNP) lead to severe combined immune deficiency (SCID) because of accumulation of purine salvage intermediates that are toxic to developing B and T cells. ADP, adenosine diphosphate; AMP, adenosine monophosphate, or adenylate; ATP, adenosine triphosphate; GDP, guanosine diphosphate; GMP, guanosine monophosphate, or guanylate; GTP, guanosine triphosphate; HPRT, hypoxanthine-guanine phosphoribosyl transferase; IMP, inosine monophosphate, or inosylate; PRPP, phosphoribosyl pyrophosphate.

Omenn Syndrome

malignant transformation, individuals with RS-SCID variants are also more likely to develop cancer.

13-5 Defects in signaling from T-cell antigen receptors can cause severe immunodeficiency.

Several gene defects have been described that interfere with signaling through the T-cell receptor (TCR) and thus block the activation of T cells early in thymic development (see Fig. 13.2). Individuals with mutations in the CD3δ, CD3ε, or CD3ζ chains of the CD3 complex have defective pre-TCR signaling and fail to progress to the double-positive stage of thymic development, resulting in SCID. Another lymphocyte signaling defect that leads to severe immunodeficiency is caused by mutations in the tyrosine phosphatase CD45. Humans and mice with CD45 deficiency show a marked reduction in peripheral T-cell numbers and also abnormal B-cell maturation. Severe immunodeficiency also occurs in individuals who make a defective form of the cytosolic protein tyrosine kinase ZAP-70, which transmits signals from the T-cell receptor (see Section 7-10). CD4 T cells emerge from the thymus in normal numbers, whereas CD8 T cells are absent. However, the CD4 T cells that mature fail to respond to antigenic stimuli.

Wiskott–Aldrich Syndrome

Wiskott–Aldrich syndrome (WAS), which is caused by a defect in the gene *WAS* on the X chromosome that encodes WAS protein (WASp), has shed new light on the molecular basis of signaling and immune synapse formation between various cells in the immune system. Although the disease affects platelets and was first described as a blood-clotting disorder, it also causes immunodeficiency that is characterized by reduced T-cell numbers, defective NK-cell cytotoxicity, and a failure of antibody responses (see Section 7-19). WASp is expressed in all hematopoietic cell lineages and is a key regulator of lymphocyte and platelet development and function through its transduction of receptor-mediated signals that induce reorganization of the cytoskeleton (see Section 9-18). Several signaling pathways downstream of the T-cell receptor are known to activate WASp (see Sections 7-19 and 9-18). Activation of WASp in turn activates the Arp2/3 complex, which is essential for initiating actin polymerization that is critical for immune synapse formation and the polarized release of effector molecules by T cells (see Sections 7-19 and 9-18). In individuals with WAS, and in mice whose *Was* gene has been knocked out, T cells fail to respond normally to T-cell receptor signaling. It has also recently been suggested that WASp is required for the suppressive function of natural T_{reg} (nT_{reg}) cells, and this may help explain why individuals with WASp are susceptible to autoimmune diseases.

13-6 Genetic defects in thymic development or function that block T-cell development result in combined immunodeficiencies.

A disorder of thymic development associated with SCID and a lack of body hair has been known for many years in mice; the mutant strain is descriptively named ***nude*** (see Section 8-11). A small number of children have been described with the same phenotype. In both mice and humans this syndrome is caused by mutations in the gene *FOXN1*, which encodes a transcription factor selectively expressed in skin and thymus. FOXN1 is necessary for the differentiation of thymic epithelium and the formation of a functional thymus. In individuals with a mutation in *FOXN1*, the lack of thymic function prevents normal T-cell development. B-cell development is normal in individuals with the mutation, yet B-cell responses are deficient because of the lack of T cells, and the response to nearly all pathogens is profoundly impaired.

DiGeorge Syndrome

DiGeorge syndrome is another disorder in which the thymic epithelium fails to develop normally, resulting in SCID. The genetic abnormality underlying

this complex developmental disorder is a deletion within one copy of chromosome 22. The deletion varies between 1.5 and 5 megabases in size, with the smallest deletion that causes the syndrome containing approximately 24 genes. The relevant gene within this interval is *TBX1*, which encodes the transcription factor T-box 1. DiGeorge syndrome is caused by the deletion of a single copy of this gene, such that individuals with this disorder are **haploinsufficient** for *TBX1*. Without the proper inductive thymic environment, T cells cannot mature and, in individuals with this syndrome, both cell-mediated immunity and T cell–dependent antibody production are impaired.

MHC Class II Deficiency

MHC Class I Deficiency

Defects in the expression of MHC molecules can lead to severe immunodeficiency as a result of effects on the positive selection of T cells in the thymus (see Fig. 13.2). Individuals with **bare lymphocyte syndrome (BLS)** lack expression of either MHC class II or MHC class I molecules, so-called BLS II or BLS I, respectively. These are also referred to simply as **MHC class II deficiency** or **MHC class I deficiency**. In the case of MHC class II deficiency, the thymus lacks MHC class II molecules. Hence, CD4 T cells cannot be positively selected, and few develop. The antigen-presenting cells in these individuals also lack MHC class II molecules, and so the few CD4 T cells that do develop cannot be stimulated by antigen. MHC class I expression is normal, and CD8 T cells develop normally. However, such individuals suffer from severe immunodeficiency, illustrating the central importance of CD4 T cells in adaptive immunity to most pathogens.

MHC class II deficiency is caused not by mutations in the MHC genes themselves but by mutations in one of several genes encoding gene-regulatory proteins that are required for the transcriptional activation of MHC class II genes. Four complementing gene defects (known as groups A, B, C, and D) have been defined in individuals who fail to express MHC class II molecules, indicating that the products of at least four different genes are required for the normal expression of these proteins. Genes corresponding to each complementation group have been identified: the *MHC class II transactivator*, or *CIITA*, is mutated in group A, and the genes *RFXANK*, *RFX5*, and *RFXAP* are mutated in groups B, C, and D, respectively (see Fig. 13.2). These last three encode proteins that are components of a multimeric complex, RFX, which is involved in the control of gene transcription. RFX binds a DNA sequence called an X-box, which is present in the promoter region of all MHC class II genes.

A more limited immunodeficiency has been observed in a small number of individuals who have almost no cell-surface MHC class I molecules (i.e., MHC class I deficiency, or BLSI). In contrast to those with MHC class II deficiency, affected individuals have normal levels of mRNA encoding MHC class I molecules and normal production of MHC class I proteins, but very few of the proteins reach the cell surface. This condition is due either to mutations in *TAP1* or *TAP2*, which encode the subunits of the peptide transporter responsible for transporting peptides generated in the cytosol into the endoplasmic reticulum where they are loaded into nascent MHC class I molecules, or to mutations in *TAPBP*, which encodes tapasin, another component of the peptide transporter complex (see Section 6-4). Although the reduction in MHC class I molecules on the surface of thymic epithelial cells results in reduced numbers of CD8 T cells (see Fig. 13.2), people with MHC class I deficiency are not abnormally susceptible to viral infections. This is surprising given the key role of MHC class I presentation and of cytotoxic CD8 T cells in combating viral infections. There is, however, evidence for TAP-independent pathways for the presentation of certain peptides by MHC class I molecules, and the clinical phenotype of *TAP1*- and *TAP2*-deficient individuals indicates that these pathways may be sufficient to allow sufficient development and function of CD8 T cells to control viruses.

Some defects in thymic cells lead to a phenotype with other effects besides those of immunodeficiency. The gene *AIRE* encodes a transcription factor that enables thymic epithelial cells to express many self proteins that mediate efficient negative selection (see Section 8-25). Defects in *AIRE* lead to a T-cell repertoire that includes cells autoreactive to self antigens, causing a complex syndrome called **APECED (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy)**, which is characterized by autoimmunity, developmental defects, and immunodeficiency (see Chapter 15). As will be discussed in Section 13-12, an important aspect of the immunodeficiency component of this syndrome results from the break in self-tolerance, which leads to blocking autoantibodies against key cytokines involved in host defense, including IFN-γ, IL-17, and IL-22.

Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy (APECED)

13-7 Defects in B-cell development result in deficiencies in antibody production that cause an inability to clear extracellular bacteria.

In addition to inherited defects in proteins that are crucial to both T-cell and B-cell development, such as RAG-1 and RAG-2, defects that are specific to B-cell development have also been identified (see Fig. 13.2). Individuals with these defects are characterized by an inability to cope with extracellular bacteria and some viruses whose efficient clearance requires specific antibodies. Pyogenic bacteria, such as staphylococci and streptococci, have polysaccharide capsules that impair recognition by the receptors on macrophages and neutrophils that stimulate phagocytosis. These bacteria escape elimination by the innate immune response and are successful extracellular pathogens, but they can be cleared by an adaptive immune response. Opsonization by antibody and complement enables phagocytes to ingest and destroy the bacteria. The principal effect of deficiencies in antibody production is therefore a failure to control infections by pyogenic bacteria. Susceptibility to some viral infections, notably those caused by enteroviruses, is also increased because of the importance of antibodies in neutralizing viruses that enter the body through the gut.

X-linked Agammaglobulinemia

The first description of an immunodeficiency disease was Ogden C. Bruton's account, in 1952, of the failure of a male child to produce antibodies. Because inheritance of this condition is X-linked and is characterized by the complete absence of immunoglobulin in the serum (**agammaglobulinemia**), it was called **Bruton's X-linked agammaglobulinemia (XLA)** (see Fig. 13.2). Since then, autosomal recessive variants of agammaglobulinemia have been described. Infants with these diseases are usually identified as a result of recurrent infections with pyogenic bacteria, such as *Streptococcus pneumoniae*, and enteroviruses that typically occur after weaning in breast-fed infants, or much earlier in infants that are not breast-fed. In this regard, it should be noted that normal infants have a transient deficiency in immunoglobulin production in the first 3–12 months of life (Fig. 13.5). Nevertheless, antibody levels in the normal newborn infant are comparable to those of the mother at birth because of the transplacental transport of maternal IgG (see Section 10-17). Breast-fed infants also receive maternal antibodies from breast milk that are protective until their endogenous antibody production begins to be established. After the infant is weaned, maternal IgG is catabolized and gradually decreases until there is no longer a maternal contribution to the infant's circulating IgG. In infants who are not breast-fed, the delay in production of endogenous IgG results in low levels in circulation between the ages of 3 months and 1 year. This can lead to a period of heightened susceptibility to infection, especially in premature babies, who are often formula-fed and begin with lower levels of maternal IgG, and also reach immune competence later after birth. Because of the transient protection afforded newborn infants by maternal antibodies,

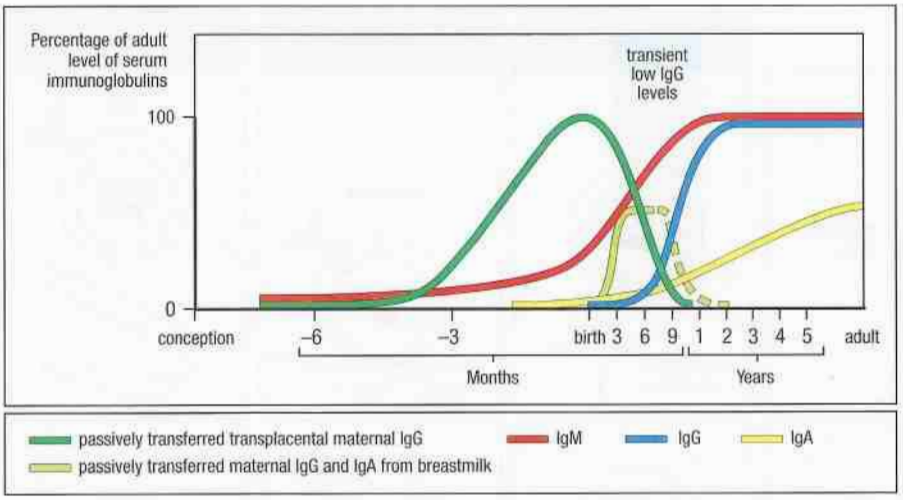

Fig. 13.5 Immunoglobulin levels in newborn infants are primarily contributed by passive transfer from the mother. Babies are born with high levels of maternal IgG, which is transported across the placenta from the mother during gestation. After birth, the production of IgM by the newborn increases almost immediately; the production of IgG by the infant, however, does not begin for about 6 months, during which time the maternal IgG that had been transferred transplacentally falls and is supplemented by maternal IgG in breast milk that is taken up in the neonatal gut. Maternal IgA is also supplied in breast milk and contributes to immune protection and establishment of the intestinal microbiome in the newborn. In infants that are not breast-fed, IgG levels are low from about the age of 3 months to 1 year, which can lead to heightened susceptibility to disease.

XLA is typically detected several months after birth, contingent on whether they are breast-fed or not, and thus when maternal antibody levels in the infant have declined.

The defective gene in XLA encodes a protein tyrosine kinase called BTK (Bruton's tyrosine kinase), which is a member of the Tec family of kinases that transduce signals through the pre-B-cell receptor (pre-BCR; see Section 7-20). As discussed in Section 8-4, the pre-BCR is composed of successfully rearranged μ heavy chains complexed with the surrogate light chain (composed of λ5 and VpreB) and with the signal-transducing subunits Igα and Igβ. Stimulation of the pre-BCR recruits cytoplasmic proteins, including BTK, which convey signals required for the proliferation and differentiation of pre-B cells. In the absence of BTK function, B-cell maturation is largely arrested at the pre-B-cell stage (see Fig. 13.2; see also Section 8-4), resulting in profound B-cell deficiency and agammaglobulinemia. Some B cells do mature, however, perhaps as a result of compensation by other Tec kinases.

During embryonic development, females randomly inactivate one of their two X chromosomes. Because BTK is required for B-lymphocyte development, only cells in which the normal allele of *BTK* is active develop into mature B cells. Thus, in all B cells in female carriers of a mutant *BTK*, the active X chromosome is the normal one and the abnormal X chromosome is inactivated. This fact allowed female carriers of XLA to be identified even before the nature of the BTK protein was known. In contrast, the active X chromosomes in the T cells and macrophages of carriers are an equal mixture of normal and *BTK* mutant X chromosomes. Nonrandom X-inactivation only in B cells shows conclusively that the gene *BTK* is required for the development of B cells but not the other cell types, and that BTK must act in the B cells themselves rather than in stromal or other cells required for B-cell development (**Fig. 13.6**).

Autosomal recessive deficiencies in other components of the pre-BCR also block early B-cell development and cause severe B-cell deficiency and congenital agammaglobulinemia similar to that of XLA. These disorders are much rarer than XLA and result from mutations in the gene that encodes the heavy chain (*IGHM*), which is the second most common cause of agammaglobulinemia, or in the genes that encode λ5 (*IGLL1*), Igα (*CD79A*), or Igβ (*CD79B*). Mutations that cripple the B-cell receptor signaling adaptor, B-cell linker protein (encoded by *BLNK*), also cause the arrest of early B-cell development that results in B-cell deficiency.

Individuals with pure B-cell defects resist many pathogens other than pyogenic bacteria. Fortunately, the latter can be suppressed with antibiotics and with monthly infusions of human immunoglobulin collected from a large pool

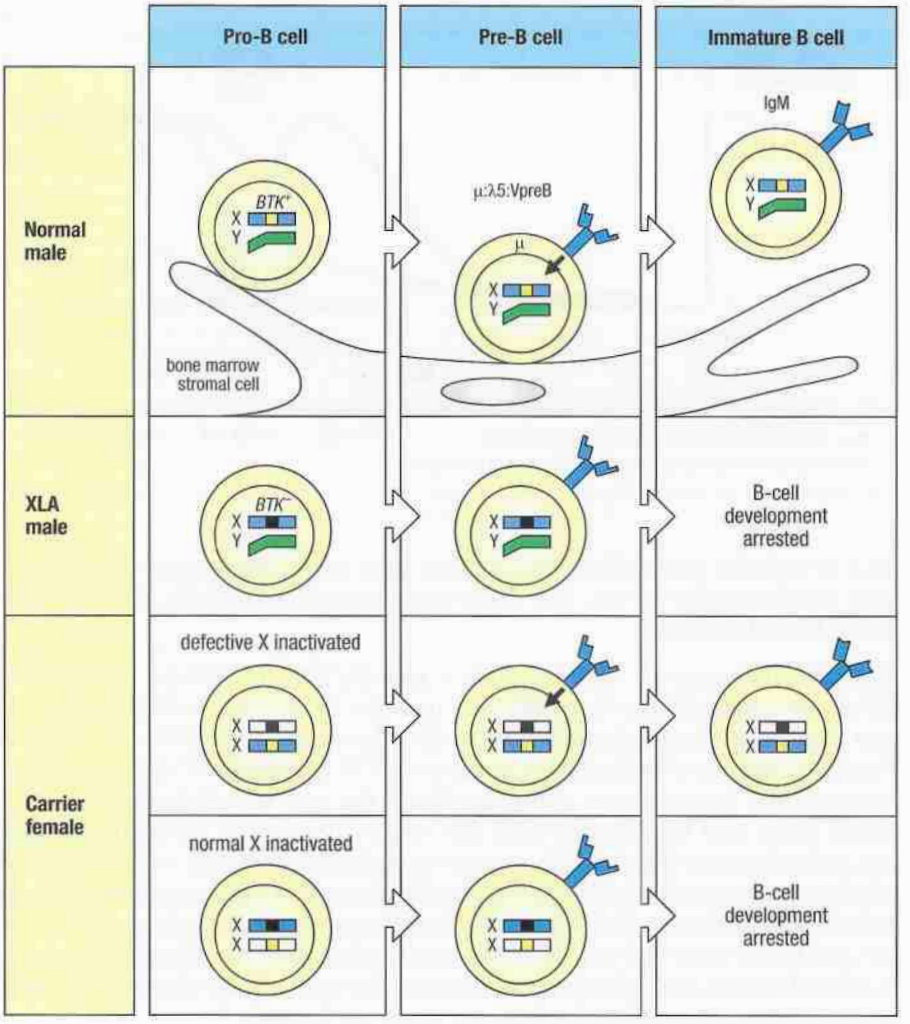

Fig. 13.6 The product of the gene *BTK* is important for B-cell development. In X-linked agammaglobulinemia (XLA), a protein tyrosine kinase of the Tec family called BTK, which is encoded on the X chromosome, is defective. In normal individuals, B-cell development proceeds through a stage in which the pre-B-cell receptor, consisting of μλ5:VpreB (see Section 8-3), transduces a signal via BTK, triggering further B-cell development. In males with XLA, no signal can be transduced and, although the pre-B-cell receptor is expressed, the B cells develop no further. In female mammals, including humans, one of the two X chromosomes in each cell is permanently inactivated early in development. Because the choice of which chromosome to inactivate is random, half of the pre-B cells in a carrier female will have inactivated the chromosome with the wild-type *BTK*, meaning that they can express only the defective *BTK* and cannot develop further. Therefore, in the carrier, mature B cells always have the nondefective X chromosome active. This is in sharp contrast to all other cell types, which have the nondefective X chromosome active in only half of their cells. Nonrandom X-inactivation in a particular cell lineage is a clear indication that the product of the X-linked gene is required for the development of cells of that lineage. It is also sometimes possible to identify the stage at which the gene product is required, by detecting the point in development at which X-inactivation develops bias. Using this kind of analysis, one can identify carriers of X-linked traits such as XLA without needing to know the nature of the mutant gene.

of donors. Because there are antibodies against many common pathogens in this pooled immunoglobulin, it serves as a fairly successful shield against infection.

13-8 Combined immunodeficiencies (CIDs) can be caused by defects in T-cell differentiation and function that impair activation of B cells, dendritic cells and macrophages, and innate effector cells.

After their development in the thymus or bone marrow, T and B cells require antigen-driven activation and differentiation to mount effective immune responses. Similar to defects in early T-cell development, defects in T-cell activation and differentiation that occur after thymic selection can have an impact on cell-mediated immunity, antibody responses, or both, the latter resulting in CID. In the case of B cells, cell-intrinsic defects in their activation and differentiation result in defects in antibody responses but have limited effects on cell-mediated immunity. A shared feature of PIDs that result from impaired T-dependent antibody responses, whether caused by defects in T-cell helper function or B cell–intrinsic defects, is a deficiency of class-switched antibody isotypes (that is, IgG, IgA, and IgE) that is typically accompanied by a compensatory increase in production of IgM antibodies, referred to as **hyper IgM syndrome**.

CD40 Ligand Deficiency

The most common cause of hyper IgM syndrome is **CD40 ligand deficiency**, or X-linked hyper IgM syndrome, which is a form of CID caused by mutations

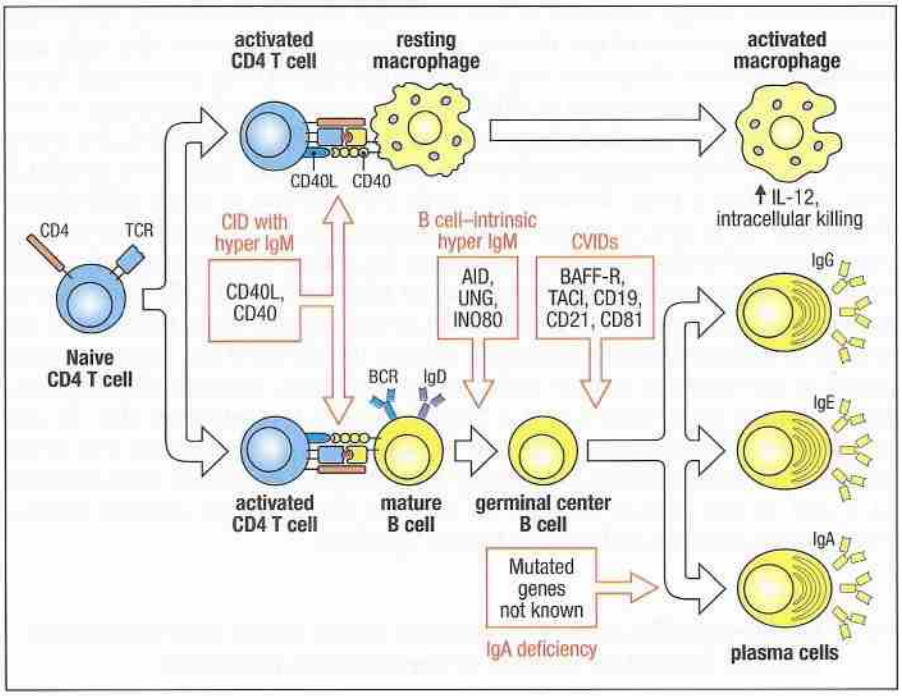

Fig. 13.7 Defects in T-cell and B-cell activation and differentiation cause immunodeficiencies. The pathways leading to activation and differentiation of naive T cells and B cells are shown. The protein products of genes known to be mutated in the relevant human immunodeficiency diseases are indicated in red boxes. BCR, B-cell receptor; CD40L, CD40 ligand; CID, combined immunodeficiency; CVIDs, common variable immunodeficiencies; TCR, T-cell receptor. Note that the defect in cytoskeletal function in Wiskott–Aldrich syndrome (WAS) affects immune-cell function at many steps in this schema and is not included in the figure for the sake of clarity.

in the gene encoding CD40 ligand, or CD154 (*CD40LG*) (Fig. 13.7). CD40 ligand is normally expressed on activated CD4 T cells, enabling them to deliver a key activating signal to classical antigen-presenting cells—B cells, dendritic cells, and macrophages—via engagement of CD40 (see Section 10-4). In individuals with damaging variants of *CD40LG*, T_{FH} cells fail to activate naive B cells to undergo differentiation into germinal center B cells, resulting in failed heavy-chain class switching, somatic hypermutation, and germinal center formation (Fig. 13.8). This results in severe reductions in circulating levels of all antibody isotypes except IgM, causing heightened susceptibility to infections that require high-affinity, class-switched antibodies for their clearance.

Because CD40 signaling is also required for the complete activation of dendritic cells and macrophages, including the heightened production of IL-12, which is important for the production of IFN-γ by T_H1 cells and NK cells (see Sections 11-3 and 11-6), individuals with CD40 ligand deficiency also have defects in type 1 immunity and thus manifest a form of CID, as well as hyper IgM syndrome. Inadequate cross-talk between T cells and dendritic cells via CD40L–CD40 interaction can lead to lower levels of co-stimulatory molecules on dendritic cells, thus impairing their ability to stimulate naive T cells (see Sections 9-11 and 9-13). Thus, in addition to their susceptibility to infection by extracellular pathogens that require class-switched antibodies, such as pyogenic bacteria, the individuals also have defects in the clearance of intracellular pathogens, such as mycobacteria, and are particularly prone to opportunistic infections by *Pneumocystis jirovecii*, which is normally killed by activated macrophages. Not unexpectedly, a similar syndrome has been identified in individuals with damaging variants in the gene encoding CD40 (*CD40*), which has been found in rare cases with an autosomal recessive variant of CID and hyper IgM syndrome (see Fig. 13.7). Here, the defective expression of CD40 by B cells, dendritic cells, and macrophages causes their inability to be activated by CD40 ligand, resulting in disease that closely phenocopies CD40 ligand deficiency.

Another CID is characterized by elevations in IgE, referred to as **hyper IgE syndrome (HIES)**, or **Job syndrome**. The most common example is **STAT3 deficiency**, which is characterized by recurrent skin and pulmonary infections caused by pyogenic bacteria, chronic mucocutaneous candidiasis

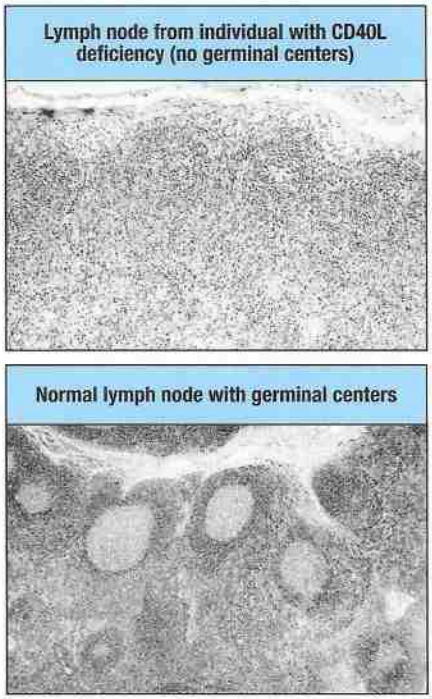

Fig. 13.8 Individuals with CD40 ligand deficiency are unable to activate B cells to form germinal centers. Lymphoid tissues in individuals with CD40 ligand deficiency, which manifests as a deficiency of high-affinity, class-switched antibody isotypes and hyper IgM syndrome, are devoid of germinal centers (top panel), unlike a normal lymph node (bottom panel). B-cell activation by T cells is required both for isotype switching and for the formation of germinal centers, where extensive B-cell proliferation takes place.

Hyper IgE Syndrome

(noninvasive fungal infection of the skin and mucosal surfaces), very high serum concentrations of IgE, chronic eczematous dermatitis or skin rash, and skeletal and dental abnormalities. The inherited defect is an autosomal dominant loss-of-function variant of STAT3, which is activated downstream of several cytokine receptors, including those for IL-6, IL-21, IL-22, and IL-23, and is central to the differentiation and/or function of T_{FH} cells, T_H17 cells, and ILC3 cells, as well as B cells. Because T_{FH} cells are deficient in these individuals, T-cell help for B cells is compromised, resulting in poor production of most class-switched antibodies. The exception is IgE, which is abnormally elevated, hence the designation of this disease as an HIES variant of CID. The cause of the elevated IgE is not understood, and it is unclear why these individuals fail to have heightened allergic responses despite the elevated IgE. Because of the defect in development of T_H17 cells and ILC3 function, recruitment of neutrophils normally orchestrated by IL-17 is defective, as is production of IL-22, the receptor for which normally activates STAT3 signaling in epithelial cells of the skin and mucosal barriers to enhance antimicrobial resistance (see Sections 11-3 and 12-20). This is thought to underlie the impaired defense against extracellular bacteria and fungi at barrier epithelia.

13-9 B cell–specific activation defects cause hyper IgM syndromes that are limited to defects in the antibody response.

Some variants of hyper IgM syndrome are due to intrinsic defects in the process of B-cell activation that impair normal development of the germinal center response, resulting in defective class switch recombination and/or somatic hypermutation. Individuals with these variants are susceptible to severe extracellular bacterial infections, but because T-cell differentiation and function are spared, they have no increased susceptibility to intracellular pathogens or opportunistic agents, such as *P. jirovecii,* and thus do not have CID. One such variant is due to loss-of-function mutations in activation-induced cytidine deaminase (AID), which is required for both isotype class switching and somatic hypermutation in B cells (see Fig. 13.7 and Section 10-7). In individuals with autosomally inherited defects in the gene that encodes AID (*AICDA*), hyper IgM syndrome is accompanied by the accumulation of defective germinal center B cells in abnormal germinal centers, causing enlargement of the lymph nodes and spleen. Other variants of B cell–intrinsic hyper IgM syndrome have been identified in individuals with autosomal recessive defects in genes that encode factors involved in class switch recombination in B cells, including the DNA repair enzyme uracil-DNA glycosylase (UNG; see Section 10-10) and the chromatin remodeling complex INO80; these individuals have normal AID function and normal somatic hypermutation, but defective class switching.

Activation-Induced Cytidine Deaminase Deficiency

13-10 Common variable immunodeficiency results from a variety of inherited defects that cause more limited defects in the antibody response.

Other examples of predominantly antibody deficiency include the most common forms of PID, referred to as **common variable immunodeficiencies (CVIDs)**. CVIDs are a clinically and genetically heterogeneous group of disorders that often go undiagnosed until late childhood or adulthood because the immune deficiency is relatively mild. Thus, CVIDs are sometimes referred to as late-onset hypogammaglobulinemias. Unlike other types of immunoglobulin deficiency, CVID is characterized by variable deficiencies in two or more antibody isotypes. Although the genetic basis for CVID is unknown in the large majority of cases, in the minority in which the affected gene has been identified, most result from B cell–intrinsic defects.

Common Variable Immunodeficiency

Defects in genes encoding receptors for the B-cell maturation and survival factors BAFF and APRIL, BAFF-R (*TNFRSF13C*) and TACI (*TNFRSF13B*), are among the identified gene variants known to cause B cell–intrinsic abnormalities that result in CVID (see Fig. 13.7 and Section 10-3). Individuals with these variants typically have decreased circulating IgG and IgA, with or without decreased IgM, but they have quite variable clinical presentations. Although some of these individuals have recurrent bacterial infections, many are asymptomatic. Other individuals with inherited B cell–intrinsic defects that result in CVID have damaging variants of the genes encoding CD19, CD21, and CD81, which are components of the B-cell co-receptor (see Section 7-20 and Fig. 13.7).

13-11 Unidentified genetic defects cause isotype-specific antibody deficiencies.

Selective **IgA deficiency**, the most common PID, exists in both sporadic and familial forms, and both autosomal recessive and autosomal dominant inheritance have been described. The etiology of IgA deficiency in most individuals is not understood, and many of these individuals are asymptomatic. In IgA-deficient individuals who do develop recurrent infections, an associated defect in one of the IgG subclasses (typically IgG2 and/or IgG4) is often found. Because secretory IgA is thought to play a role in homeostatic regulation of the microbiota in mucosal tissues (for example, the intestinal tract), there is an increased incidence of microbiota-associated immune-mediated disease in these individuals (for example, inflammatory bowel disease).

Similarly to individuals with selective IgA deficiency, individuals with selective **IgM deficiency** have normal levels of the other immunoglobulin isotypes and lack a defined genetic basis for their PID. In contrast to IgA deficiency, however, selective IgM deficiency is rare, and these individuals tend to have recurrent bacterial infections in infancy that are often severe, particularly those caused by encapsulated organisms, such as *Pneumococcus* species.

13-12 Normal pathways for host defense against different infectious agents are pinpointed by genetic deficiencies of cytokine pathways central to type 1/T_H1 and type 3/T_H17 responses.

Inherited defects in cytokines that are involved in the development and function of different effector T-cell subsets have been defined, as have defects in the receptors or the signaling pathways through which they act. In contrast to the T-cell immunodeficiencies considered earlier, here we consider deficiencies that do not have major defects in antibody production. A small number of families have been discovered that have individuals who suffer from persistent and sometimes fatal attacks by intracellular pathogens normally restrained by type 1 immunity, especially *Mycobacterium, Salmonella,* and *Listeria* species. These microbes are specialized for survival within macrophages, and their eradication requires enhanced microbicidal activities induced by IFN-γ produced by type 1 cells: NK cells, ILC1 cells, and T_H1 cells (see Section 11-2). Accordingly, susceptibility to these infections is conferred by a variety of inherited mutations that impair or abolish the function of IL-12 or IFN-γ, key cytokines in the development and functions of type 1 cells (Fig. 13.9). Individuals with mutations in the genes encoding the p40 subunit of IL-12 (*IL12B*), the IL-12 receptor β_1 chain (*IL12RB1*), and the two subunits (R1 and R2) of the IFN-γ receptor (*IFNGR1* and *IFNGR2*) have been identified. Although affected individuals have heightened susceptibility to the more virulent *Mycobacterium tuberculosis*, they suffer more frequently from the

Interferon-γ Receptor Deficiency

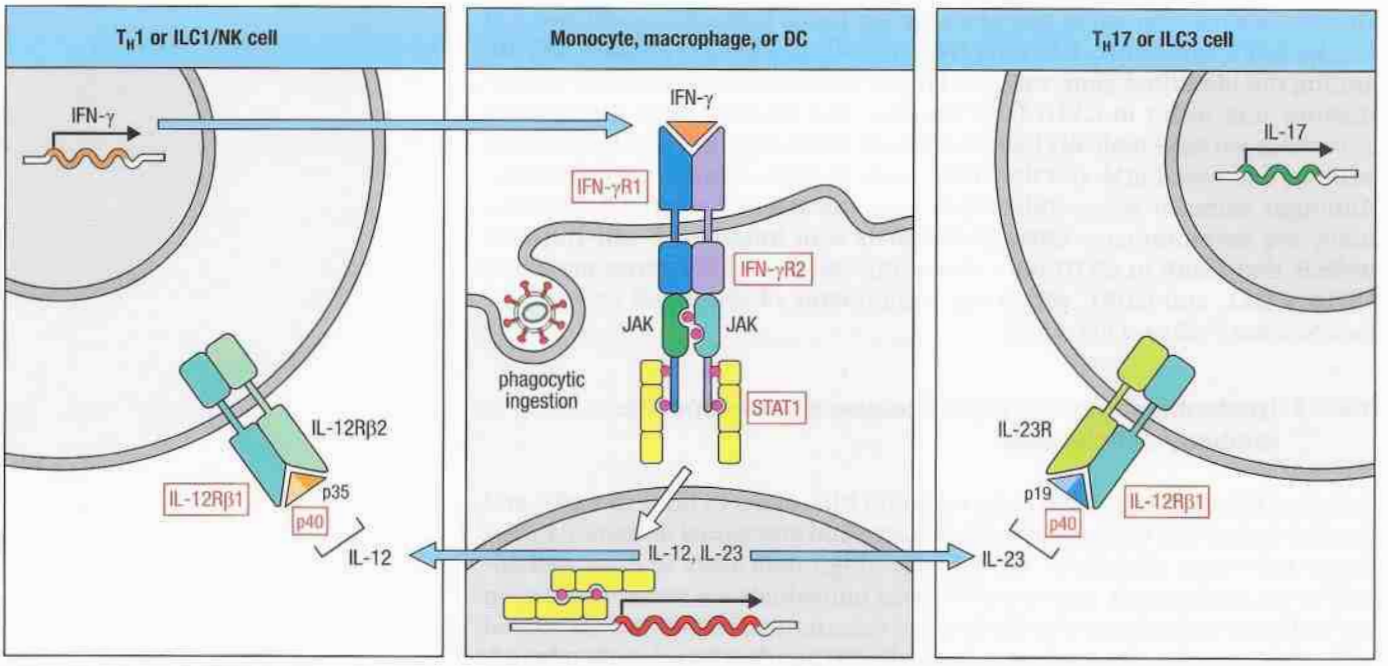

Fig. 13.9 Inherited defects in effector cytokine pathways that impair type 1/T_H1 and type 3/T_H17 immunity. Shown are pathways in IL-12, IL-23, and IFN-γ signaling for which inherited defects have been described. Note that defects in IL-12p40 (p40) and IL-12Rβ1 result in impaired function of both ILC1 cells/NK cells/T_H1 cells and ILC3 cells/T_H17 cells because these subunits are shared, respectively, by IL-12 and IL-23, and their receptors. Also, because STAT1 is activated by the receptors of type II interferon (IFN-γ) and type I interferons (IFN-α and IFN-β, not shown), defects in STAT1 result in impaired antibacterial and antiviral immune defense, whereas deficiency in either of the IFN-γ receptor subunits (IFN-γR1 or IFN-γR2) primarily results in impaired defense against intracellular bacteria.

non-tuberculous, or atypical, opportunistic strains of mycobacteria, such as *Mycobacterium avium*, likely due to the greater prevalence of atypical strains in the environment. They may also develop disseminated infection after vaccination with *Mycobacterium bovis* bacillus Calmette–Guérin (BCG), the strain of *M. bovis* that is used as a live vaccine against *M. tuberculosis*. Because the IL-12p40 subunit is shared by IL-12 and IL-23, IL-12p40 deficiency results in a broader infectious disease risk due to defective type 1 and type 3 (T_H17/ILC3) functions (**Fig. 13.10**; see also Fig. 13.9). Similarly, deficiency of IL-12Rβ1 chain, which is shared by the IL-12 and IL-23 receptors, results in broader susceptibilities than the deficiencies of IFN-γ or its receptor.

Fig. 13.10 Immune deficiencies with defects in T_H17/ILC3 function. Nearly all T_H17/ILC3 immune deficiencies result in chronic mucocutaneous candidiasis (CMC). *Deficiencies of IL-12p40 and IL-12Rβ1 also result in T_H1/ILC1/NK cell deficits. †It is currently unclear whether STAT1 gain-of-function mutations cause ILC3 deficits in addition to reduced numbers of T_H17 cells.

Disease	Mutated gene	Inheritance	Immune phenotype	Associated infections
STAT3 deficiency; hyper IgE syndrome (Job syndrome)	*STAT3*	Autosomal dominant	Deficit of IL-17–producing T_H17 and ILC3 cells; hyper IgE	CMC, *Staphylococcus aureus*, *Aspergillus*
IL-12p40 deficiency	*IL12B*	Autosomal recessive	Deficit of IL-17–producing T_H17 and ILC3 cells*	Intracellular and extracellular bacteria, CMC
IL-12Rβ deficiency	*IL12RB1*	Autosomal recessive	Deficit of IL-17–producing T_H17 and ILC3 cells*	Intracellular and extracellular bacteria, CMC
IL-17RA deficiency	*IL17RA*	Autosomal recessive	No IL-17 response	CMC, pyogenic bacteria
IL-17F deficiency (partial)	*IL17F*	Autosomal recessive	Impaired IL-17F function	CMC, pyogenic bacteria
CARD9 deficiency	*CARD9*	Autosomal recessive	Deficit of IL-17–producing T_H17 and ILC3 cells	CMC and severe *Candida*/dermatophyte infections
STAT1 gain-of-function (GOF) mutation	*STAT1*	Autosomal dominant	Deficit of IL-17–producing T_H17 and ILC3 cells†	CMC, pyogenic bacteria
APECED syndrome	*AIRE*	Autosomal recessive	Neutralizing antibodies: IL-17A, IL-17F +/– IL-22	CMC

Autosomal recessive loss-of-function mutations in *STAT1* impair IFN-γ receptor signaling and are also associated with increased susceptibility to infections by mycobacterial and other intracellular bacteria (see Fig. 13.9). However, because of the shared function of STAT1 in IFN-α receptor signaling in response to IFN-α and IFN-β (type I interferons), individuals with STAT1 defects are also susceptible to viral infections. Notably, individuals with partial loss of function of STAT1 have been identified who are susceptible to mycobacterial infections, but not viral infections, suggesting a more stringent requirement of STAT1 in protection against the former.

In addition to the T_H17-related defects described earlier for STAT3-deficient HIES (see Section 13-8), other defects in cytokine-mediated functions of this pathway have been identified that lack the hyper IgE component. Whereas heightened susceptibility to intracellular bacteria is a feature common to immunodeficiencies that impair type 1 immunity, heightened susceptibility to infections by fungi (e.g., *Candida albicans*) and pyogenic bacteria (e.g., *Staphylococcus aureus*) are characteristics of these type 3 deficiencies. This reflects the specialized function of T_H17 cells and ILC3 cells in barrier defense against fungi and extracellular bacteria. Inherited deficiencies in IL-17RA, the shared receptor component for homodimeric and heterodimeric IL-17F–IL-17A ligands, as well as deficiency of IL-17F itself, confer susceptibility to these infectious agents and thus identify a key role for IL-17 cytokines in host defense against them. A similar susceptibility to chronic mucocutaneous candidiasis and pyogenic bacteria has been found in individuals with autosomal dominant, gain-of-function mutations in *STAT1*. Because T_H17 cell development is impaired by STAT1 signaling downstream of several cytokine receptors (for example, type I and type II IFN receptors), individuals with these mutations have impaired type 3 defenses because of heightened STAT1 activity. Note that this is in contrast to individuals with loss-of-function *STAT1* mutations, who are predisposed to intracellular bacterial infections because of defective type 1 immunity.

In addition to inherited defects in effector cytokine genes, some forms of immunodeficiency result in the production of neutralizing autoantibodies against these cytokines. This results in infectious risks similar to those caused by primary cytokine deficiencies. Most individuals with APECED syndrome (caused by defects in *AIRE*; see Section 13-6) develop chronic mucocutaneous candidiasis that is due to the development of autoantibodies against IL-17A, IL-17F, and/or IL-22. Individuals with neutralizing autoantibodies against IFN-γ who have impaired protection against atypical mycobacteria have also been reported, consistent with impaired type 1 responses in these individuals.

13-13 Inherited defects in the cytolytic pathway of lymphocytes can cause uncontrolled lymphoproliferation and inflammatory responses to viral infections.

Hemophagocytic Lymphohistiocytic Syndrome

Cytotoxic granules are formed from components of late endosomes and lysosomes. Once formed, there are multiple steps in the exocytosis of cytotoxic granules from cytotoxic cells and their delivery to target cells. The importance of the cytolytic pathway in immune regulation is highlighted by inherited defects that impair key steps in either the formation or exocytosis of cytotoxic granules (**Fig. 13.11**). These result in a severe and often fatal condition, known as **hemophagocytic lymphohistiocytic (HLH) syndrome**, which manifests as uncontrolled activation and expansion of CD8 T lymphocytes and macrophages that infiltrate multiple organs, causing tissue necrosis and organ failure. The hyperactive immune response is thought to reflect the inability of cytotoxic cells to destroy infected targets, and possibly themselves, after an initiating viral infection, particularly by a herpes family virus such as Epstein–Barr virus (EBV). In this regard it is notable that despite the impaired release

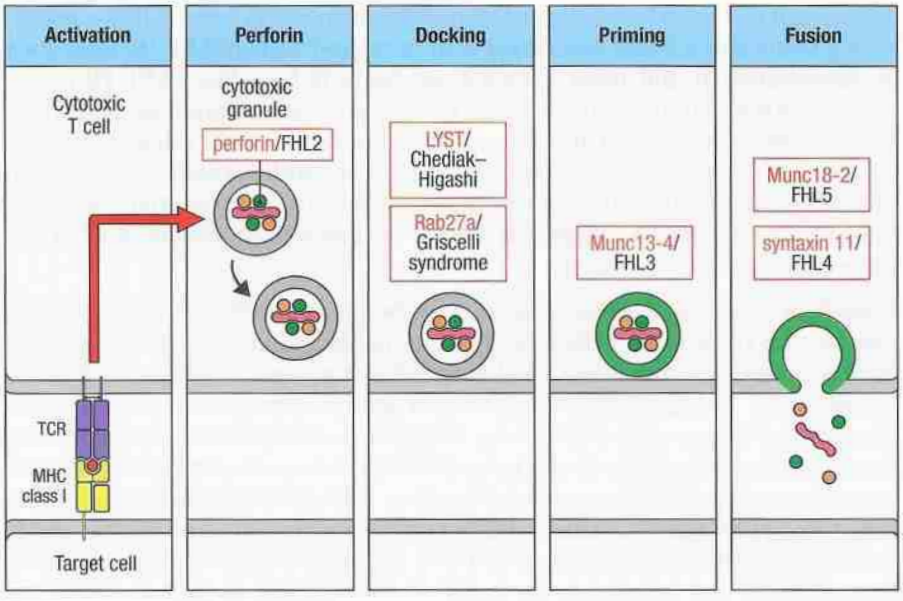

Fig. 13.11 Defects in components involved in the exocytosis of cytotoxic granules cause familial hemophagocytic lymphohistiocytosis (FHL) syndromes. After antigen recognition, there is polarization of perforin-containing cytotoxic granules of the cytotoxic T lymphocyte (CTL) toward the target cell at the site of immunological synapse formation. Cytotoxic granules are transported along microtubules to the plasma membrane, where they dock through a Rab27a-dependent interaction. Docked vesicles are primed by Munc13-4–mediated triggering of a conformational change in syntaxin 11, which is part of a large SNARE (soluble *N*-ethylmaleimide–sensitive factor accessory protein receptor) complex connecting the docked vesicle with the plasma membrane. Through the actions of Munc18-2, a fusion reaction is initiated via the syntaxin 11–containing SNARE complex that releases the contents of the cytotoxic granules into the synapse-bounded intercellular space, allowing perforin-mediated pore formation in the target-cell plasma membrane. The sites in the exocytic pathway that are affected by inherited defects in each of the proteins highlighted in red are indicated, as are the associated familial hemophagocytic lymphohistiocytosis syndromes.

of cytotoxic granules, the release of IFN-γ by cytotoxic T lymphocytes (CTLs) and NK cells of individuals with this disorder is not typically impaired, which contributes to the heightened activity of macrophages and the associated inflammatory disorder caused by an increased release of pro-inflammatory cytokines such TNF, IL-6, and macrophage colony-stimulating factor (M-CSF). The activated macrophages phagocytose blood cells, including erythrocytes and leukocytes, which gives the syndrome its name.

There are multiple autosomal recessive variants of HLH, also referred to as **familial hemophagocytic lymphohistiocytosis (FHL)**, that are distinguished by the protein in the cytolytic pathway that is affected (see Fig. 13.11). Examples include inherited deficiencies of the following: the cytotoxic granule protein perforin, which is required for pore formation in the target cell (and when defective is associated with the syndrome FHL2); the priming protein, Munc13-4 (FHL3); syntaxin 11 (FHL4), a member of the SNARE family of proteins that mediate membrane fusion; and Munc18-2 (FHL5), a protein involved in the reorganization of SNARE proteins to activate the fusion process. Because components of the biogenesis and exocytosis of cytotoxic granules are shared with other secretory vesicles, such as lysosomes, additional immune defects can occur in affected individuals, as can nonimmune defects. In particular, a subset of the immunodeficiencies that affect cytotoxic granule function are also characterized by partial loss of skin pigmentation. This is due to defects in vesicular transport proteins that are also required for the formation or exocytosis of melanosomes, organelles that store the skin pigment melanin in melanocytes. Examples of these immunodeficiencies include **Chediak–Higashi syndrome**, caused by autosomal recessive mutations in the protein LYST (or CHS1), which regulates lysosomal trafficking, and **Griscelli syndrome**, caused by mutations in a small GTPase, Rab27a, which is integral to the tethering of certain vesicles, including cytotoxic granules, to cytoskeletal structures to enable their intracellular trafficking.

Chediak–Higashi Syndrome

In Chediak–Higashi syndrome, abnormal giant lysosomes and granules accumulate in T lymphocytes, myeloid cells, platelets, and melanocytes. The hair is typically a metallic silver color, vision is poor because of abnormalities in retinal pigment cells, and platelet dysfunction causes increased bleeding. Because the phagocytes of these individuals have defective phagolysosomal fusion, the individuals experience defective killing of intracellular and extracellular pathogens. In addition, they have defective cytolytic activity of CTLs and NK cells, thought to be due to the abnormal enlargement of cytotoxic

granules that fail to dock properly. Affected children therefore suffer early in life from severe, recurrent infections by a range of bacteria and fungi. This is typically followed by development of hemophagocytic lymphohistiocytosis, often triggered by viral infection such as EBV, leading to an accelerated phase of the disease. Three variants of Griscelli syndrome have been identified, each caused by a distinct gene defect: in the type 2 variant (*RAB27A* mutation), the defect results in both immunodeficiency and pigment abnormalities; in types 1 and 3, only the pigment abnormalities are found. Although the immune defects in children with type 2 Griscelli syndrome have much in common with those of Chediak–Higashi syndrome, their myeloid cells lack the giant intracellular granules that are characteristic of the latter.

13-14 X-linked lymphoproliferative syndrome is associated with fatal infection by Epstein–Barr virus and the development of lymphomas.

In some primary immunodeficiencies, there is unique susceptibility to a single pathogen. Such is the case for two rare X-linked immunodeficiencies with a similar lymphoproliferative defect that results from vulnerability to a herpes family virus, the Epstein–Barr virus (EBV), albeit via independent mechanisms. EBV specifically infects B cells and typically causes a self-limiting infection in normal individuals, which is the result of active control of the virus by the actions of NK cells, NKT cells, and cytotoxic T cells that have specificity for B cells expressing EBV antigens. After the development of immunity to EBV, the virus is not completely cleared, but is maintained in a latent state in infected B cells (see Section 13-27). In the presence of certain types of immunodeficiency, however, this control can break down, resulting in overwhelming EBV infection (severe infectious mononucleosis) that is accompanied by unrestrained proliferation of EBV-infected B cells and cytotoxic T cells, hypogammaglobulinemia (low levels of circulating immunoglobulins), and the potential for the development of lethal, non-Hodgkin's B-cell lymphomas. These occur in the rare immunodeficiency **X-linked lymphoproliferative (XLP) syndrome**. XLP syndrome results from mutations in one of two X-linked genes: the SH2 domain–containing gene 1A (*SH2D1A*), which encodes SAP [signaling lymphocyte activation molecule (SLAM)-associated protein], or the X-linked inhibitor of apoptosis gene (*XIAP*).

In XLP1, which accounts for approximately 80% of individuals with this syndrome, the defect in SAP results in defective coupling of immune-cell receptors of the SLAM family to the Src family tyrosine kinase Fyn in T cells, NKT cells, and NK cells (Fig. 13.12). SLAM family members interact through

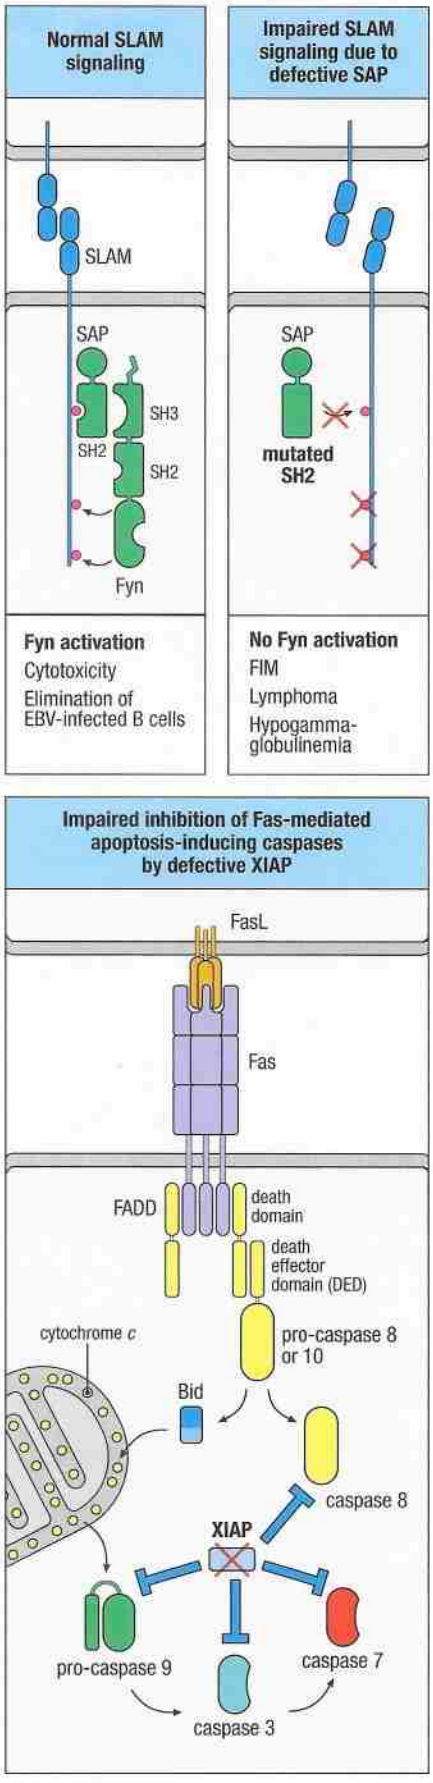

Fig. 13.12 X-linked lymphoproliferative (XLP) syndrome is caused by inherited defects in SAP and XIAP, resulting in abnormal SLAM and TNF family receptor signaling, respectively. SLAM is an immune receptor family, members of which are expressed by T cells, B cells, NK cells, dendritic cells, and macrophages. Signaling is initiated via homotypic or heterotypic interactions between family members. SLAM signaling recruits the Src homology 2 (SH2) domain–containing factor SAP, which recognizes tyrosine-based motifs in the cytoplasmic domain of SLAM to activate the Src-related tyrosine kinase Fyn (left upper panel). Fyn then phosphorylates additional tyrosine residues of SLAM to recruit additional signaling components. Mutation in SAP in individuals with XLP1 (right upper panel) disrupts activation of Fyn and SLAM signaling, thereby impairing T- and NK-cell cytotoxicity, which results in severe Epstein–Barr virus (EBV) infections (fulminant infectious mononucleosis, or FIM) and lymphoma. Defective SLAM signaling also impairs up-regulation of expression of the T-cell co-stimulator ICOS (inducible co-stimulatory protein) in T_{FH} cells, which results in impaired antibody responses. Activation of apoptosis-inducing caspases by TNF family receptors, such as Fas, is normally inhibited by XIAP (lower panel). XIAP interacts with both initiator caspases (8 and 9) and executioner caspases (3 and 7) to inhibit their actions, such as cleavage and activation of the Bcl-2 family sentinel protein, Bid. In individuals with XLP2, XIAP is defective, resulting in abnormal regulation of caspase activation that leads to the complex clinical phenotype, which includes lymphoproliferation and defective control of EBV virus.

X-linked Lymphoproliferative Syndrome

homotypic or heterotypic binding to modulate the outcome of interactions between T cells and antigen-presenting cells and between NK cells and their target cells. In the absence of SAP, ineffective EBV-specific cytotoxic T-cell and NK-cell responses are made, and there is severe deficiency of NKT cells, indicating that SAP has a nonredundant role in the control of EBV infection and the development of NKT cells. There is unchecked proliferation of EBV-reactive cytotoxic T cells and NK cells that results in systemic macrophage activation, inflammation, and hemophagocytic features similar to those that occur in immunodeficiencies caused by defects in the cytolytic pathway (see Section 13-13). Moreover, defective SLAM signaling between T_{FH} cells and B cells of individuals with XLP1 causes impaired T-dependent antibody responses and hypogammaglobulinemia.

Defects in the XIAP protein, which normally binds the TNF receptor–associated factors TRAF1 and TRAF2 and inhibits the activation of apoptosis-inducing caspases (see Section 7-23), leads to a similar X-linked syndrome called **XLP2** (see Fig. 13.12). XIAP deficiency results in the enhanced apoptosis and turnover of activated T cells and NK cells. Paradoxically, this leads to a lymphoproliferative phenotype similar to that of XLP1, the basis of which is not well understood. As in XLP1, there is severe depletion of NKT cells in XLP2, indicating that, like SAP, XIAP is required for the normal maintenance of these cells. Also as in XLP1, there is defective control of EBV infection in XLP2, although this is less prominent. The exact reason for the impaired suppression of EBV in these immunodeficiencies remains to be defined.

13-15 Immunodeficiency is caused by inherited defects in the development of dendritic cells.

Dendritic cells (DCs) are specialized antigen-presenting cells that link innate and adaptive immunity through their central role in activating naive T cells. We have already considered PIDs that include impaired functions of DCs (for example, IL-12p40 deficiency, CD40 deficiency; see Sections 13-12 and 13-8). Here we consider PIDs associated with impaired development of DCs. Our understanding of the diversity and function of DCs has advanced rapidly from studies of mice having lineage-specific, gene-targeted deletions of transcription factors that result in the loss of subsets of these cells, and from the defects in protection against specific pathogens that result as a consequence of the loss of specific DC subsets (see Section 9-7). In humans, where study of the development and function of DCs is more challenging, and in whom clinical workup for dendritic-cell deficiencies has not been a standard component of PID patient studies, the identification of PIDs that result from damaging variants in genes that impact DC development has lagged. Moreover, while defects in transcription factors that affect DC development have begun to be identified, these often affect other immune-cell lineages, complicating the immunodeficiency phenotype.

An autosomal dominant mutation in GATA2 has been identified in the largest group of individuals that have an inherited deficiency of dendritic cells. Affected individuals develop a progressive loss of all subsets of dendritic cells (conventional and plasmacytoid) and monocytes, as well as reduced numbers of B cells and NK cells, a condition that has been termed DCML (dendritic cell, monocyte, B and NK lymphoid) deficiency. Although T-cell numbers are normal in these individuals, their function becomes impaired as dendritic cells are lost. The loss of products of several hematopoietic lineages, but not all, suggests redundancy of the function of GATA2 in unaffected lineages. The basis for the progressive decline in products of the affected lineages is unknown but is thought to reflect a role for GATA2 in maintaining stem-cell progenitors that seed these populations. Given the deficiency of all dendritic and monocyte cells, the immune defects in these individuals are diverse, as are pathogen

susceptibilities. These individuals also have a substantial risk of hematologic malignancies.

Rare inherited defects in interferon regulatory factor 8 (IRF8) are associated with developmental abnormalities of monocytes and dendritic cells. In an autosomal recessive form, there is loss of monocytes and all types of circulating dendritic cells (conventional and plasmacytoid dendritic cells), as well as NK-cell deficiency. This suggests a difference in the role of IRF8 in the development of human and mouse DCs, as deficiency of the latter targeted to myeloid cells results in a relatively specific deficiency of type 1 conventional dendritic cells (cDC1 cells). Because dendritic cells are the primary antigen-presenting cells for naive T cells, this deficiency in humans results in impaired development of effector T cells, and these individuals are susceptible to a range of severe opportunistic infections early in life, including those caused by intracellular bacteria, viruses, and fungi.

13-16 Defects in complement components and complement-regulatory proteins cause defective humoral immune function and tissue damage.

The diseases discussed so far are mainly due to defects that have substantial impact on the adaptive immune system. In the next few sections we look at selected PIDs that are limited to cells and molecules of the innate immune system. We start with the complement system, which can be activated by any of three pathways that converge on the cleavage and activation of complement component 3 (C3), allowing it to bind covalently to pathogen surfaces where it acts as an opsonin (discussed in Chapter 2). Not surprisingly, the spectrum of infections associated with complement deficiencies overlaps substantially with that seen in individuals with deficiencies in antibody production. In particular, there is increased susceptibility to extracellular bacteria that require opsonization by antibody and/or complement for efficient clearance by phagocytes (Fig. 13.13). Defects in the activation of C3 by any of the three pathways, as well as defects in C3 itself, are associated with increased susceptibility to infection by a range of pyogenic bacteria, including *Streptococcus*

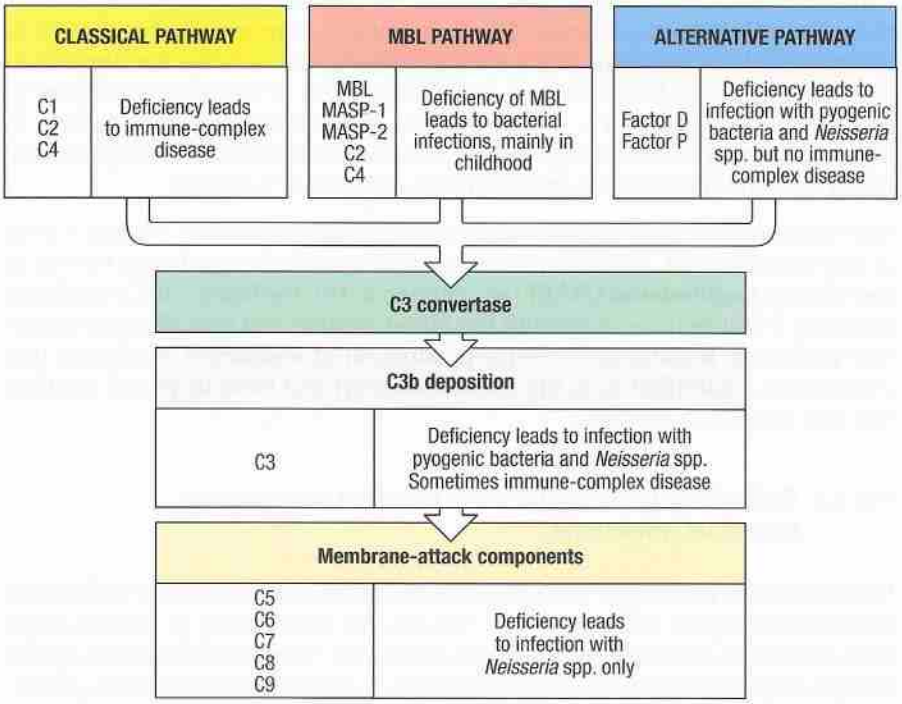

Fig. 13.13 Defects in complement components are associated with susceptibility to certain infections and the accumulation of immune complexes. Defects in the early components of the alternative pathway and in C3 lead to susceptibility to extracellular pathogens, particularly pyogenic bacteria. Defects in the early components of the classical pathway predominantly affect the processing of immune complexes and the clearance of apoptotic cells, leading to immune-complex disease. Deficiency of mannose-binding lectin (MBL), the recognition molecule of the mannose-binding lectin pathway, is associated with bacterial infections, mainly in early childhood. Defects in the membrane-attack components are associated only with susceptibility to strains of *Neisseria* species, the causative agents of meningitis and gonorrhea, implying that the effector pathway is important chiefly in defense against these organisms.

pneumoniae, emphasizing the role of C3 as a central effector that promotes the phagocytosis and clearance of encapsulated bacteria.

Deficiency of C8 Complement Component

In contrast, defects in the membrane-attack components of complement (C5–C9) downstream of C3 activation have more limited effects and result almost exclusively in susceptibility to *Neisseria* species. A similar susceptibility to *Neisseria* species is found in individuals with defects in the alternative complement pathway components, factor D and factor P, indicating that defense against these bacteria, which can survive intracellularly, is largely mediated via antibody-independent extracellular lysis by the membrane-attack complex. Data from large population studies in Japan, where endemic *Neisseria meningitidis* infection is rare, show that the risk each year of infection with this organism is approximately 1 in 2,000,000 to a normal person. This compares with a risk of 1 in 200 to a person in the same population who has an inherited deficiency of one of the membrane-attack complex proteins—a 10,000-fold increase in risk.

The early components of the classical complement pathway are particularly important for the elimination of immune complexes and apoptotic cells, which can cause significant pathology in autoimmune diseases such as systemic lupus erythematosus. This aspect of inherited complement deficiency is discussed in Chapter 15. Deficiency of mannose-binding lectin (MBL), which initiates complement activation independently of antibody (see Section 2-6), is relatively common (found in more than 5% of the population). In the majority of individuals who have reduced but not absent levels, MBL deficiency is often clinically silent. However, in those with complete MBL deficiency, there is increased susceptibility to bacterial infections, such as pneumonia or meningitis in early childhood. A similar phenotype is found in individuals with defects in the gene that encodes the MBL-associated serine protease-2 (*MASP2*).

Systemic Lupus Erythematosus

Hereditary Angioedema

Another set of complement-related diseases is caused by defects in complement-control proteins (Fig. 13.14). Deficiencies in decay-accelerating factor (DAF) or protectin (CD59), membrane-associated control proteins that protect the surfaces of the body's cells from complement activation, lead to destruction of red blood cells, resulting in the disease **paroxysmal nocturnal hemoglobinuria**, as discussed in Section 2-17. Deficiencies in soluble complement-regulatory proteins such as factor I and factor H have various outcomes. Homozygous **factor I deficiency** is a rare defect that results in uncontrolled activity of the alternative pathway C3 convertase, leading to a *de facto* C3 deficiency (see Section 2-16). Deficiencies in membrane cofactor of proteolysis (MCP), factor I, or factor H can also cause a condition known as **atypical hemolytic uremic syndrome**, so called because it leads to lysis of red blood cells (hemolysis) and impaired kidney function (uremia).

Complement protein	Effects of deficiency
C1, C2, C4	Immune-complex disease
C3	Susceptibility to encapsulated bacteria
C5–C9	Susceptibility to *Neisseria*
Factor D, Factor P (properdin)	Susceptibility to encapsulated bacteria and *Neisseria* but no immune-complex disease
Factor I	Similar effects to deficiency of C3
MCP, factor I, or factor H	Atypical hemolytic uremic syndrome
Polymorphisms in factor H	Age-related macular degeneration
DAF, CD59	Autoimmune-like conditions, including paroxysmal nocturnal hemoglobinuria
C1INH	Hereditary angioedema (HAE)

Fig. 13.14 Defects in complement-control proteins are associated with a range of diseases.

A striking consequence of the loss of a complement-regulatory protein is seen in individuals with C1-inhibitor defects, which cause the syndrome known as **hereditary angioedema (HAE)** (see Section 2-16). Deficiency of C1 inhibitor results in a failure to regulate both the blood clotting and complement activation pathways, leading to excessive production of vasoactive mediators that cause fluid accumulation in the tissues (edema) and local laryngeal swelling that can result in suffocation.

13-17 Defects in phagocytic cells result in widespread bacterial infections.

Deficiencies in phagocyte numbers or function can be associated with severe immunodeficiency; indeed, a total absence of neutrophils is incompatible with survival in a normal environment. Phagocyte immunodeficiencies can be grouped into four general types: deficiencies in phagocyte production, phagocyte adhesion/motility, phagocyte activation by pattern-recognition receptors

Disease	Examples	Gene defect	Inheritance	Immune defect	Common infections
Severe congenital neutropenia	Elastase-2 deficiency (SCN1)	*ELANE*	AD	Neutrophil deficiency	Severe pyogenic bacterial infections
	GFI-1 deficiency (SCN2)	*GFI1*	AD		Severe pyogenic bacterial infections
	HAX1 deficiency (SCN3, or Kostmann's disease)	*HAX1*	AR		Severe pyogenic bacterial infections
	G6PC3 deficiency (SCN4)	*G6PC3*	AR		Severe pyogenic bacterial infections
Leukocyte adhesion deficiency	β2 integrin deficiency (LAD-1)	*ITGB2*	AR	Defective leukocyte extravasation	Ulcerating skin infections without pus
	GDP-fucose transporter deficiency (LAD-2)	*SLC35C1*	AR		Recurrent bacterial infections
	Kindlin-3 deficiency (LAD-3)	*FERMT3*	AR		Severe bacterial infections
TLR/IL-1R signaling defects	MyD88 deficiency	*MYD88*	AR	Impaired TLR and IL-1 receptor signaling	Noninvasive bacterial infections, skin and respiratory tract
	IRAK4 deficiency	*IRAK4*	AR		Noninvasive bacterial infections, skin and respiratory tract
	TLR-3 deficiency	*TLR3*	AD or AR	Impaired types I and III interferon responses	Herpes simplex and varicella-zoster encephalitis
	TRAF3 deficiency	*TRAF3*	AD		Herpes simplex and varicella-zoster encephalitis
Non-TLR PRR signaling defect	CARD9 deficiency	*CARD9*	AR	Defective phagocyte recognition of fungi; impaired T_H17 response	Invasive fungal infections
Chronic granulomatous disease	X-linked CGD	*CYBB*	XL	Impaired intracellular killing in neutrophils and monocyte/macrophages	Severe, recurrent bacterial infections of barrier tissues

Fig. 13.15 Defects in phagocytic cells are associated with persistence of bacterial infection, as well as some fungal and viral infections. Defects in neutrophil development caused by congenital neutropenias (for example, elastase-2 deficiency; HAX1 deficiency) result in profound defects in antibacterial defense. Impairment of the leukocyte integrins with a common β_2 subunit (CD18) or defects in the selectin ligand sialyl-Lewis^X prevent phagocytic cell adhesion and migration to sites of infection (leukocyte adhesion deficiency). Inability to transmit signals through Toll-like receptors (TLRs), due to defects in MyD88 or IRAK4, for example, or through non-TLR sensor molecules (for example, CARD9 deficiency) impairs the proximal sensing of many infectious agents by innate immune cells. The respiratory burst is defective in chronic granulomatous disease [for example, deficiency of NADP oxidase 2 (NOX2), which is encoded by *CYBB*], as well as in glucose-6-phosphate dehydrogenase (G6PD) deficiency and myeloperoxidase (MPO) deficiency (the latter two not shown). In chronic granulomatous disease (CGD), infections persist because neutrophil and macrophage activation is defective, leading to chronic stimulation of CD4 T cells and hence to granulomas. These diseases illustrate the critical role of phagocytes in removing and killing pathogenic bacteria. AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

(PRRs), and phagocyte killing of microorganisms (Fig. 13.15). We consider each in turn.

Severe Congenital Neutropenia

Inherited deficiencies of neutrophil production (**neutropenias**) are classified as either **severe congenital neutropenia (SCN)** or **cyclic neutropenia**. In severe congenital neutropenia, which can be inherited as a dominant or recessive trait, the neutrophil count is persistently less than 0.5×10^9 per liter of blood (normal numbers are 3×10^9 to 5.5×10^9 per liter). Cyclic neutropenia is characterized by fluctuation in neutrophil numbers from near normal to very low or undetectable with an approximate cycle time of 21 days, resulting in periodicity of infectious risk. The most common variant, SCN1, is caused by sporadic or autosomal dominant mutations of the gene that encodes neutrophil elastase (*ELANE*), a component of the azurophilic, or primary, granules involved in the degradation of phagocytosed microbes. Altered targeting of defective elastase-2 to granules causes apoptosis of developing myelocytes and a developmental block at the promyelocyte–myelocyte stage. Some mutations of *ELA2* cause cyclic neutropenia; how the mutant elastase causes a 21-day cycle in neutropenia is still a mystery. A rare autosomal dominant variant, SCN2, is caused by mutations in the oncogene *GFI1*, which encodes a transcriptional repressor that acts on *ELA2*. This finding arose from the

unexpected observation that mice lacking the protein Gfi-1 are neutropenic because of overexpression of *Ela2*.

Autosomal recessive forms of SCN have also been identified. Deficiency of the mitochondrial protein HAX1 leads to increased apoptosis in developing myeloid cells, resulting in a severe neutropenia referred to as SCN3, or **Kostmann's disease** (see Fig. 13.15). The heightened sensitivity of developing neutrophils to apoptosis is highlighted by SCN4, which is associated with genetic defects in glucose metabolism. Individuals with recessive mutations in the genes encoding the glucose-6-phosphatase catalytic subunit 3 (*G6PC3*) also demonstrate increased apoptosis during granulocyte development that results in neutropenia. Acquired neutropenia associated with chemotherapy, malignancy, or aplastic anemia is also associated with a similar spectrum of severe pyogenic bacterial infections. Finally, neutropenia can also be a feature of other PIDs, including CD40 ligand deficiency, CVID, XLA, Wiskott–Aldrich syndrome, and GATA2 deficiency. In some individuals with these PIDs, there is formation of autoantibodies that lead to accelerated destruction of neutrophils.

Defects in the migration of phagocytic cells to extravascular sites of infection can cause serious immunodeficiency. Leukocytes reach such sites by emigrating from blood vessels in a tightly regulated process (see Fig. 3.30). Deficiencies in the molecules involved in each stage of this process can prevent neutrophils and macrophages from penetrating infected tissues and are referred to as **leukocyte adhesion deficiencies (LADs)** (see Fig. 13.15). Deficiency in the leukocyte integrin common β_2 subunit CD18, which is a component of LFA-1, MAC-1, and p150:p95, prevents the migration of leukocytes into an infected site by abolishing the cells' ability to adhere tightly to the endothelium. Because it was the first LAD to be characterized, it is now referred to as type 1 LAD, or LAD-1, and is the most common variant of LAD. Reduced rolling of leukocytes on the endothelium has been described in rare individuals who lack the sialyl-Lewis^X antigen because of a deficiency in the GDP-fucose–specific transporter that is involved in the biosynthesis of sialyl-Lewis^X and other fucosylated ligands for the selectins. This is referred to as type 2 LAD, or LAD-2. Type 3 LAD, or LAD-3, results from deficiency of kindlin-3, a protein involved in the induction of the high-affinity binding state of β integrins required for firm adhesion. Each variant of LAD has an autosomal recessive pattern of inheritance and causes severe, life-threatening bacterial or fungal infections early in life that are characterized by impaired wound healing and, in pyogenic bacterial infections, the absence of pus formation. The infections that occur in these individuals are resistant to antibiotic treatment. LAD-3 is also associated with defects in platelet aggregation that cause increased bleeding.

Leukocyte Adhesion Deficiency

A key step in the activation of innate immune cells, including phagocytes, is their recognition of microbial-associated molecular patterns through pattern-recognition receptors (PRRs), such as Toll-like receptors, or TLRs (see Section 3-5). Several primary immunodeficiencies have been identified that are caused by defects in intracellular signaling components of TLRs. Signaling through all TLRs except TLR-3 requires the adaptor protein MyD88, which recruits and activates the kinases IRAK4 and IRAK1 required for downstream activation of the NFκB and MAP kinase pathways (see Fig. 13.15; see also Section 3-7). Autosomal recessive mutations in the genes encoding MyD88 or IRAK4 have a similar phenotype: recurrent, severe peripheral and invasive infections by pyogenic bacteria that elicit little inflammation, known as a **'cold' pyogenic infection**. Because TLRs and IL-1 family receptors are structurally related and are part of the same superfamily (IL-1 receptor/TLR superfamily), many of the signaling functions of MyD88 and IRAK4 molecules are shared with IL-1 family receptors. Thus, at least part of the immune defect in individuals with inherited abnormalities in these molecules may be attributed to aberrant signaling by IL-1 family members. Notably, increased viral infections are not typical in individuals with MyD88 mutations, despite this protein's role in

Interleukin-1 Receptor–Associated Kinase 4 Deficiency

signaling by each of the nucleic acid–sensing TLRs except TLR-3 (for example, TLR-7, TLR-8, and TLR-9). This indicates that activation of interferon regulatory factors (IRFs) that induce interferon responses downstream of these TLRs remains intact despite the defects in MyD88.

Recurrent Herpes Simplex Encephalitis

Remarkably, of the 10 TLRs found in humans, defects in only one—TLR-3—have been definitively linked to a PID (see Fig. 13.15). While defects in other TLRs have been identified (for example, TLR-4), they have not been associated with an overt immunodeficiency phenotype, likely reflecting a substantial level of redundancy. On the other hand, individuals with hemizygous (dominant) and homozygous (recessive) mutations in the gene encoding TLR-3, which senses double-stranded RNA, have recurrent herpes simplex virus 1 (HSV-1) or varicella-zoster virus (VZV) infections of the central nervous system (HSV or VZV encephalitis) because of impaired production of type I and type III interferons that act to limit viral infection of the CNS by enhancing blood–brain barrier function. Also, cells of the nervous system preferentially express the type III IFN receptor component, IFNLR1, rather than the type I IFN receptor, and rely on type III IFNs produced downstream of TLR-3 signaling to enhance antiviral resistance in the CNS.

Individuals with inherited deficiencies in molecules involved in TLR-3 signaling (for example, TRIF, TRAF3, TBK1, and IRF3), are similarly susceptible to herpes viral encephalitis, as are individuals with mutations in the TLR-transport protein UNC93B1, which is required for the transport of TLR-3 from the endoplasmic reticulum to the endolysosome. Notably, leukocytes from these individuals have no defect in their response to TLR-3 ligands or HSV-1, indicating redundancy of TLR-3 function in these cells, but not in those of the central nervous system. Similarly, these individuals show only a limited predisposition to other viral infections, implying the existence of TLR-3–independent protection against most other types of viral infection.

Genetic defects that affect signaling by PRRs other than TLRs have been described. CARD9 is an adaptor molecule involved in signaling downstream of C-type lectin receptors expressed on myeloid cells (see Fig. 13.15). Dectin-1, Dectin-2, and macrophage-inducible C-type lectin (MINCLE) each recognize fungal-associated molecular patterns that signal through CARD9 to induce secretion of pro-inflammatory cytokines, including IL-6 and IL-23. Autosomal recessive CARD9 deficiency results in impaired T_H17 cell responses to fungi, with the result that these individuals, similar to those with inborn errors of IL-17 immunity (for example, IL-17RA deficiency and IL-17F deficiency; see Section 13-12), suffer chronic mucocutaneous candidiasis. However, in addition, these individuals suffer more invasive infections by *Candida* spp. and dermatophytes, which are ubiquitous filamentous fungi that normally cause common superficial skin and nail infections, such as tinea pedis ('athlete's foot').

Chronic Granulomatous Disease

Most of the other known defects in phagocytic cells affect either their ability to ingest microbes or their ability to destroy microbes once ingested (see Fig. 13.15). Individuals with **chronic granulomatous disease (CGD)** are highly susceptible to bacterial and fungal infections and form granulomas as a result of an inability to kill bacteria ingested by phagocytes (see Fig. 13.15; see also Section 3.2). The defect in this case is in the production of reactive oxygen species (ROS) such as the superoxide anion. Discovery of the molecular defect in this disease gave weight to the idea that these agents killed bacteria directly; this notion has since been challenged by the finding that the generation of ROS is not itself sufficient to kill target microorganisms. It is now thought that ROS cause an influx of K^+ ions into the phagocytic vacuole, increasing the pH to the optimal level for the action of microbicidal peptides and proteins, which are the key agents in killing the invading microorganism.

Genetic defects affecting any of the constituent proteins of the NADPH oxidase expressed in neutrophils and monocytes (see Section 3-2) can cause

Disease (common abbreviation)	Clinical features	Inheritance	Mutated gene	Protein (alternative name)
Familial Mediterranean fever (FMF)	Periodic fever, serositis (inflammation of the pleural and/or peritoneal cavity), arthritis, acute-phase response	Autosomal recessive	*MEFV*	Pyrin
TNF receptor–associated periodic syndrome (TRAPS) (also known as familial Hibernian fever)	Periodic fever, myalgia, rash, acute-phase response	Autosomal dominant	*TNFRSF1A*	TNF-α 55 kDa receptor (TNFR-I)
Pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA)		Autosomal dominant	*PSTPIP1*	CD2-binding protein 1
Muckle–Wells syndrome	Periodic fever, urticarial rash, joint pains, conjunctivitis, progressive deafness	Autosomal dominant	*NLRP3*	Cryopyrin
Familial cold autoinflammatory syndrome 1 (FCAS1) (familial cold urticaria)	Cold-induced periodic fever, urticarial rash, joint pains, conjunctivitis			
Chronic infantile neurologic cutaneous and articular syndrome (CINCA)	Neonatal-onset recurrent fever, urticarial rash, chronic arthropathy, facial dysmorphia, neurologic involvement			
Hyper IgD syndrome (HIDS)	Periodic fever, elevated IgD levels, lymphadenopathy	Autosomal recessive	*MVK*	Mevalonate synthase
Blau syndrome	Granulomatous inflammation of skin, eye, and joints	Autosomal dominant	*NOD2*	NOD2

Fig. 13.16 The autoinflammatory diseases. CD2-binding protein 1 is also known as PSTPIP1.

chronic granulomatous disease. Individuals with these diseases have an inability to clear certain bacteria, which in some cases leads to the formation of granulomas. Deficiencies in glucose-6-phosphate dehydrogenase (G6PD) and myeloperoxidase (MPO) also impair intracellular bacterial killing and lead to a similar, although less severe, phenotype.

13-18 Mutations in the molecular regulators of inflammation can cause uncontrolled inflammatory responses that result in 'autoinflammatory disease.'

Hereditary Periodic Fever Syndromes

There are a small number of diseases in which mutations in genes that control the life, death, and pro-inflammatory cytokine release of monocytes and neutrophils are associated with severe inflammatory disease. Although they do not lead to immunodeficiency, we have included them here because they are single-gene defects affecting a crucial aspect of innate immunity—the inflammatory response. These conditions represent a failure of the mechanisms that normally limit inflammation and are known as **autoinflammatory diseases**, which can lead to inflammation even in the absence of infection (Fig. 13.16).

One group of autoinflammatory diseases is characterized by dysregulation of the inflammasome. These disorders result either from impaired dampening of inflammasome activity or intrinsic hyperactivity of the inflammasome, which normally regulates apoptosis and release of pro-inflammatory cytokines such as IL-1β by myeloid cells in response to inflammation and the stress response (see Section 3-11 and Figs. 3.20 and 3.21). Patients with **familial Mediterranean fever (FMF)** suffer episodic attacks of severe inflammation, which can occur at various sites throughout the body and are associated with fever, an acute-phase response (see Section 3-9), and severe malaise. The pathogenesis of FMF was a mystery until its cause was discovered to result from impaired expression of the gene *MEFV* (so named for its association with Mediterranean fever), which encodes a protein called **Pyrin**. Pyrin, and the pyrin domains of NLRPs, exemplified by NLRP3 (or cryopyrin), interact to restrain inflammasome activity. The absence of functional

Pyrin, as occurs in FMF, leads to unregulated inflammatory cytokine release and defective apoptosis, resulting in uncontrolled local and systemic inflammation (see Fig. 13.16). Mutations in the gene encoding PSTPIP1 (proline-serine-threonine phosphatase-interacting protein 1), which interacts with Pyrin, are associated with another dominantly inherited autoinflammatory syndrome—**pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA)**. The defective variants of *PSTPIP1* result in increased binding of Pyrin to PSTPIP1, which is thought to sequester Pyrin and limits its normal regulatory function.

Muckle–Wells syndrome and **familial cold autoinflammatory syndrome 1 (FCAS1)** are caused by gain-of-function mutations of *NLRP3*, whereas **familial cold autoinflammatory syndrome 2 (FCAS2)** results from gain-of-function mutations in *NLRP12* (see Fig. 13.16). Hyperactivity of NLRP3 or NLRP12 resulting from these mutations leads to unregulated overproduction of pro-inflammatory cytokines. Individuals with these dominantly inherited syndromes present with episodes of fever—which is induced by exposure to cold in the case of FCAS—as well as urticarial rash, joint pains, and conjunctivitis. Damaging variants of *NLRP3* are also associated with the autoinflammatory disorder **chronic infantile neurologic cutaneous and articular syndrome (CINCA)**, in which short recurrent fever episodes in infancy are common, although severe arthropathic, neurologic, and dermatologic symptoms predominate. Because a common feature of each of these disorders is inflammasome-mediated elevation of IL-1β production, treatment with anti-inflammatory agents such as NSAIDs and corticosteroids can be effective, and patients often respond dramatically to the drugs that block IL-1 signaling, including anakinra, an injectable, recombinant preparation of the IL-1 receptor antagonist (IL-1RA), and the fully human anti-IL-1β monoclonal antibody canakinumab (see Section 16-27).

A disease with similar clinical manifestations, but caused by non-inflammasome-related defects, is **TNF receptor–associated periodic syndrome (TRAPS)** (see Fig. 13.16). As the name implies, TRAPS is caused by mutations in the gene encoding TNF-α receptor I (*TNFRSF1A*). Patients with TRAPS have reduced levels of TNFR-I, which leads to increased levels of pro-inflammatory TNF-α in the circulation because it is not regulated by binding to this receptor. This increase, in turn, leads to elevation of other pro-inflammatory cytokines, including IL-1β. The disease responds to therapeutic blockade with anti-TNF agents, such as etanercept, a recombinant form of the TNF receptor; adalimumab and infliximab, human TNF-blocking monoclonal antibodies; and IL-1β blockade by anakinra and canakinumab.

13-19 Factor-replacement therapies, hematopoietic stem-cell transplantation, and gene therapy can be used successfully to correct genetic defects.

In some PIDs, immune deficiency is amenable to factor-replacement therapy, which is the periodic administration of a recombinant or natural protein that is deficient in an individual to restore functional levels. For example, periodic administration of recombinant adenosine deaminase (ADA) or IFN-γ has been used successfully to treat patients who have ADA-deficient SCID and some patients who have chronic granulomatous disease, respectively. Similarly, immunoglobulins pooled from healthy donors, called intravenous Ig (IVIG) therapy, can be administered via injection to patients who have agammaglobulinemia variants or CVID. Advances in the design and engineering of recombinant monoclonal antibodies is also enabling more targeted Ig-replacement therapies for individuals whose PID makes them particularly susceptible to certain types of infections that can be prevented by neutralizing antibodies.

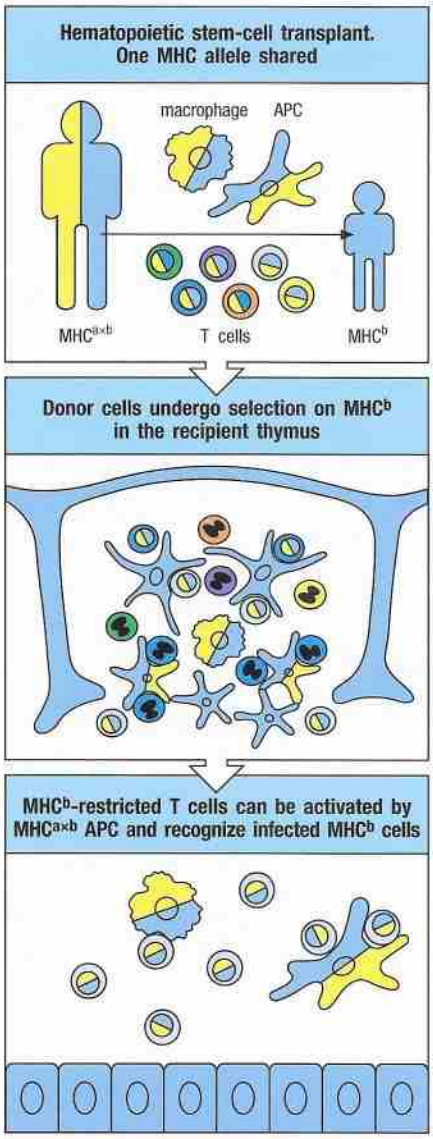

Fig. 13.17 The donor and the recipient of a hematopoietic stem cell (HSC) graft must share at least some MHC molecules to restore immune function. An HSC transplant from a genetically different donor is illustrated in which the donor marrow cells share some MHC molecules with the recipient. The shared MHC type is designated 'b' and illustrated in blue; the MHC type of the donor HSCs that is not shared is designated 'a' and illustrated in yellow. In the recipient, developing donor lymphocytes are positively selected on MHC^{b}-expressing thymic epithelial cells and are negatively selected by the recipient's stromal epithelial cells and at the cortico-medullary junction by encounter with dendritic cells derived from both the donor HSCs and residual recipient dendritic cells. The negatively selected cells are shown as apoptotic cells. The donor-derived antigen-presenting cells (APCs) in the periphery can activate T cells that recognize MHC^{b} molecules; the activated T cells can then recognize the recipient's infected MHC^{b}-bearing cells.

It is also possible to correct the defects in lymphocyte development that lead to SCID and some other immunodeficiency phenotypes by replacing the defective cellular component, generally by hematopoietic stem cell (HSC) transplantation (Fig. 13.17; see also Section 15-25). The main difficulties in these therapies result from human leukocyte antigen (HLA) polymorphism. To be useful, the graft must share some HLA alleles with the host. As we learned in Section 8-21, the HLA alleles expressed by the thymic epithelium determine which T cells can be positively selected. When HSCs are used to restore immune function to individuals with a normal thymic stroma, both the T cells and the antigen-presenting cells are derived from the graft. Therefore, unless the graft shares at least some HLA alleles with the recipient, the T cells that are selected on host thymic epithelium cannot be activated by graft-derived antigen-presenting cells. There is also a danger that mature, post-thymic T cells that contaminate donor HSCs prepared from the peripheral blood or bone marrow might recognize the host as foreign and attack it, causing **graft-versus-host disease (GVHD)** (Fig. 13.18). This can be overcome by depleting the donor graft of mature T cells. For immunodeficiency diseases other than SCID where there are residual T cells and NK cells in the recipient, some form of myeloablative treatment (destruction of the bone marrow, typically using cytotoxic drugs or irradiation) is often carried out before transplantation, both to generate space for engraftment of the transplanted HSCs and to minimize the threat of **host-versus-graft disease (HVGD)** (see Fig. 13.18). The intensity of the myeloablative regimen is dependent on the nature of the immunodeficiency. For diseases where persistence of the patient's cells can be tolerated, engraftment of only a fraction of donor HSCs is sufficient for cure, and non-myeloablative chemotherapy may suffice prior to HSC transplantation. In conditions that require complete elimination of the patient's blood cells and full engraftment of donor cells (for example, XLP), more intensive (myeloablative) chemotherapy may be required.

Graft-Versus-Host Disease

Because many of the gene defects that cause inherited immunodeficiencies have been identified, an alternative therapeutic approach is **somatic gene therapy**. This strategy involves the isolation of HSCs from the patient's bone marrow or peripheral blood, introduction of a normal copy of the defective gene by the use of a viral vector, and reinfusion of the corrected stem cells into the patient. Initially, retroviral vectors were used for gene-therapy trials, but use of these ceased because of severe complications in some patients. Although the genetic defect was corrected in patients with X-linked SCID, CGD, and WAS who received this treatment, some patients developed leukemia because of insertion of the retrovirus within a proto-oncogene. The inability to control the site in the genome in which retrovirally encoded genes insert and the use of viral vectors with strong promoters that can transactivate neighboring genes make this treatment problematic. More recently, the use of self-inactivating retroviral and lentiviral vectors for gene correction has shown promise as a means of avoiding this complication. As an example, retrovirally mediated gene therapy for SCID caused by ADA deficiency is now approved in

Europe and has not shown the complications of some previous gene-therapy treatments. New efforts to implement CRISPR-mediated gene editing without off-target gene effects is a rapidly evolving technology. This approach offers the promise of 'repairing' specific gene defects in patient-derived stem cells *ex vivo* before reinfusion, but it is not yet established. Until better methods for introduction of corrected genes into self-renewing stem cells are identified, allogeneic HSC transplantation will remain the standard treatment for many primary immunodeficiencies.

13-20 Noninherited, secondary immunodeficiencies are major predisposing causes of infection and death.

The primary immunodeficiencies have taught us much about the biology of specific immune-system proteins. Fortunately, these conditions are rare. In contrast, secondary immunodeficiency is relatively common. Malnutrition devastates many populations around the world, and a major feature of malnutrition is secondary immunodeficiency. Secondary immunodeficiency particularly affects cell-mediated immunity, and death in famines is frequently caused by infection. Measles, which itself causes immunosuppression, is an important cause of death in malnourished children. In the developed world, measles is an unpleasant illness, but major complications are uncommon. In contrast, measles in the malnourished has a high mortality. Tuberculosis is another important infection in the malnourished. In mice, protein starvation causes immunodeficiency by affecting antigen-presenting cell function, but in humans it is not clear how malnourishment specifically affects immune responses. Links between the endocrine and immune systems may provide part of the answer. Adipocytes (fat cells) produce the hormone leptin, levels of which are related directly to the amount of fat present in the body; leptin levels therefore fall during starvation when fat is consumed. Both mice and humans with genetic leptin deficiency have reduced T-cell responses, and in mice the thymus atrophies. In both starved mice and those with inherited leptin deficiency, these abnormalities can be reversed by the administration of leptin.

Secondary immunodeficiency states are also associated with hematopoietic tumors, such as leukemia and lymphomas. Myeloproliferative diseases, such as leukemia, can be associated with deficiencies of neutrophils (neutropenia) or an excess of immature myeloid progenitors that lack functional properties of mature neutrophils, either of which increases susceptibility to bacterial and fungal infections. Destruction or invasion of peripheral lymphoid tissue by lymphomas or metastases from other cancers can promote opportunistic infections.

Congenital asplenia (a rare inherited absence of the spleen), surgical removal of the spleen, or destruction of spleen function by certain diseases is associated with a lifelong predisposition to overwhelming infection by *S. pneumoniae*, graphically illustrating the role of mononuclear phagocytic cells within the spleen in the clearance of this organism from blood. Individuals who have lost spleen function should be vaccinated against pneumococcal infection and are often counseled to take prophylactic antibiotics throughout their lives.

Secondary immunodeficiency is also a complication of certain medical therapies. A major complication of cytotoxic drugs used to treat cancer is immunosuppression and increased susceptibility to infection. Many of these drugs kill all dividing cells, including normal cells of the bone marrow and lymphoid systems. Infection is thus one of the major side effects of cytotoxic drug therapy. Immune suppression to induce host tolerance of solid-organ allografts, such as kidney or heart transplants, also carries a substantial increased risk for infection and even for malignancy.

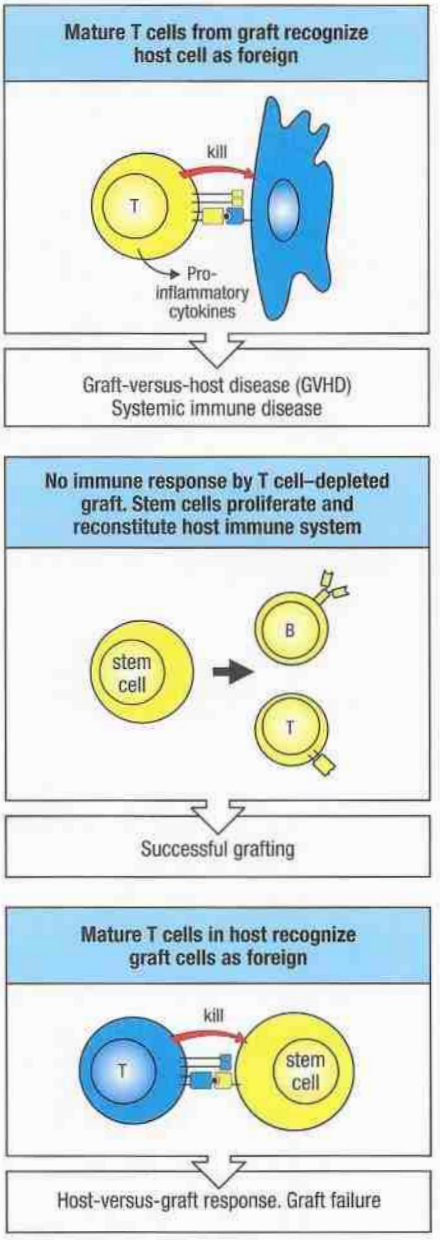

Fig. 13.18 Grafting of bone marrow can be used to correct immunodeficiencies caused by defects in lymphocyte maturation, but two problems can arise. First, if there are mature T cells in the bone marrow, they can attack cells of the host by recognizing their MHC antigens, causing graft-versus-host disease (top panel). This can be prevented by T-cell depletion of the donor bone marrow (center panel). Second, if the recipient has competent T cells, these can attack the bone marrow stem cells (bottom panel). This causes failure of the graft by the usual mechanism of transplant rejection (see Chapter 15).

Congenital Asplenia

The growing use of biologic therapies to treat some forms of allograft rejection, malignancies, autoimmune disease, and autoinflammatory disorders (see Section 16-27) has led to an increased risk of infection because of their immunosuppressive effects, while illuminating how specific pathways are involved in immunity to particular infections. For example, administration of antibodies that block TNF-α in patients with rheumatoid arthritis, inflammatory bowel disease, or TRAPS has been associated with infrequent but increased instances of infectious complications, including the risk of *de novo* infections (for example, *Listeria monocytogenes* and certain opportunistic infections, such as *Pneumocystis jirovecii*), as well as reactivation of latent *Mycobacterium tuberculosis* or varicella-zoster virus infection. Because of the risk of reactivation of latent tuberculosis in these patients, pretreatment screening for a positive TB test is now routine prior to anti-TNF therapy, as is screening for certain latent viral infections. Similarly, use of rituximab—a depleting monoclonal antibody that targets the CD20 co-receptor component on B cells and is used to treat some B-cell lymphomas and leukemias (see Section 16-19) and patients who have certain forms of allograft rejection or autoimmunity—carries a significant risk for reactivation of active hepatitis B virus infection, as well as JC virus reactivation, which causes progressive multifocal leukoencephalopathy (PML), a highly lethal CNS infection. Similar to the widening use of biologics, the advent of pharmacologic inhibitors of JAK kinases ('jakinibs') that impair STAT signaling in immune cells in the treatment of these diseases increases the risk of infectious complications and may also provide insights into the immune pathways that utilize them. As the use of biologic and jakinib-based therapies grows, so too will the risk of infectious complications due to secondary immunodeficiencies.

Summary.

Genetic defects can occur in almost any molecule involved in the immune response. These defects give rise to characteristic immunodeficiency diseases, which, although rare, provide much information about the development and functioning of the immune system in normal humans. Inherited immunodeficiencies illustrate the vital role of the adaptive immune response and T cells, in particular, without which cell-mediated immunity and humoral immunity both fail. Inherited immunodeficiencies have provided information about the separate roles of B lymphocytes in humoral immunity and of T lymphocytes in cell-mediated immunity, the importance of phagocytes and complement in humoral immunity and innate immunity, and the specific functions of a growing number of cell-surface and signaling molecules in the adaptive immune response. There are also some inherited immune disorders whose causes we still do not understand. The study of these diseases will undoubtedly teach us more about the normal immune response and its control. Acquired defects in the immune system—the secondary immunodeficiencies—are much more common than the primary inherited immunodeficiencies. In the next part of this chapter, we briefly consider general mechanisms by which successful pathogens evade or subvert immune defenses, and in the final part of the chapter, we detail how extreme subversion of the immune system by one pathogen, the human immunodeficiency virus (HIV), has created a major pandemic characterized by the acquired immune deficiency syndrome (AIDS) in affected individuals.

Evasion and subversion of immune defenses.

In the previous part of the chapter, we learned how specific defects in immune pathways lead to infection, often by microbes that would normally be defeated by a healthy immune system. These 'opportunistic' infections often dominate

the clinical expression of inherited immunodeficiencies because the causative organisms are ubiquitous and abundant in the environment. A minority of microbes are true pathogens that can infect those with normal immune defenses. A defining feature of pathogens is their ability to avoid immune destruction by components of the innate and adaptive immune systems, at least long enough to replicate in the infected host and spread to new hosts. At one end of the spectrum are pathogens that establish an acute infection, replicate quickly, and find a new host before they are cleared by a successful immune response; at the other end are pathogens that establish chronic infections, persisting long-term in the host while evading elimination by immune defenses. Successful pathogens use different strategies to these ends and over millions of years of coevolution with their hosts have evolved remarkably diverse strategies for avoiding detection and destruction by the immune system, often employing several strategies that subvert immunity at multiple points. The anti-immune strategies employed by pathogens are as sophisticated as the immune system itself. They must be in order for pathogens to achieve success against the diverse strategies that vertebrates have evolved to ensure host protection.

Viruses, bacteria, and protozoan (unicellular) or metazoan (multicellular) parasites can all act as pathogens. While fungi and helminthic (metazoan) parasites are major causes of common skin infections and intestinal worm infestation, respectively, they do not typically cause life-threatening infections in normal people and will not be considered further here. In contrast, a select number of viruses, bacteria, and protozoan parasites are the major causes of morbidity and mortality due to infectious agents. The human immunodeficiency virus (HIV, cause of AIDS), *Mycobacterium tuberculosis* (cause of tuberculosis), and *Plasmodium falciparum* (cause of malaria) are the three greatest infectious disease threats to humans; each of these pathogens infects more than 100 million people worldwide and kills 1 million to 2 million people annually. Although the strategies for survival within, and propagation between, hosts differ for each type of pathogen, many of the innate and adaptive immune mechanisms employed to thwart the pathogen are the same. Here we briefly consider the lifestyle and principal immune responses elicited by different types of pathogens and the strategies the pathogens employ to evade or subvert the immune system.

13-21 Extracellular bacterial pathogens have evolved different strategies to avoid detection by pattern-recognition receptors and destruction by antibody, complement, and antimicrobial peptides.

Extracellular bacterial pathogens replicate outside of host cells, whether on the surfaces of barrier tissues they colonize (for example, gastrointestinal or respiratory tracts) or in tissue spaces or blood after invasion across barrier epithelia. There are both Gram-negative and Gram-positive pathogenic species. As discussed in Section 11-11, these bacteria typically elicit type 3 immunity, which orchestrates neutrophilic responses, the development of opsonizing and complement-fixing antibodies, and the production of antimicrobial peptides by barrier epithelial cells and immune cells that clear these microbes from barrier epithelia and prevent their invasion. Some of the microbial-associated molecular patterns (MAMPs) expressed by Gram-negative and Gram-positive bacteria are distinct, but they share similar immune-cell activating properties.

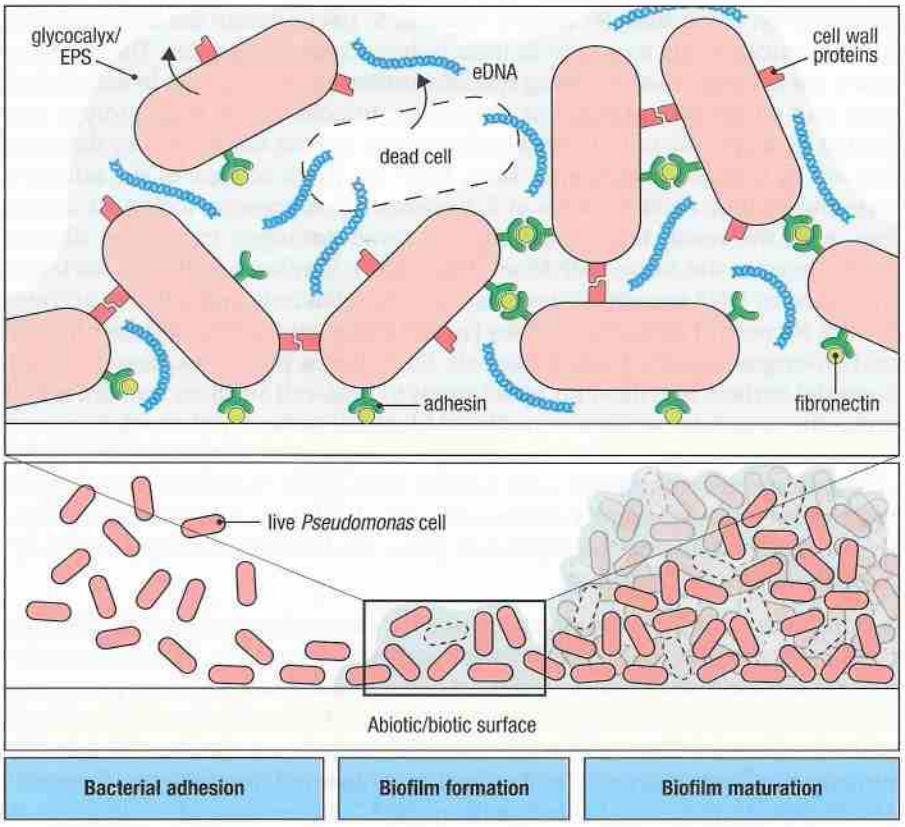
Gram-negative pathogens contain lipopolysaccharide (LPS), a potent activator of TLR-4, in their outer cell membrane, whereas the cell walls of both Gram-positive and Gram-negative pathogens contains peptidoglycans, which activate TLR-2 and NOD1 and NOD2. One strategy of immune evasion used by these pathogens, therefore, is the shielding of their surface MAMPs to avoid detection of the MAMPs by pattern-recognition receptors (PRRs) on immune cells (Fig. 13.19).

Bacterial strategy	Mechanism	Result	Examples
Extracellular bacteria			
Shielding or inhibition of MAMPs	Capsular polysaccharide	Block detection of lipopolysaccharide (LPS)	*K. pneumoniae*
	Hypoacylation of lipid A	Antagonism of TLR-4	*P. gingivalis*
	Coating of bacterium by host proteins (e.g., fibrin)	Block detection of peptidoglycan	*S. aureus*
Antigenic variation	Modulation of expressed pili, fimbriae	Antibodies that block bacterial attachment become ineffective	*N. gonorrhoeae*, *E. coli*
Inhibition of opsonization	Secretion of complement-degrading factors	Cleavage of complement components	*N. meningitidis*, *P. aeruginosa*, *S. aureus*
	Capsular polysaccharide	Block fixation of complement	*S. pneumoniae*, *H. influenzae*, *K. pneumoniae*
	Expression of Fc-binding surface molecules (e.g., Protein A)	Prevents binding of antibody to Fc receptors of phagocytes	*S. aureus*
	Production of biofilms	Shielding of bacteria from phagocytosis	*S. epidermidis*, *S. aureus*, *P. aeruginosa*
Inhibition/scavenging of reactive oxygen species (ROS)	Secretion of catalase and superoxide dismutase	Neutralize ROS produced by NADPH and myeloperoxidase (MPO)	*S. aureus*, *B. abortus*
Resistance to antimicrobial peptides (AMPs)	Secretion of AMP-degrading peptidases	Cleavage of AMPs	*E. coli*
	Modulation of cell membrane phospholipids	Prevents binding, functional insertion of AMPs in cell membrane	*S. aureus*
Intracellular bacteria			
Antigenic variation	Modulation of expressed pili, fimbriae	Antibodies that block bacterial attachment become ineffective	*Salmonella* spp.
Inhibition of MAMP recognition/ signaling	Production of peptidoglycan hydrolase	Block detection of peptidoglycan by NODs	*L. monocytogenes*
	Secretion of intracellular toxins	Block NFκB and MAP kinase signaling pathways	*Y. pestis*
Resistance to anti-microbial peptides	Secretion of AMP-degrading peptidases	Cleavage of AMPs	*Y. pestis*
	Modulation of cell membrane phospholipids	Prevents binding, functional insertion of AMPs in cell membrane	*Salmonella* spp.
Inhibition of fusion of phagosome with lysosome	Release of bacterial cell wall components	Inhibits phago-lysosomal fusion	*M. tuberculosis*, *M. leprae*, *L. pneumophila*
Survival within phagolysosome	Waxy, hydrophobic cell wall containing mycolic acids and other lipids	Resistance against lysosomal enzymes	*M. tuberculosis*, *M. leprae*
Escape from phagosome	Production of hemolysins (e.g., listeriolysin O)	Lysis of phagosome; escape into cytosol	*L. monocytogenes*, *Shigella* spp.

Fig. 13.19 Mechanisms used by bacteria to subvert the host immune system.

Several Gram-negative pathogens modify the lipid A core of LPS with carbohydrates and other moieties that interfere with TLR-4 binding. Indeed, some bacteria produce variants of lipid A that act as TLR-4 antagonists rather than agonists. Both Gram-negative and Gram-positive pathogens have evolved mechanisms to modulate recognition of the peptidoglycan fragments by the intracellular PRRs, NOD1 and NOD2 (see Section 3-8), which impairs innate immune activation. NOD1 normally detects γ-glutamyl diaminopimelic acid (iE-DAP), which is found in peptidoglycans produced by Gram-negative and rod-shaped Gram-positive pathogens such as *Salmonella* and *Listeria*, respectively. NOD2 normally detects muramyl dipeptide, which is a component of peptidoglycans of most bacteria. Bacteria can modify the glycans found in the peptidoglycans of their cell walls to avoid cleavage by lysozyme, which is normally involved in the release of peptidoglycan fragments sensed by NOD receptors. They can also modify the stem peptides of peptidoglycans, which contribute to NOD1 recognition. Finally, some bacteria produce hydrolases that degrade peptidoglycan in a manner to render it less detectable by NOD receptors.

A limited number of Gram-positive pathogens can also shield their outer cell membrane with a thick carbohydrate capsule. In addition to inhibiting recognition of peptidoglycan and activation of the alternative pathway of complement, the capsule prevents antibody and complement deposition on the bacterial cell membrane, thereby avoiding direct damage by the membrane-attack complex of the complement cascade. The capsule also impairs clearance of the pathogen by phagocytes (see Fig. 13.19). A similar strategy is employed by both Gram-negative and Gram-positive bacteria, including those that lack a capsule, through the secretion of extracellular polymeric substances (EPSs) to create **biofilms**, which protect them from immune clearance. Biofilms are composed of exopolysaccharides (for example, cellulose), proteins, and nucleic acids and in which are embedded a community of bacteria—as opposed to free-living, or planktonic, cells (Fig. 13.20). While the latter are more easily phagocytosed and delivered to lysosomal compartments where they can be destroyed, bacteria embedded within biofilms are more difficult to ingest and



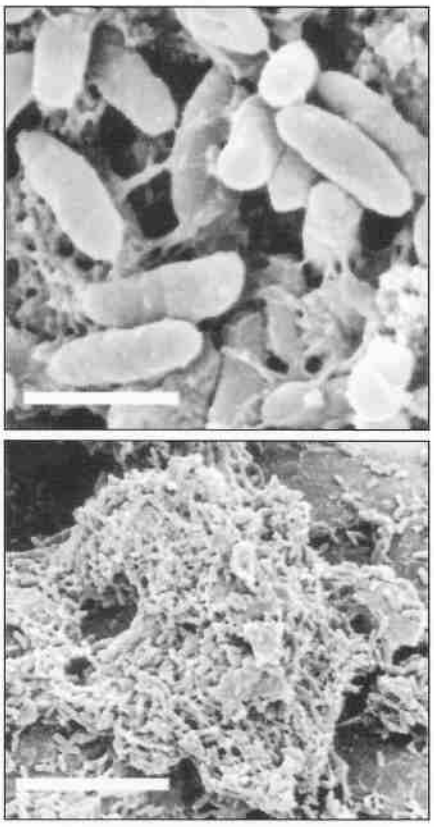


Fig. 13.20 The formation of biofilms by bacteria restrains immune clearance. Biofilms represent one mechanism by which microbes evade host immune defenses. They can form on either living tissues (biotic surface) or foreign material introduced into the body (abiotic surface), such as intravenous catheters or medical implants, and provide a source for recurrent seeding of the host by microbes. Biofilms form when free-living, or planktonic, microbial cells—in this case the Gram-negative bacterium *Pseudomonas aeruginosa*—attach to a surface or tissue (bacterial adhesion; shown is attachment to fibronectin in a tissue) and grow on it, producing an extracellular matrix (glycocalyx, or extracellular polymeric substance; EPS) that is composed of secreted proteins, glycans, and lipids, as well as the extravasated DNA (eDNA) of dying cells. This supports the microbial community and shields it from antimicrobial defenses, including antibodies, complement, and phagocytic cells. The photos (right panels) are scanning electron micrographs of a biofilm of *Pseudomonas aeruginosa* on an abiotic surface. Note the strands of glycocalyx (EPS) that connect and envelope individual bacteria. The upper and lower scale bars indicate 1 μm and 10 μm, respectively.

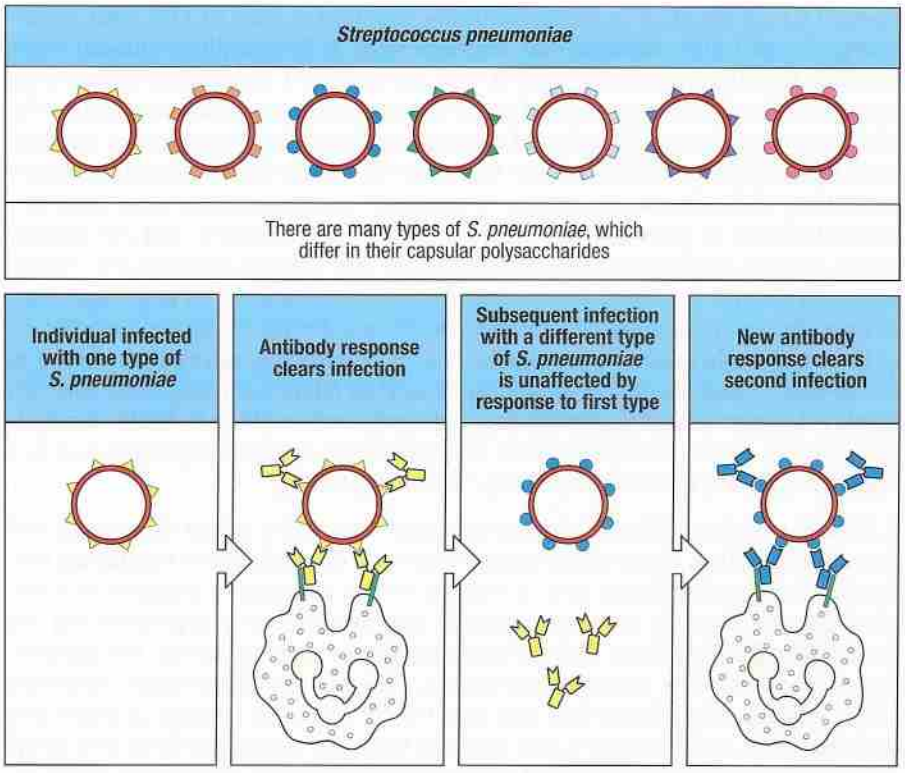

Streptococcus pneumoniae
There are many types of S. pneumoniae, which differ in their capsular polysaccharides
Individual infected with one type of S. pneumoniae
Antibody response clears infection
Subsequent infection with a different type of S. pneumoniae is unaffected by response to first type
New antibody response clears second infection

Fig. 13.21 Host defense against *Streptococcus pneumoniae* is type specific. The different strains of *S. pneumoniae* have antigenically distinct capsular polysaccharides. The capsule prevents effective phagocytosis until the bacterium is opsonized by specific antibody and complement, allowing phagocytes to destroy it. Antibody against one type of *S. pneumoniae* does not cross-react with the other types, so an individual immune to one type has no protective immunity to a subsequent infection with a different type. An individual must generate a new adaptive immune response each time he or she is infected with a different type of *S. pneumoniae*.

destroy. In addition to resisting host-clearance mechanisms, biofilms also enable long-term colonization on surfaces of host tissues by facilitating the sharing of resources within the mini-consortium of cooperating bacteria.

In the case of *Streptococcus pneumoniae*, an important cause of bacterial pneumonia, the carbohydrate capsule also serves as a platform for **antigenic variation** to modulate the expression of surface antigenic epitopes recognized by antibody. More than 90 known types of *S. pneumoniae* are distinguished by differences in the structure of their polysaccharide capsules. The different types are distinguished by using specific antibodies as reagents in serological tests and so are often known as **serotypes**. Infection with one serotype can lead to type-specific immunity, which protects against reinfection by that type but not by a different serotype. Thus, from the point of view of the adaptive immune system, each serotype of *S. pneumoniae* represents a distinct organism, with the result that essentially the same pathogen can cause disease many times in the same individual (Fig. 13.21). Similarly, antigenic variation mediated by DNA rearrangement also occurs in bacteria and helps to account for the success of *Neisseria* species (which cause gonorrhea and meningitis) and enteropathogenic *Escherichia coli*. Fimbriae or pili are expressed on the bacterial surface and used for attachment to host-cell surfaces and are major antigenic targets for antibody-mediated blockade of bacterial attachment and colonization. The gene locus encoding the expressed *Neisseria* pilus (*pilE*) can undergo recombination with partial pilin genes stored in 'silent' (*pilS*) loci to generate a constantly shifting pilus for display on the bacterial surface. By constantly changing the expressed pilus, the bacterium evades antibody-mediated immune clearance.

Among other anti-immune strategies used by extracellular pathogens are strategies to inhibit different aspects of the complement cascade. Because complement is central to the clearance of most extracellular bacteria, these pathogens have evolved multiple strategies to interfere with different components of each pathway of complement activation. Examples include expression of Fc-binding proteins that block activation of the classical pathway of complement (for example, Protein A); mechanisms to inactivate the C3 convertase, which impacts all

complement pathways; decoration of the bacterial surface with host inhibitors of complement (for example, factor H and C4b-binding protein, or C4BP); and the release of proteases that can cleave key complement components (Fig. 13.22; see also Section 2-18). Bacterial proteases that can cleave antibody bound to the bacterial surface also exist (for example, staphylokinase, or SAK). These bacteria have also evolved mechanisms to defeat antimicrobial peptides (AMPs), such as defensins and cathelicidins. These small cationic and amphipathic peptides exert their antimicrobial activity by inserting into negatively charged cell membranes to generate pores that lyse the bacterium (see Section 2-4). Pathogens can alter their cell membrane composition to minimize AMP binding and can also produce proteases that degrade the AMPs.

An unusual feature of Gram-negative pathogens, including both extracellular and intracellular bacteria, is their capacity to inject immune modulatory

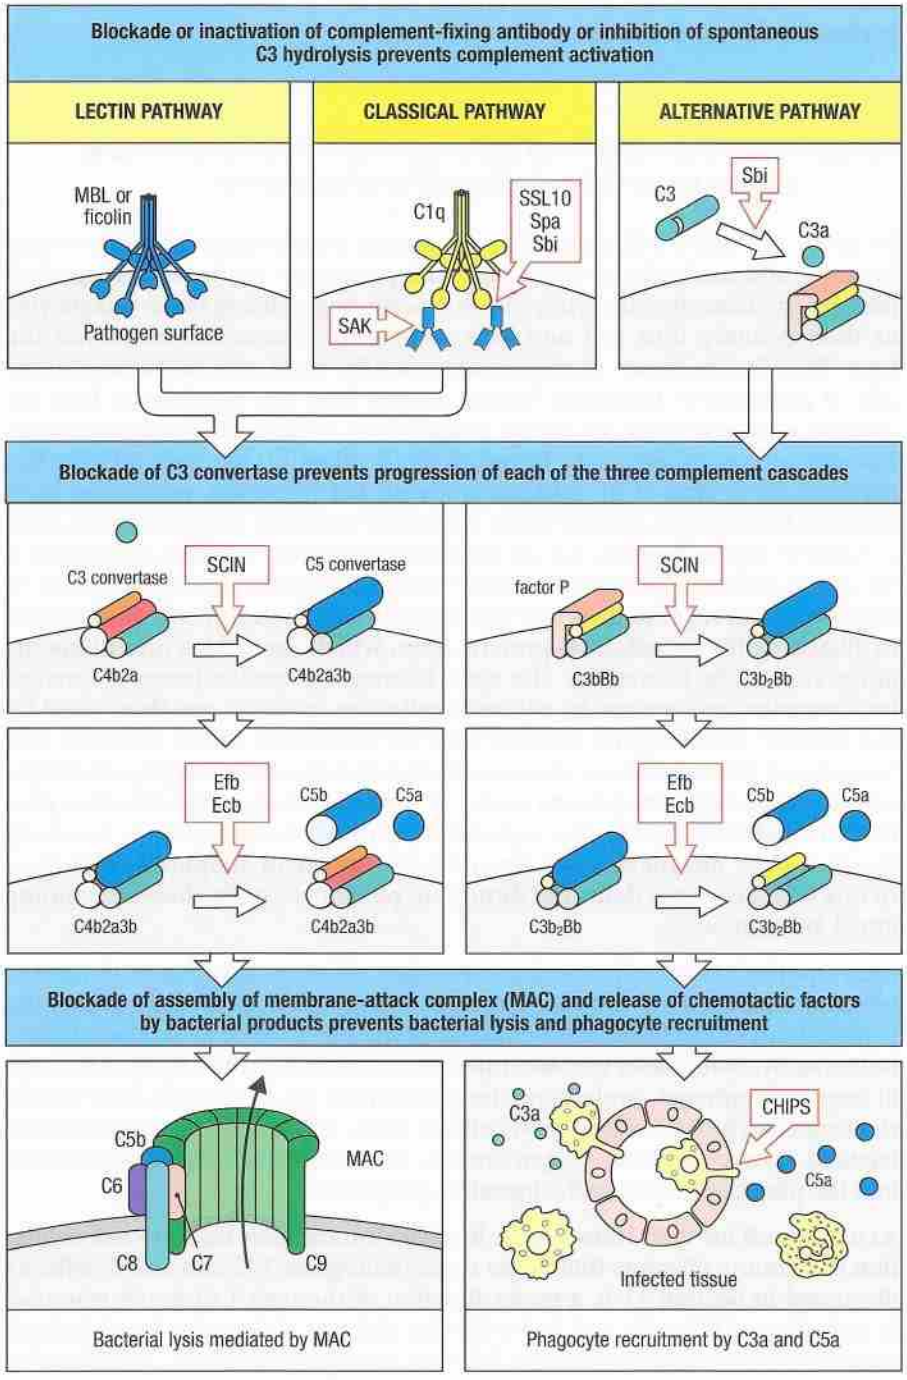

Fig. 13.22 Pathogenic bacteria target multiple steps in the complement cascade to subvert immunity. Extracellular pathogens can subvert all three branches of the complement cascade (lectin, classical, and alternative pathways) to evade immune destruction. Highlighted are several products of the Gram-positive bacteria, *Staphylococcus aureus*, which is remarkably versatile in the products it makes to inhibit different steps in the complement cascade. Examples of bacterial proteins produced by *S. aureus* and the sites of their actions in each cascade are indicated in red boxes: SAK (staphylokinase) cleaves IgG and removes it from the bacterial surface, while SSL10 (staphylococcal superantigen-like protein 10) binds IgG and blocks initiation of the classical pathway; Sbi (second immunoglobulin binding protein) and Spa (staphylococcal protein A) block C1q binding to the Fc portion of immunoglobulin, also blocking initiation of the classical pathway, while Sbi can also interfere with activation of the alternative pathway; SCIN (staphylococcal complement inhibitor) stabilizes C3 convertase in an inactive state; Ecb (extracellular complement-binding protein) and Efb (extracellular fibrinogen-binding protein) bind C3d and inactivate both C3 and C5, preventing C5 convertase activity; and CHIPS (chemotaxis inhibitory protein of staphylococcus) blocks the C5a receptor on phagocytes.

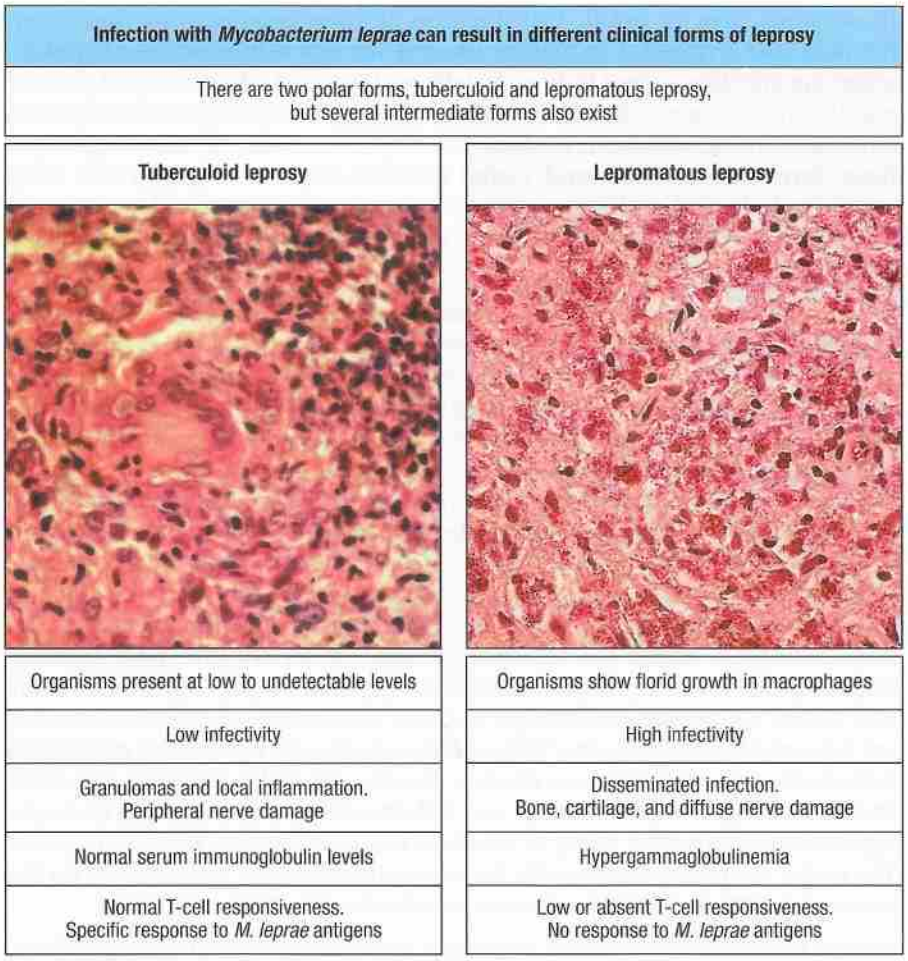
bacterial proteins directly into host cells via specialized structures: the type III and type IV secretion systems (T3SS and T4SS, respectively), as discussed in Chapter 12 (see Section 12-20 and Fig. 12.39). These needle-like structures, or **injectisomes**, assemble on the bacterial surface and dock with the plasma membrane of target cells to provide a conduit through which bacterial proteins are secreted directly into the cytosol of host cells. A range of bacterial virulence factors that aid in subverting the host immune response are delivered via this mechanism, including bacterial factors that block signaling cascades central to the inflammatory response: NFκB and MAP kinases. Among the most remarkable of these are the Yersinia outer proteins (Yops) produced by *Yersinia pestis*, the causative agent of bubonic plague. Secretion of several of these factors (for example, YopH, YopE, YopO, and YopT) into phagocytes disrupts the actin cytoskeleton, which is essential for phagocytosis. The essential roles played by T3SS or T4SS in immune subversion by a number of Gram-negative pathogens are demonstrated by the loss of pathogenicity of mutant bacteria lacking components of these structures.

13-22 Intracellular bacterial pathogens can evade the immune system by seeking shelter within phagocytes.

To avoid the major effectors directed against extracellular bacteria—complement and antibodies—some bacterial pathogens have evolved specialized mechanisms for surviving within macrophages, using these phagocytes as their primary host cell and as a vehicle for dissemination within the host. This 'Trojan horse' strategy is achieved by three general tactics: blockade of phagosome–lysosome fusion; escape from the phagosome into the cytosol; and resistance to killing mechanisms within the phagolysosome. *Mycobacterium tuberculosis*, for example, is taken up by macrophages but prevents the fusion of the phagosome with the lysosome, protecting itself from the bactericidal actions of the lysosomal contents. Other bacteria, such as *Listeria monocytogenes*, escape from the phagosome into the cytoplasm of the macrophage, where they multiply. They then spread to adjacent cells in the tissue without emerging into the extracellular environment. They do this by hijacking the cytoskeletal protein actin, which assembles into filaments at the rear of the bacterium. The actin filaments drive the bacteria forward into vacuolar projections to adjacent cells; the vacuoles are then lysed by the *Listeria*, releasing the bacteria into the cytoplasm of the adjacent cell. Moreover, *Listeria* has been shown to induce the expression of phosphatidylserine on the outer membrane leaflet of bacteria-containing blebs that protrude from infected cells; the expression of phosphatidylserine is normally recognized by phagocytes as a signal for the uptake of apoptotic cell debris. In this way, *Listeria* is delivered directly to phagocytic cells, thereby avoiding attack by antibodies.

After uptake, *Salmonella* species use a type III secretion system to secrete effectors such as SifA into the host cytosol and membranes in order to alter the composition of the *Salmonella*-containing vacuole so as to avoid destruction. Remarkably, *Salmonella* can also inject factors that delay the apoptotic death of host macrophages, prolonging the phagocytes' life spans until their bacterial cargo can be delivered to new cellular hosts. Other actions of intracellular bacteria counter reactive oxygen species or microbicidal peptides delivered into the phagolysosome by the ingesting phagocyte.

As a trade-off for their intracellular lifestyle, intracellular bacteria risk activation of immune effectors that target these pathogens: NK cells and T cells. As discussed in Section 11-6, a major function of the type 1 immune response is activation of NK cells and T_H1 cells that activate phagocytes for enhanced intracellular killing by secretion of IFN-γ or expression of CD40L. Additionally,



Infection with *Mycobacterium leprae* can result in different clinical forms of leprosy
There are two polar forms, tuberculoid and lepromatous leprosy, but several intermediate forms also exist
Tuberculoid leprosy
Lepromatous leprosy
Organisms present at low to undetectable levels
Organisms show florid growth in macrophages
Low infectivity
High infectivity
Granulomas and local inflammation. Peripheral nerve damage
Disseminated infection. Bone, cartilage, and diffuse nerve damage
Normal serum immunoglobulin levels
Hypergammaglobulinemia
Normal T-cell responsiveness. Specific response to *M. leprae* antigens
Low or absent T-cell responsiveness. No response to *M. leprae* antigens

Fig. 13.23 T-cell and macrophage responses to *Mycobacterium leprae* are sharply different in the two polar forms of leprosy. Infection with *M. leprae*, whose cells stain as small, dark red dots in the photographs, can lead to two very different forms of disease. In tuberculoid leprosy (left), growth of the organism is well controlled by T_H1-like cells that activate infected macrophages. The tuberculoid lesion contains granulomas and is inflamed, but the inflammation is local and causes only local effects, such as peripheral nerve damage. In lepromatous leprosy (right), infection is widely disseminated, and the bacilli grow uncontrolled in macrophages; in the late stages of disease there is major damage to connective tissues and to the peripheral nervous system. Cytokines typically produced by T_H2 cells (IL-4, IL-5, and IL-10) dominate in the lepromatous form, whereas cytokines produced by T_H1 cells (IL-2, IFN-γ, and TNF-β dominate in the tuberculoid form. It therefore seems that T_H1-like cells predominate in tuberculoid leprosy, and T_H2-like cells predominate in lepromatous leprosy. IFN-γ would be expected to activate macrophages, enhancing the killing of *M. leprae*, whereas IL-4 can actually inhibit the induction of bactericidal activity in macrophages.

those intracellular pathogens that have evolved mechanisms to escape the phagosome, such as *Listeria*, generate cytosolic peptides that feed the MHC class I antigen presentation pathway and thus induce cytotoxic T-cell responses that target their host cell for destruction. In leprosy, a disease caused by skin and peripheral nerve infection with *Mycobacterium leprae,* effective host defense requires macrophage activation by NK and T_H1 cells (Fig. 13.23). Like *M. tuberculosis, M. leprae* is able to persist and grow in macrophage vesicles and is normally restrained, but not cleared, by a type 1 host response. In individuals who mount normal type 1 immune responses, few live bacteria are found, little antibody is produced, and, although skin and peripheral nerves are damaged by the inflammatory responses associated with macrophage activation, the disease progresses slowly and the individuals typically survive. Because of its similarities to tuberculosis, this variant is called tuberculoid leprosy. This is in contrast to lepromatous leprosy, in which type 1 responses to *M. leprae* are deficient, and an ineffective type 2 response is mounted instead. This results in abundant growth of the bacterium in macrophages and gross tissue destruction that is eventually fatal if untreated. Although high levels of antibacterial antibodies are produced in individuals with lepromatous leprosy, probably due to the high bacterial load, the antibodies are ineffective at controlling infection because they do not reach the intracellular bacteria.

13-23 Immune evasion is also practiced by protozoan parasites.

Most common protozoan parasites, such as *Plasmodium* and *Trypanosoma* species, have complex life cycles: part of the life cycle occurs in humans, and part occurs in an intermediate host, such as an arthropod vector (for example,

mosquitoes, flies, or ticks). Transmission of these organisms by their intermediate host is unusual, in that the normal barriers to infection are bypassed when the infectious agent is directly delivered to blood. Thus, many of the normal innate immune defenses associated with barrier function are completely bypassed during infection. Further, the most successful of these organisms have developed complex and varied immune-evasion strategies that often result in 'hide-and-seek' type chronic infections characterized by episodic disease manifestations, despite their eliciting antibody- and cell-mediated adaptive immune responses.

As described earlier for some bacterial pathogens (see Section 13-21), *Trypanosoma brucei*, a causative agent of trypanosomiasis, or sleeping sickness, has evolved a remarkable capacity for antigenic variation to evade the antibody response elicited in infected humans. The trypanosome is coated with a single type of glycoprotein, the variant-specific glycoprotein (VSG), which elicits a potent protective antibody response that rapidly clears most of the parasites. The trypanosome genome, however, contains about 1000 VSG genes, each encoding a protein with distinct antigenic properties. A VSG gene is expressed by being placed into the active expression site in the parasite genome. Only one VSG gene is expressed at a time, and it can be changed by a gene rearrangement that places a new VSG gene into the expression site (**Fig. 13.24**). So, under the selective pressure of an effective host antibody response, the few trypanosomes within the population that express a different VSG escape elimination and multiply to cause a recurrence of disease. Antibodies are then made against the new VSG, and the whole cycle is repeated, resulting in periods of active and quiescent disease. The chronic cycles of antigen clearance lead to immune-complex damage and inflammation, and eventually to neurological damage, resulting finally in the coma that gives sleeping sickness its name. The cycles of evasive action make trypanosome infections very difficult for the immune system to defeat, and they are a major health problem in Africa.

Caused by *Plasmodium* species, malaria is another serious and widespread disease. Like *Trypanosoma brucei*, *Plasmodium* species vary their antigens to avoid elimination by the immune system. In addition, plasmodia undergo different parts of their life cycle in different cellular hosts within humans. Initial infection occurs by the sporozoite form of the organism, which is transmitted by the bite of an infected mosquito and targets hepatocytes in the liver. Here, the organism replicates rapidly to produce merozoites that burst from infected hepatocytes to infect circulating red blood cells. Thus, as the immune system focuses its efforts on the eradication of the parasite in the liver, the parasite morphs and escapes to its second cellular host, red blood cells. And because red blood cells are the only cells in the body that lack MHC class I molecules, antigens produced by the merozoites within infected red blood cells escape detection by CD8 T cells, preventing cytotoxic destruction of the infected cells. This represents one of the most elegant adaptations to evade cell-mediated immunity.

Immune subversion is also practiced by protozoan parasites. *Leishmania major*, which is transmitted to dermal tissues of humans by the bite of sandflies, is an obligate intracellular parasite that replicates within tissue macrophages.

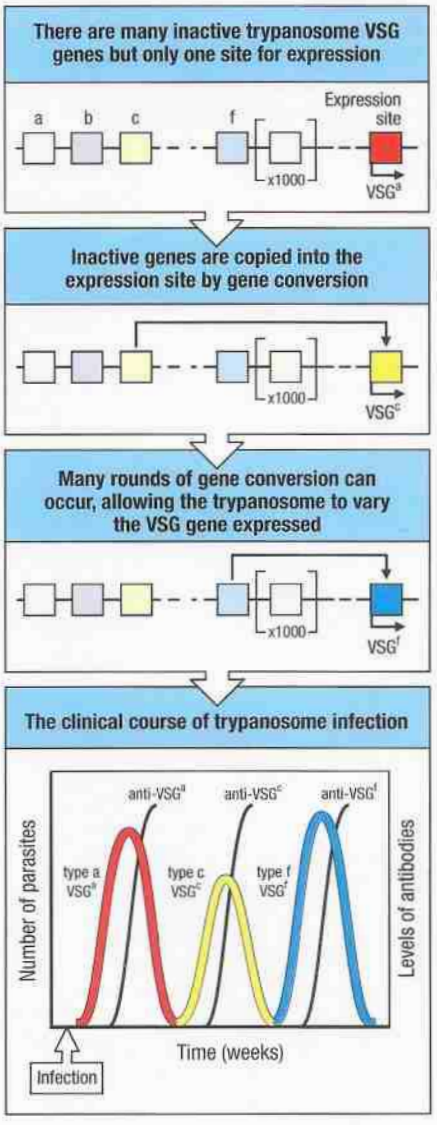


Fig. 13.24 Antigenic variation in trypanosomes allows them to escape immune surveillance. The surface of a trypanosome is covered with a variant-specific glycoprotein (VSG). Each trypanosome has about 1000 genes encoding different VSGs, but only the gene in a specific expression site within the telomere at one end of the chromosome is active. Although several genetic mechanisms have been observed for changing the VSG gene expressed, the usual mechanism is gene conversion. An inactive gene, which is not at the telomere, is copied and transposed into the telomeric expression site, where it becomes active. When an individual is first infected, antibodies are raised against the VSG initially expressed by the trypanosome population. A small number of trypanosomes spontaneously switch their VSG gene to a new type, and although the host antibody eliminates the initial variant, the new variant is unaffected. As the new variant grows, the whole sequence of events is repeated.

Like other intracellular pathogens that reside within phagocytic vesicles, *L. major* requires a type 1 immune response for its eradication. Through mechanisms that are incompletely understood, *L. major* specifically inhibits the production of IL-12 by its macrophage host, thereby inhibiting the production of IFN-γ by NK cells and inhibiting the differentiation and function of T_H1 cells. In addition, *L. major* has been shown to actively induce IL-10–producing T_{reg} cells to suppress clearance of the infection.

13-24 Many viruses target type I and type III interferon pathways to impair host antiviral defense.

Viruses are both the simplest and most diverse of pathogens. They can replicate only within nucleated cells, relying on host cellular machinery to replicate and propagate themselves. As obligate intracellular pathogens, viruses activate receptors that recognize nonmammalian DNA and RNA structures in endosomal vesicles during virus entry into the cell (for example, TLRs 3, 7, 8, and 9) or cytosolic PRRs that detect viral genomic DNA or RNA and their intermediates during viral replication (for example, RIG-I, MDA-5, cGAS, IFI16, and NOD2) (Fig. 13.25). While the endosomal TLRs are especially prevalent on innate sensor cells—including dendritic cells, monocyte/macrophages, granulocytes, and barrier epithelial cells—the cytosolic sensors are ubiquitously expressed. Viral recognition directly induces production of type I and type III interferons, which up-regulate cell-intrinsic antiviral **restriction factors** that impair different aspects of viral replication in both infected and uninfected cells. Although the signaling outputs of the type I and type III interferon receptors are nearly identical (see Section 3-22), their cellular distribution differs such that the type I receptor (IFNAR; IFN-α/β) is nearly ubiquitous, whereas the type III receptor (IFNLR; IFN-λ 1, 2, 3, or 4) is restricted to epithelial cells of mucosal barrier tissues, such as the gastrointestinal, respiratory, and urogenital tracts, and to hepatocytes in the liver and neuronal cells.

Although many cell types produce type I interferons, plasmacytoid dendritic cells are specialized for high levels of type I interferon production early in viral infections and, along with NK cells, play a central role in early antiviral host defense before the adaptive response matures. The type I interferons engage multiple arms of adaptive immunity by promoting: differentiation of T_{FH} cells that provide help for production of opsonizing and complement-fixing virus-specific antibodies that block viral entry into uninfected cells and activate complement to destroy enveloped viruses; differentiation of T_H1 cells, which produce type II interferon (IFN-γ) to enhance intracellular interference pathways, MHC class I and class II antigen processing and presentation, and inflammatory responses; and differentiation of cytolytic CD8 T cells, which destroy virally infected cells and also produce IFN-γ.

Viruses have evolved a remarkable diversity of strategies to impair interferon responses. The fact that most viruses devote at least a part of their limited genomes to gene products that target interferon production and/or signaling indicates the importance of this cytokine family in host antiviral defense. Examples of virally encoded proteins that interfere with nearly every step of these pathways have been described (see Fig. 13.25), whether targeting the receptors that recognize them, the signaling pathways that induce interferons, the receptors for interferons, or the signals shared downstream of their receptors that activate target cells to up-regulate cell-intrinsic antiviral actions.

13-25 RNA viruses use different mechanisms of antigenic variation to keep a step ahead of the adaptive immune system.

In addition to the diverse strategies employed by viruses to overcome interferon-induced host defense, some of the strategies used by viruses are specific

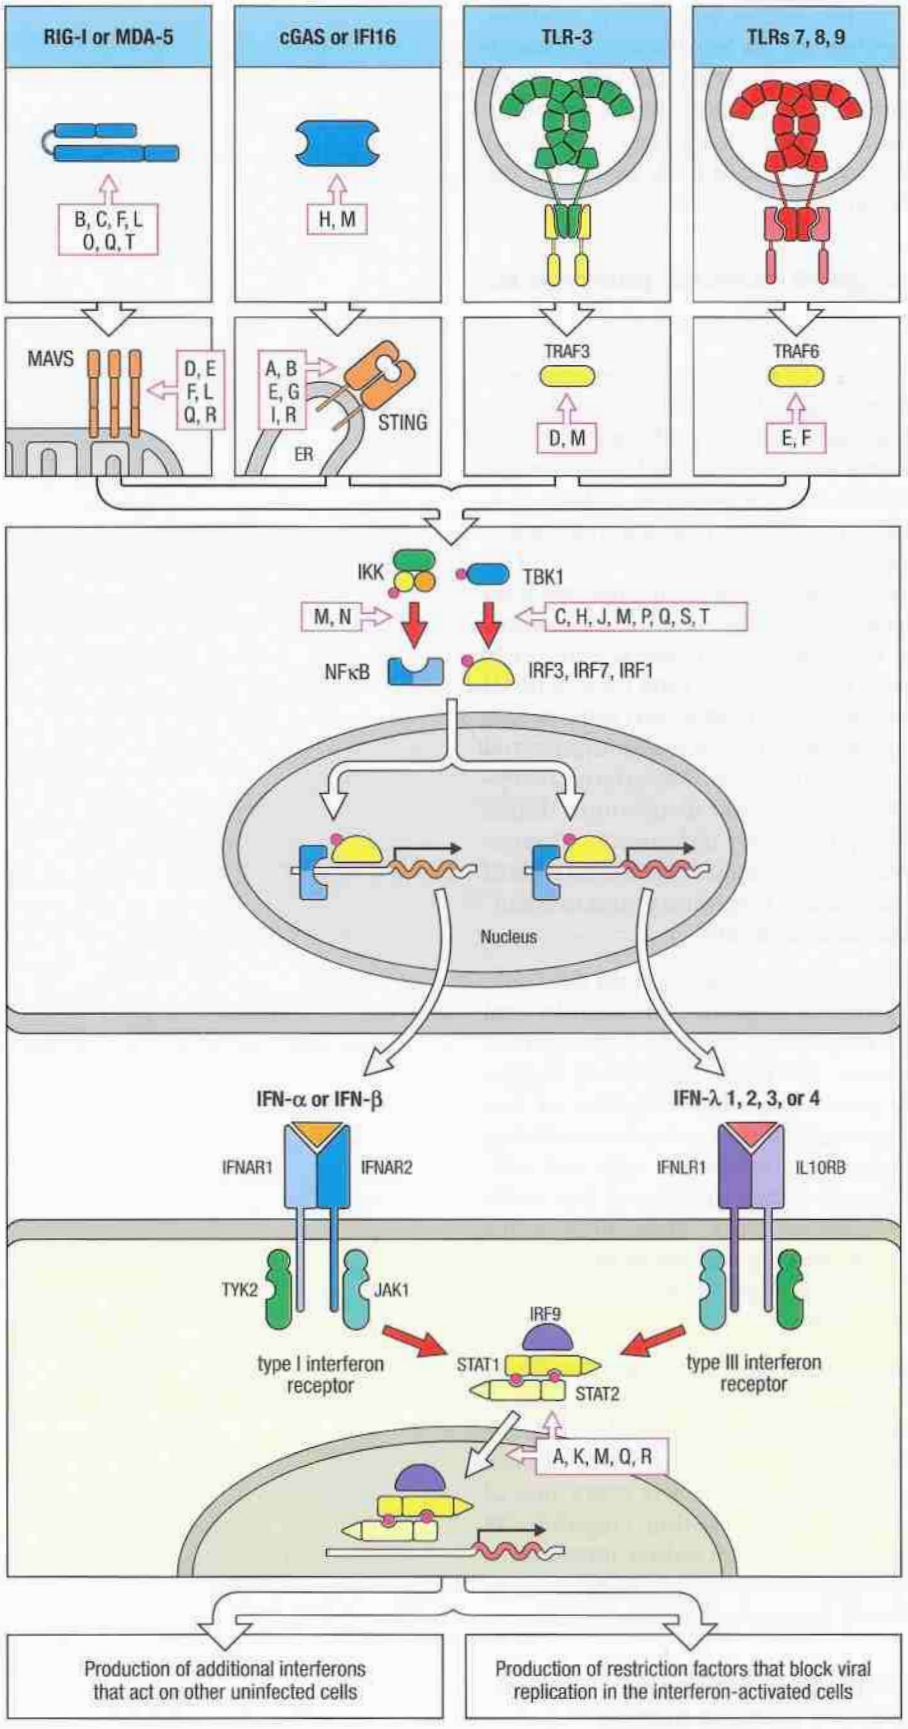

Fig. 13.25 The induction of and response to type I interferons are major targets for immune subversion by viruses. Several pattern-recognition receptors that recognize microbial forms of DNA and RNA produced in the course of viral infection and replication activate the production of type I and type III interferons by the infected cell. Heterodimeric receptors for these cytokines (IFNAR1/IFNAR2 or IFNLR1/IL10RB, respectively) are expressed on nearly all cells of the body and activate STAT1 and STAT2 to amplify production of type I and type III interferons and induce expression of restriction factors that block replication of viruses. Shown in the red boxes and the accompanying key are sites in the interferon signaling cascades at which the indicated viruses interfere.

A – Adenovirus	K – HSV-2

I – HPV	S – Sendai virus
J – HSV-1	T – Vaccinia virus

to the type of viral genome. RNA viruses must replicate their genomes using RNA polymerases, which lack the proofreading ability of DNA polymerase. A consequence is that RNA viruses have a greater rate of mutation than DNA viruses, with the practical consequence that RNA viruses cannot support large genomes. However, this also affords them opportunities for rapidly altering antigenic epitopes targeted by the adaptive immune system as a mechanism for immune evasion. Further, some RNA viruses have segmented genomes, which lend themselves to reassortment during viral replication. Both of these mechanisms are used by influenza virus, a common seasonal respiratory pathogen that causes acute infections and has been responsible for several major pandemics. At any one time, a single virus type is responsible for most cases of influenza throughout the world. The human population gradually develops protective immunity to this virus type, chiefly through the production of neutralizing antibody directed against the viral hemagglutinin, the main surface protein of the influenza virus, which is responsible for viral binding to and entry into cells. Because the virus is rapidly cleared from immune individuals, it might be in danger of running out of potential hosts were it not able to use both mutation mechanisms to alter its antigenic type (see Section 12-23 and Fig. 12.45).

The first mutation mechanism, caused by point mutations in the genes encoding the two major viral surface glycoproteins—hemagglutinin and neuraminidase—is called **antigenic drift** (see Section 12-23 and Fig. 12.45). Every 2–3 years a variant flu virus arises with mutations that allow it to evade neutralization by the antibodies present in the population. Other mutations may affect epitopes in viral proteins that are recognized by T cells, particularly cytotoxic CD8 T cells, with the consequence that cells infected with the mutant virus also escape destruction. People immune to the old flu virus are thus susceptible to the new variant, but because the changes in the viral proteins are relatively minor, there is still some cross-reaction with antibodies and memory T cells produced against the previous variant, and most of the population still has some level of immunity. Thus, epidemics resulting from antigenic drift are typically mild.

Antigenic changes in influenza virus that result from reassortment of the eight segments of its RNA genome are known as **antigenic shifts** and result in major changes in the hemagglutinin expressed by the virus (see Section 12-23 and Fig. 12.45). Antigenic shifts result from co-infection of a host cell by two (or more) variants of influenza, often in a nonhuman viral host, such as a bird or a pig—hence the terms avian or swine flu, respectively. Antigenic shift can lead to reassortment of the segmented RNA genome of the human influenza virus and animal influenza viruses in an animal host, in which, for example, the hemagglutinin gene from the animal virus replaces the hemagglutinin gene in the human virus. These new, antigen-shifted viruses have large changes in their surface proteins (for example, hemagglutinin), and therefore T cells and antibodies produced in earlier infections are not protective. Accordingly, new strains that result from antigen shifts can cause severe infection that spreads rapidly and widely, causing the global influenza pandemics that occur every 10–50 years. These pandemics are typically associated with more severe disease, often with substantial mortality, because the new viral proteins are recognized poorly, if at all, by antibodies and T cells directed against the previous variant.

Hepatitis C virus (HCV) is an RNA virus that can cause both acute and chronic infections of the liver. Although complete resolution of HCV may occur in ~20–40% of individuals with acute hepatitis, as is the case for hepatitis B virus, or HBV (a DNA virus), hepatitis C can cause chronic hepatitis, liver cirrhosis, and in some cases hepatocellular carcinoma. HCV is the most common cause of blood-borne chronic infection in the United States and the leading viral cause of liver cirrhosis and liver transplantation. As with influenza virus, HCV has a high capacity for mutation of immune epitopes that allow it to evade elimination. The RNA polymerase that the HCV uses to replicate its genome lacks

proofreading capacity. This contributes to a high viral mutation rate that can change viral antigenicity; rapid alteration of T-cell epitopes selects for escape variants of HCV that evade cytolytic T-cell responses. However, unlike influenza, the viral surface glycoprotein responsible for binding of HCV to hepatocytes (E2, which binds CD81) presents a difficult target against which to produce effective neutralizing antibodies, due both to its heavy glycosylation in the region of CD81 binding and its high rate of mutation. Antibody responses against HCV are therefore of limited effectiveness, which has impaired the development of an effective vaccine. Fortunately, new antiviral therapies (direct-acting antivirals, or DAAs) that target multiple steps in the virus life cycle have replaced older interferon-based therapies and now have a cure rate of ~95%.

13-26 DNA viruses use multiple mechanisms to subvert CTL and NK-cell responses.

Of all the pathogens, DNA viruses that can establish chronic infections have evolved the greatest diversity of mechanisms for subverting or escaping immune defenses (Fig. 13.26). Unlike RNA viruses, DNA viruses have relatively low mutation rates and are thus less able to employ antigenic variation

Fig. 13.26 Mechanisms used by viruses of the herpes and pox families to subvert the host immune system.

Viral strategy	Specific mechanism	Result	Virus examples
Inhibition of inflammatory response	Viral interference in interferon induction and signaling	Impedes interferon response	HCV, HBV, herpesviruses, adenovirus
	Virally encoded chemokine receptor homolog, e.g., β-chemokine receptor	Sensitizes infected cells to effects of β-chemokine; advantage to virus unknown	Cytomegalovirus
	Virally encoded soluble cytokine receptor, e.g., IL-1 receptor homolog, TNF receptor homolog, interferon-γ receptor homolog	Blocks effects of cytokines by inhibiting their interaction with host receptors	Vaccinia Rabbit myxoma virus
	Viral inhibition of adhesion molecule expression, e.g., LFA-3, ICAM-1	Blocks adhesion of lymphocytes to infected cells	Epstein–Barr virus
	Protection from NFκB activation by short sequences that mimic TLRs	Blocks inflammatory responses elicited by IL-1 or bacterial pathogens	Vaccinia
Blocking of antigen processing and presentation	Inhibition of MHC class I expression	Impairs recognition of infected cells by cytotoxic T cells	Herpes simplex Cytomegalovirus
	Inhibition of peptide transport by TAP	Blocks peptide association with MHC class I	Herpes simplex
Inhibition of humoral immunity	Virally encoded Fc receptor	Blocks effector functions of antibodies bound to infected cells	Herpes simplex Cytomegalovirus
	Virally encoded complement receptor	Blocks complement-mediated effector pathways	Herpes simplex
	Virally encoded complement control protein	Inhibits complement activation by infected cell	Vaccinia
Immunosuppression of host	Virally encoded cytokine homolog of IL-10	Inhibits T_H1 lymphocytes Reduces interferon-γ production	Epstein–Barr virus

to evade immune defenses. However, because their lower rate of mutation allows them to support much larger genomes, these viruses have been able to accommodate a remarkable number of viral genes that encode proteins that can subvert nearly every aspect of antiviral defense. In the case of pox viruses, adenovirus, and especially herpesviruses, large DNA viruses that will be our focus here, more than 50% of the genome can be dedicated to immune evasion–related genes. Further, some of these viruses, particularly the herpesviruses, have evolved mechanisms that allow them to enter a state known as **latency**, in which the virus is not actively replicated. In the latent state, the virus does not cause disease; however, because no viral peptides are produced to load MHC class I molecules that signal the virus's presence to cytolytic T cells, it cannot be eliminated and can establish life-long infections. As we will discuss in Section 13-27, latent infections can be reactivated, resulting in recurrent illness. Of the eight types of herpesviruses that infect humans, at least one of the five most common types—herpes simplex virus (HSV)-1 and HSV-2 (both of which can cause labial and genital herpes), Epstein–Barr virus (EBV; which causes infectious mononucleosis), varicella-zoster virus (which causes chickenpox and shingles), and cytomegalovirus (CMV)—infects nine out of 10 people and typically establishes lifelong latency. Here we highlight major mechanisms by which these viruses succeed.

Central to the long-term survival of the DNA viruses is evasion of CTLs and NK cells. The presentation of viral peptides by MHC class I molecules at a cell surface signals CD8 T cells to kill the infected cell. Many of the large DNA viruses evade immune recognition by producing proteins called **immunoevasins**, which prevent the appearance of viral peptide:MHC class I complexes on the infected cell (Fig. 13.27). Indeed, at least one viral inhibitor of every key step in the processing and presentation of peptide:MHC class I complexes has been described. Some immunoevasins block peptide entry into the endoplasmic reticulum (ER) by targeting the TAP transporter (Fig. 13.28, top panel). Viral proteins can also prevent peptide:MHC complexes from reaching the cell surface by retaining MHC class I molecules in the ER (Fig. 13.28, middle panel). Several viral proteins catalyze the degradation of newly synthesized MHC class I molecules by a process known as **dislocation**, which initiates the pathway normally used to degrade misfolded ER proteins by directing them back

ANIMATION 13.1

Virus	Protein	Category	Mechanism
Herpes simplex virus 1	ICP47	Blocks peptide entry to endoplasmic reticulum	Blocks peptide binding to TAP
Human cytomegalovirus (HCMV)	US6		Inhibits TAP ATPase activity and blocks peptide release into endoplasmic reticulum
Bovine herpesvirus	UL49.5		Inhibits TAP peptide transport
Adenovirus	E19	Retention of MHC class I in endoplasmic reticulum	Competitive inhibitor of tapasin
HCMV	US3		Blocks tapasin function
Murine cytomegalovirus (CMV)	m152		Down-regulation of host MHC class I
HCMV	US2	Degradation of MHC class I (dislocation)	Transports some newly synthesized MHC class I molecules into cytosol
Murine gamma-herpesvirus 68	mK3		E3 ubiquitin ligase activity
Murine CMV	m4	Binds MHC class I at cell surface	Interferes with recognition by cytotoxic lymphocytes by an unknown mechanism

Fig. 13.28 The peptide-loading complex in the endoplasmic reticulum is targeted by viral immunoevasins. The top panel shows blockade of peptide entry to the endoplasmic reticulum (ER). The cytosolic ICP47 protein from herpes simplex virus (HSV)-1 prevents peptides from binding to TAP in the cytosol, whereas the US6 protein from human CMV interferes with the ATP-dependent transfer of peptides through TAP. The middle panel shows the retention of MHC class I molecules in the ER by the adenovirus E19 protein. This binds certain MHC molecules and retains them in the ER through an ER-retention motif, at the same time competing with tapasin to prevent association with TAP and peptide loading. The bottom panel shows how the murine gamma-herpesvirus mK3 protein, an E3 ubiquitin ligase, targets newly synthesized MHC class I molecules. mK3 associates with tapasin:TAP complexes and directs the addition of ubiquitin subunits with K48 linkages (see Section 7-5) to the cytoplasmic tail of the MHC class I molecule. The polyubiquitination of the cytoplasmic tail of the MHC class I molecule initiates the process of degradation of the MHC molecule by the proteasomal pathway.

into the cytosol (Fig. 13.28, bottom panel). By preventing the formation of stably assembled and folded peptide:MHC class I complexes, these viral proteins divert the peptide:MHC class I complexes into the ER-associated degradation (ERAD) pathway for disposal. Through these multiple mechanisms, viral factors impair or completely block the presentation of viral peptides to CTLs. The actions of viral inhibitors are not limited to the MHC class I pathway, as viral inhibitors of the MHC class II processing pathway have also been described; these inhibitors ultimately target CD4 T cells. Finally, as many viruses target cells other than dendritic cells, their antigens come to the attention of CD8 T cells via cross-presentation by cDC1 cells. Viral mechanisms that interfere with this pathway are not well understood, although it is known that because the viruses are not required to persist in dendritic cells, the viruses can block recognition and destruction of their cellular hosts even after primed CTL effectors have been generated.

In addition to their role in the acute innate response to viral infection, a major function of NK cells is the recognition and cytolysis of cells that have down-regulated MHC class I molecules to evade detection by CTLs. Accordingly, viruses that target the MHC class I pathway have also evolved mechanisms to repress the cytolytic activity of NK cells. Strategies here include, but are not limited to, expression of viral homologs of MHC class I that engage killer inhibitory receptors (KIRs) and leukocyte inhibitory receptors (LIRs). For example, human CMV produces a homolog of HLA class I called UL18, which binds LIR-1 on NK cells and provides an inhibitory signal that blocks NK-cell cytolysis. Viral products have been defined that also antagonize activating receptors on NK cells, as well as inhibit NK-cell effector pathways.

DNA viruses have evolved mechanisms to subvert additional functions of the immune system. The mechanisms used include the expression of viral homologs of cytokines or chemokines and their receptors, and viral proteins that bind cytokines or their receptors to inhibit their actions (Fig. 13.29). Poxviruses (for example, smallpox, vaccinia) in particular have evolved a remarkable array of decoy viral receptors for cytokines and chemokines. As noted previously, because all three types of interferons (types I, II, and III) are major effector cytokines in antiviral defense, diverse viral strategies are centered on the inhibition of this family of cytokines, whether by production of decoy receptors or inhibitory binding proteins, inhibition of JAK–STAT signaling by IFN receptors, inhibition of cytokine transcription, or interference with transcription factors induced by IFNs (see Fig. 13.29). Viral homologs of immunosuppressive cytokines are also produced. CMV and EBV impair antiviral responses by producing homologs of the cytokine IL-10, which down-regulate the production of several pro-inflammatory cytokines by immune cells, including IFN-γ, IL-12 and IL-23, IL-1, IL-6, and TNF-α. This can promote tolerogenic rather than immunogenic adaptive responses to viral antigens. Several viruses also interfere with chemokine responses by producing either decoy chemokine receptors or chemokine homologs that interfere

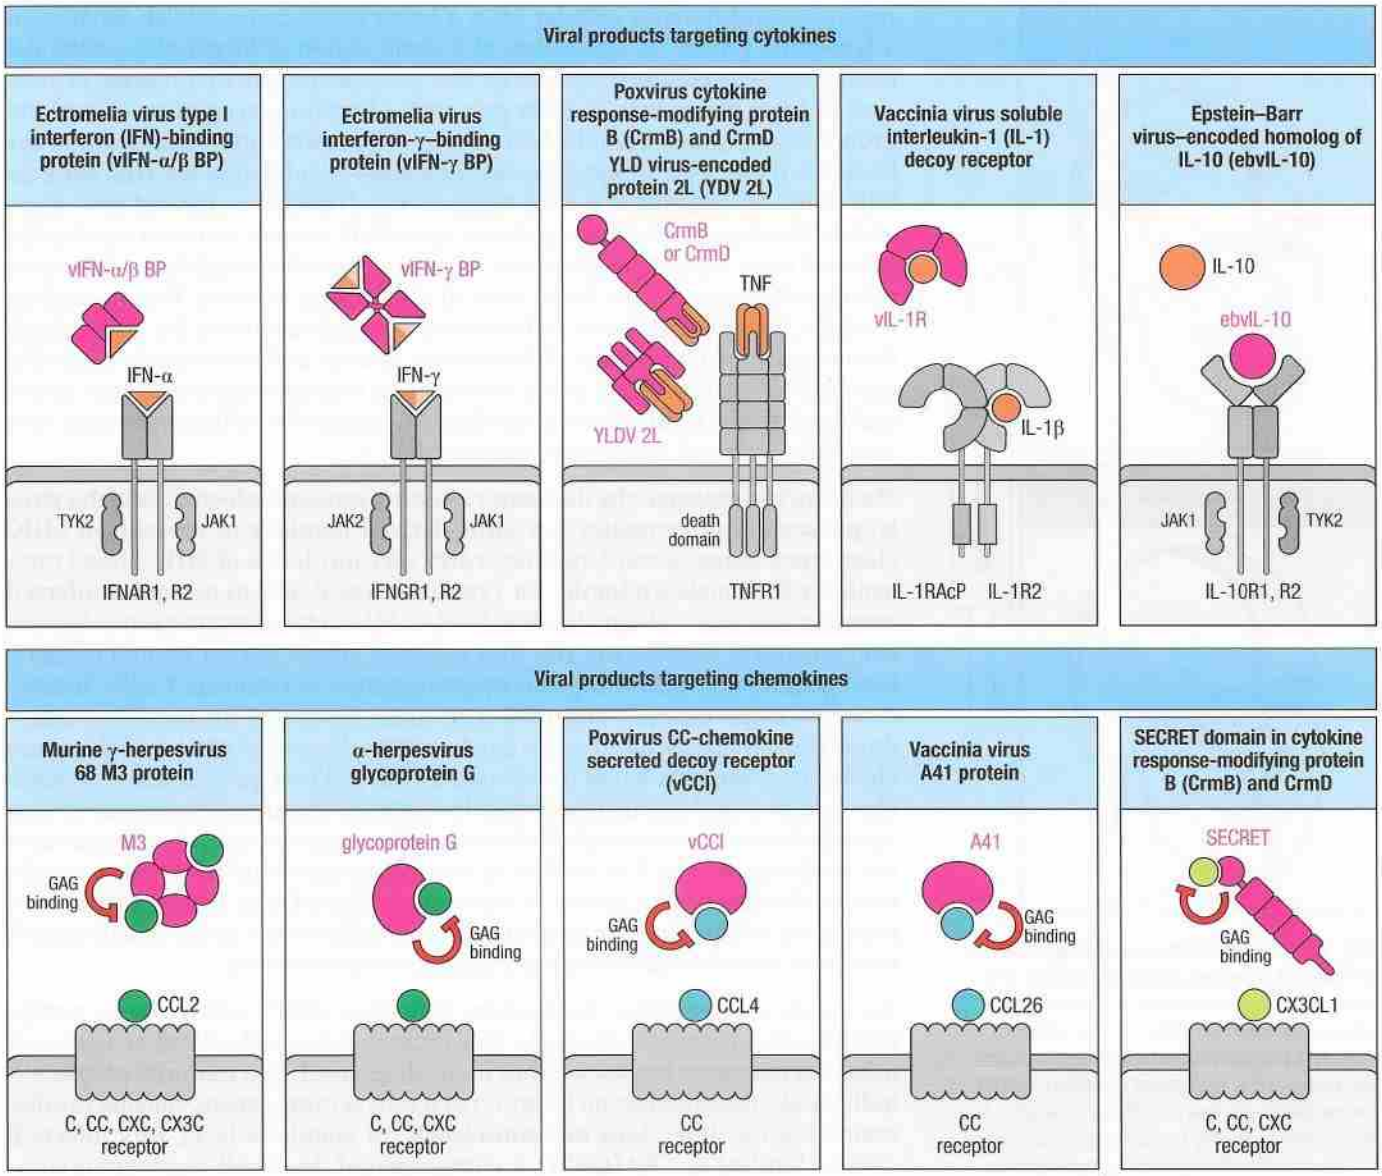

Fig. 13.29 Poxviruses and herpesviruses target cytokines, chemokines, and their receptors as mechanisms of immune evasion. Shown are examples of virally produced cytokines (upper panel) and chemokines (lower panel) that interfere with a variety of immune activating or repressive pathways to interfere with host defense. In addition to blocking binding of chemokines to their target receptor, each of the viral products shown in the lower panels also blocks the glycosaminoglycan (GAG)-binding domain of the targeted chemokines, thereby preventing chemokine binding to cell surfaces or the extracellular matrix.

with natural ligand-induced signaling through chemokine receptors (see Fig. 13.29). Collectively, herpesviruses and poxviruses produce more than 40 viral homologs of receptors belonging to the seven transmembrane-spanning G protein–coupled chemokine receptor (viral GPCR; vGPCR) superfamily.

13-27 Viruses that establish latency persist in vivo by ceasing to replicate until immunity wanes.

As mentioned in the previous section, a major class of viral agents that cause latent infections in humans are the herpesviruses—large, enveloped DNA viruses characterized by the ability to establish lifelong infections. While we have considered a number of strategies by which these viruses subvert immunity, they have also evolved mechanisms to maintain their genome within the nucleus of infected cells indefinitely without replicating. In contrast to an actively **lytic, or productive, phase** of the viral life cycle, wherein the virus

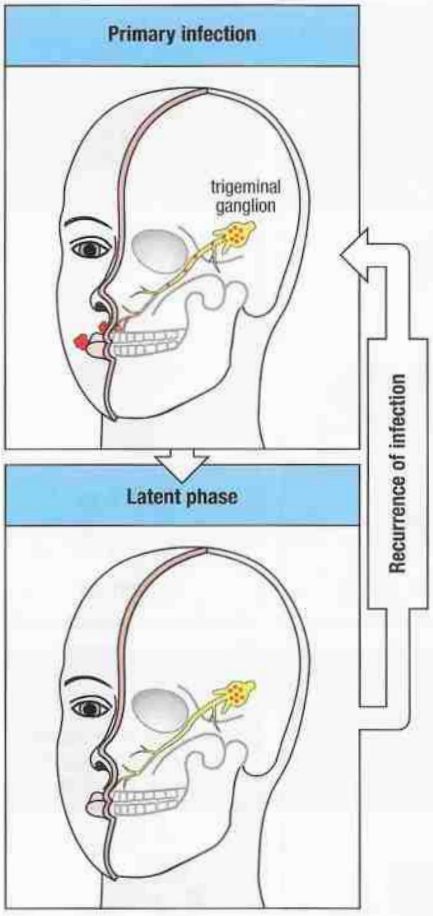

Fig. 13.30 Persistence and reactivation of herpes simplex virus infection. The initial infection in the skin is cleared by an effective immune response, but residual infection persists in sensory neurons such as those of the trigeminal ganglion, whose axons innervate the lips. When the virus is reactivated, usually by some environmental stress and/or alteration in immune status, the skin in the area served by the nerve is reinfected from virus in the ganglion, and a new cold sore results. This process can be repeated many times.

Acute Infectious Mononucleosis

replicates and lyses its cellular host, a herpesvirus can establish latency, or a **lysogenic phase**, by expression of a small region of its genome called the latency-associated transcript (LAT). LAT encodes factors that repress expression of other viral genes, thereby preventing immune recognition of the viral proteins those genes encode. LAT also interferes with apoptotic death of the host cell, thereby prolonging the cell's life span—and that of the viral genome it harbors. An example is herpes simplex virus (HSV), the cause of cold sores, which infects epithelial cells and then spreads to sensory neurons serving the infected area. An effective immune response controls the epithelial infection, but the virus persists in a latent state in the sensory neurons. Factors such as sunlight, bacterial infection, or hormonal changes reactivate the virus, which then travels down the axons of the sensory neuron and reinfects the epithelial tissues (Fig. 13.30). At this point, the immune response again becomes active and controls the local infection by killing the epithelial cells, producing a new sore. This cycle can be repeated many times.

There are two reasons why the sensory neuron remains infected: first, the virus is quiescent and generates few virus-derived peptides to present on MHC class I molecules; second, neurons carry very low levels of MHC class I molecules, which makes it harder for cytotoxic CD8 T cells to recognize infected neurons and attack them. The low level of MHC class I expression is beneficial because it reduces the risk that neurons, which have a limited capacity for regeneration, will be targeted inappropriately by cytotoxic T cells. It does, however, make neurons attractive as cellular reservoirs for persistent infections. Herpesviruses often enter latency: varicella-zoster virus, which causes chickenpox, remains latent in one or a few dorsal root ganglia after the acute illness is over and can be reactivated by stress or immunosuppression. It then spreads down the nerve and reinfects the skin to cause the disease **herpes zoster**, or **shingles**, which is marked by the reappearance of the classic varicella rash in the area of skin served by the infected dorsal root. Unlike herpes simplex virus, which reactivates frequently, varicella-zoster virus usually reactivates only once in a lifetime in an immunocompetent host.

Yet another herpesvirus, the Epstein–Barr virus (EBV), establishes a persistent infection in most individuals. EBV enters latency in B cells after a primary infection that often passes without being diagnosed. In a minority of infected individuals, the initial acute infection of B cells is more severe, causing the disease known as **infectious mononucleosis**, or glandular fever. EBV infects B cells by binding to CR2 (CD21), a component of the B-cell co-receptor complex, and to MHC class II molecules. In the primary infection, most of the infected cells proliferate and produce virus, leading in turn to the proliferation of antigen-specific T cells and the excess of mononuclear white cells in the blood that gives the disease its name. Virus is released from the B cells, destroying them in the process, and virus can be recovered from saliva. The infection is eventually controlled by virus-specific cytotoxic CD8 T cells, which kill the infected proliferating B cells. A fraction of memory B lymphocytes become latently infected, however, and EBV remains quiescent in these cells.

These two forms of infection (subclinical infections and infectious mononucleosis) are accompanied by quite different patterns of expression of viral genes. EBV has a large DNA genome encoding more than 70 proteins. Many of these are required for viral replication and are expressed by the replicating virus, providing a source of viral peptides by which infected cells can be recognized. In a latent infection, the virus survives within the host B cells without replicating, and a very limited set of viral proteins is expressed. One of these is the Epstein–Barr virus nuclear antigen 1 (EBNA-1), which is needed to maintain the viral genome. EBNA-1 interacts with the proteasome (see Section 6-6) to prevent its own degradation into peptides that would otherwise elicit a T-cell response.

Latently infected B cells can be isolated by culturing B cells from individuals who have apparently cleared their EBV infection: in the absence of T cells,

latently infected cells retaining the EBV genome become transformed into so-called immortal cell lines, the equivalent of tumorigenesis *in vitro*. Infected B cells occasionally undergo malignant transformation *in vivo*, giving rise to a B-cell lymphoma called Burkitt's lymphoma. In this lymphoma, expression of the peptide transporters TAP-1 and TAP-2 is down-regulated (see Section 6-3), and so cells are unable to process endogenous antigens for presentation on HLA class I molecules (the human MHC class I). This deficiency provides one explanation for how these tumors escape attack by cytotoxic CD8 T cells. Individuals with acquired and inherited immunodeficiencies of T-cell function have an increased risk of developing EBV-associated lymphomas, presumably as a result of a failure of immune surveillance.

13-28 DNA and RNA viruses can induce exhaustion of CTL and NK cell responses, thereby impairing the antiviral response.

In addition to immune-evasion mechanisms, both HCV and HBV, and members of the herpesvirus family (for example, CMV), among others, have been shown to promote chronic infection by inducing 'exhaustion' of antiviral CD8 T cells and NK cells (Fig. 13.31). In the case of an inability to completely clear antigen, such as occurs with viruses that can evade immune clearance and/or establish latency, or in the setting of chronic type I IFN signaling, CTLs and NK cells undergo an altered programming that impairs their proliferation and function. Such cells are characterized by their expression of a set of immune checkpoint inhibitory receptors, including CTLA-4, LAG-3, TIM-3, or the programmed death-1 (PD-1) receptor (see Section 7-25), which deliver signals that suppress CTL and NK-cell effector functions when activated by their ligands. It is thought that this mechanism has evolved to restrain immune-mediated damage to host cells. Evidence that immune checkpoint inhibition represents an active mechanism to restrain NK and CD8 T-cell function comes from studies showing that blockade of the PD-L1–PD-1 interaction or CTLA-4 can restore antiviral effector function and decrease viral load. A similar mechanism of immune-cell exhaustion is shared with failed antitumor responses, where effective immune-evasion strategies by malignant cells activate this program in NK and CD8 T cells. New immunotherapies that block these inhibitory pathways (**checkpoint blockade**) are showing considerable promise in the treatment of malignancies (see Section 16-13) and are also being studied for efficacy in treating some chronic viral infections.

Summary.

Infectious agents can cause recurrent or persistent disease by avoiding normal host-defense mechanisms or by subverting these mechanisms to promote their own replication. There are many different ways of evading or subverting

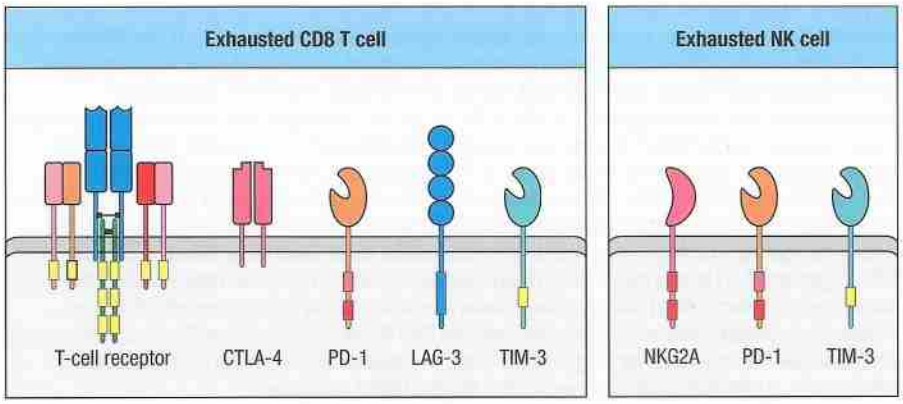

Fig. 13.31 Chronic viral infection can induce exhaustion of CTLs and NK cells. When the immune system is unable to successfully clear a viral infection, chronic stimulation of cytolytic T cells (left panel) and NK cells (right panel) results in the up-regulation of a set of inhibitory receptors that repress activation of the cytolytic machinery of these cells, resulting in impaired antiviral immunity.

the immune response. Antigenic variation, latency, resistance to immune effector mechanisms, and suppression of the immune response all contribute to persistent and medically important infections. In some cases, the immune response is part of the problem: some pathogens use immune activation to spread infection, and others would not cause disease if it were not for the immune response. Each of these mechanisms teaches us something about the nature of the immune response and its weaknesses, and each requires a different medical approach to prevent or to treat infection.

Acquired immune deficiency syndrome.

The most extreme example of immune subversion by a pathogen is the **acquired immune deficiency syndrome (AIDS)** caused by the **human immunodeficiency virus (HIV)**. The disease is characterized by a progressive loss of CD4 T cells, which, when sufficiently depleted, results in high susceptibility to opportunistic infections and certain malignancies. To date, the earliest documented case of HIV infection in humans was identified in a sample of serum from Kinshasa (Democratic Republic of the Congo) that was stored in 1959. It was not until 1981, however, that the first cases of AIDS were officially reported. Because the disease seemed to be spread by contact with body fluids, the cause was suspected to be a new virus, and by 1983 the causative agent, HIV, was isolated and identified.

There are at least two types of HIV—HIV-1 and HIV-2—that are closely related. While both viruses are transmitted by sexual contact and blood-borne exposure (for example, blood transfusion, shared needles), HIV-1 replicates to higher viral loads in blood and is therefore more easily transmitted; HIV-1 has a high rate of transmission from mother to child, which is uncommon in HIV-2. Although in individuals who progress to AIDS, disease is indistinguishable, HIV-1 progresses to AIDS more rapidly and with greater incidence than HIV-2. HIV-1 is therefore by far the most prevalent cause of AIDS worldwide. And while both HIV-1 and HIV-2 are endemic to West Africa, HIV-2 is rarely found elsewhere.

Both HIV-1 and HIV-2 seem to have originally spread to humans from other primate species in Africa. Viral genome sequencing of isolates suggests that the primate precursor of HIV-1, simian immunodeficiency virus (SIV), has passed to humans on at least four independent occasions from chimpanzees or western gorillas, whereas HIV-2 originated in the sooty mangabey (Fig. 13.32). The best estimate is that the most prevalent of the four major variants of HIV-1, group M (responsible for ~99% of HIV-1 infections worldwide), was transmitted to humans from chimpanzees in the first half of the 20th

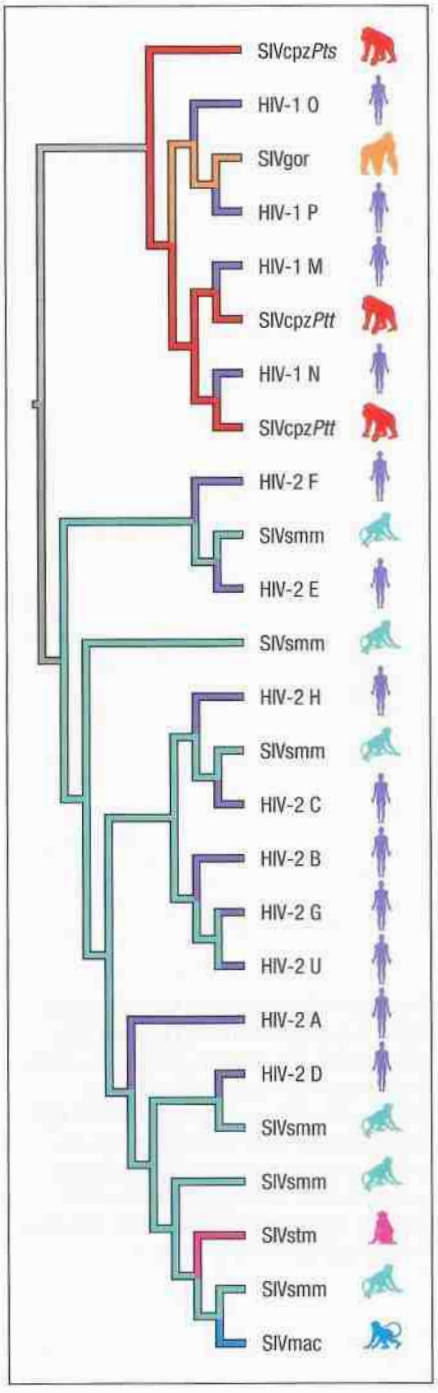

Fig. 13.32 Phylogenetic origins of HIV-1 and HIV-2. HIV-1 shows marked genetic variability and is classified on the basis of genomic sequence into four major groups: M (main), O (outlier), N (non-M, non-O), and P (non-M, non-N, non-O), which are further diversified into subtypes, or clades, that are designated by the letters A to K. In different parts of the world, different subtypes predominate. Phylogenetic analyses of chimpanzee simian immunodeficiency virus (SIVcpz), gorilla SIV (SIVgor), and HIV-1 sequences demonstrate that the four groups of HIV-1 (M, N, O, and P) originated from four independent cross-species transmission events: two transfers of SIVcpz*Ptt* from central chimpanzees (subspecies *Pan troglodytes troglodytes*, or *Ptt*) gave rise to HIV-1 groups M and N, while two transfers of SIVgor from western lowland gorillas (subspecies *Gorilla gorilla gorilla*) gave rise to HIV-1 groups O and P. Similarly, separate zoonotic transmissions of SIVsmm from sooty mangabey monkeys to humans are responsible for at least nine different lineages of HIV-2 (groups A–H and a newly described lineage, U). SIVstm and SIVmac resulted from experimental infections of stump-tailed macaques and rhesus macaques with SIVsmm, respectively. Abbreviations: cpz*Pts*, chimpanzee *Pan troglodytes schweinfurteii*; cpz*Ptt*, chimpanzee *Pan troglodytes troglodytes*; mac, macaque; SIV, simian immunodeficiency virus; smm, sooty mangabey monkey; stm, stump-tailed macaque.

century; transmission of group O also dates to the early 20th century, whereas the two other HIV-1 variants (groups N and P) appear to have been transmitted more recently. As for other zoonotic infections where there has been insufficient time for pathogen and host to coevolve to an equilibrium that attenuates virulence, SIV is generally less pathogenic in its nonhuman primate host than is HIV in its human host. Thus, whereas development of AIDS is nearly universal in HIV-1–infected humans that do not receive treatment, development of AIDS in SIV-infected nonhuman primates is considerably more variable, with some primates failing to develop disease at all, whereas others, such as chimpanzees, do develop AIDS—indicating that they, like humans, were infected by SIV relatively recently.

HIV infection does not immediately cause AIDS. Without treatment, the average time to development of AIDS after infection of adults is several years. The long delay between infection and development of symptomatic immune deficiency reflects the unusual cellular host for viral replication—CD4 T cells, as well as the nature of the immune response to the virus. HIV is now pandemic, and despite great strides made in treatment and prevention that have followed from a greater understanding of the pathogenesis and epidemiology of the disease, almost 690,000 people died of AIDS-related causes in 2020, and an estimated 38 million are infected by HIV worldwide, presaging the death of many from AIDS for years to come (**Fig. 13.33**). In sub-Saharan Africa, which accounts for more than two-thirds of the global incidence, 1 in every 20 adults is infected. Indeed, prior to the development of effective therapies for preventing both the progression of HIV to AIDS and its transmission, HIV/AIDS had become the most deadly single infectious agent in the short time following its identification as a new human pathogen. However, as we will see, despite the elusiveness of a cure for HIV/AIDS or development of an effective vaccine, the success of current therapies in preventing transmission of the virus has resulted in an accelerating decline in the incidence of new cases of HIV infections worldwide since its peak in 1997, and the number of annual deaths from HIV/AIDS has also steadily declined since its peak in the early 2000s. Among the regions with the most rapid declines in incidence of new infections

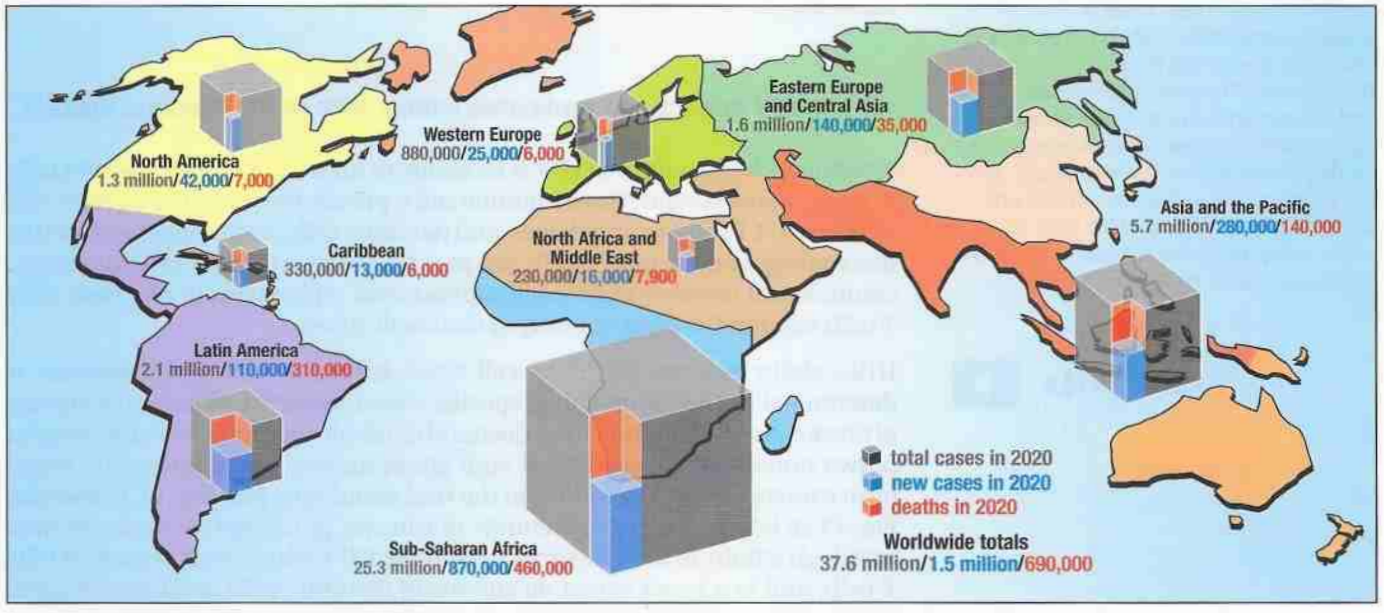

Fig. 13.33 The incidence of new HIV infection is increasing more slowly in many regions of the world, but AIDS is still a major disease burden. The number of individuals living with HIV/AIDS is large and continues to grow, although the number of new infections in 2020 decreased by more than one-third since the peak of the epidemic. Worldwide, in 2020, it is estimated that there were around 38 million individuals infected with HIV, including some 1.5 million new cases, 160,000 of which were in children. There were approximately 690,000 deaths from AIDS in 2020, a decrease of almost 40% since the peak in 2005. New infections in children have declined almost 70% since 2000, with 160,000 new cases in 2020. (AIDS Epidemic Update, UNAIDS/World Health Organization, 2021.)

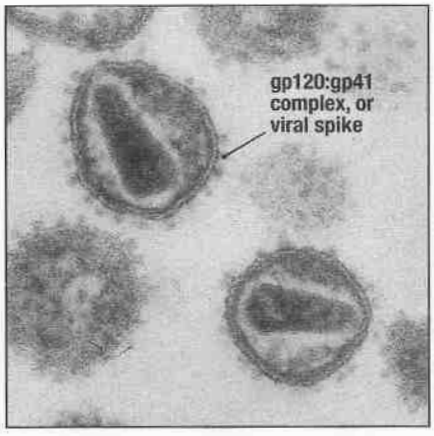

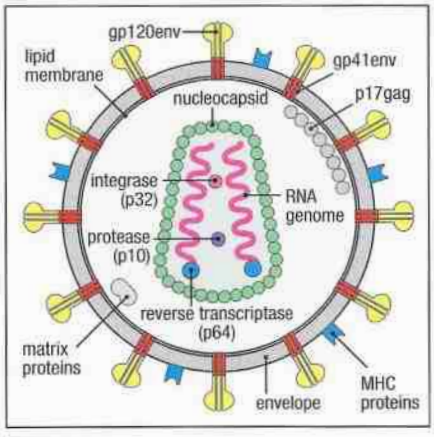

Fig. 13.34 The virion of human immunodeficiency virus (HIV). The virus illustrated is HIV-1, the leading cause of AIDS. The virion is roughly spherical and measures 120 nm in diameter, or about 60 times smaller than the T cells it infects. The HIV envelope protein (Env), which binds the host cell, is composed of a trimer of gp120:gp41 heterodimers. The three viral enzymes that are packaged in the virion—reverse transcriptase, integrase, and protease—are shown schematically in the viral capsid. The p17gag protein is a structural component of the nucleocapsid core of the virus. In reality, many molecules of these enzymes are contained in each virion.

ANIMATION 13.2

is sub-Saharan Africa. Still, there are focal areas of increasing incidence (for example, Eastern Europe and Central Asia).

13-29 HIV is a retrovirus that establishes a chronic infection that slowly progresses to AIDS.

HIV is an enveloped RNA virus whose structure is shown in Fig. 13.34. Each virus particle, or virion, is decorated with a trimeric viral envelope protein that is used by the virus to infect target cells and contains two copies of an RNA genome and numerous copies of viral enzymes that are required to establish infection in the cellular host. HIV is an example of a **retrovirus**, so named because the viral genome must be transcribed from RNA into DNA in the infected cell—the reverse (*retro*) of the usual pattern of transcription—by the viral **reverse transcriptase** enzyme. This generates a DNA intermediate that is integrated into the host-cell chromosomes to enable viral replication. RNA transcripts produced from the integrated viral DNA serve both as mRNAs to direct the synthesis of viral proteins and later as the RNA genomes of new viral particles. These escape from the cell by budding from the plasma membrane, each enclosed in a membrane envelope.

HIV belongs to a group of retroviruses called the **lentiviruses**, from the Latin *lentus*, meaning 'slow,' because of the gradual course of the diseases that they cause. These viruses persist and continue to replicate for many years before causing overt signs of disease. In the case of HIV, the virus targets cells of the immune system itself, producing an initial acute infection that is often associated with symptoms initially but is then controlled to the point that infection is not apparent—but rarely leading to an immune response that can prevent ongoing replication of the virus. Thus, although the initial acute infection does seem to be controlled by the immune system, HIV establishes latency within cells of the immune system and replicates periodically to infect new cells for many years. As will be discussed later, this ultimately depletes key cells of the immune system—particularly CD4 T cells, resulting in immune deficiency, or AIDS, which leads to opportunistic infections and/or malignancy that cause death.

13-30 HIV infects and replicates within cells of the immune system.

A defining characteristic of HIV is its ability to infect and replicate within cells of the immune system. Three immune cell types are the primary targets of HIV uptake: CD4 T cells, macrophages, and dendritic cells. And while it is clear that macrophages and dendritic cells can pass the virus on to other cells, it remains controversial whether these cells support viral replication. In any case, CD4 T cells support the great majority of viral replication.

HIV's ability to enter particular cell types, known as its cellular **tropism**, is determined by the expression of specific receptors for the virus on the surface of those cells. HIV enters cells by means of its envelope (Env) protein, a complex of two noncovalently associated viral glycoproteins, gp120 and gp41, which form trimers that are embedded in the viral membrane (see Fig. 13.34 and also Fig. 13.36 later). The gp120 subunits of trimeric gp120:gp41 complexes bind with high affinity to the cell-surface molecule CD4, which is expressed on CD4 T cells, and to a lesser extent on subsets of dendritic cells and macrophages. Before fusion and entry of the virus, gp120 must also bind a co-receptor on the host cell. The major co-receptors are the chemokine receptors CCR5 and CXCR4 (Fig. 13.35). While CCR5 is predominantly expressed on subsets of effector memory (T_{EM} and T_{RM}) CD4 T cells, dendritic cells, and macrophages, CXCR4 is expressed primarily by naive and central memory (T_{CM}) CD4 T cells. After initial binding to CD4, gp120 undergoes a conformational change that

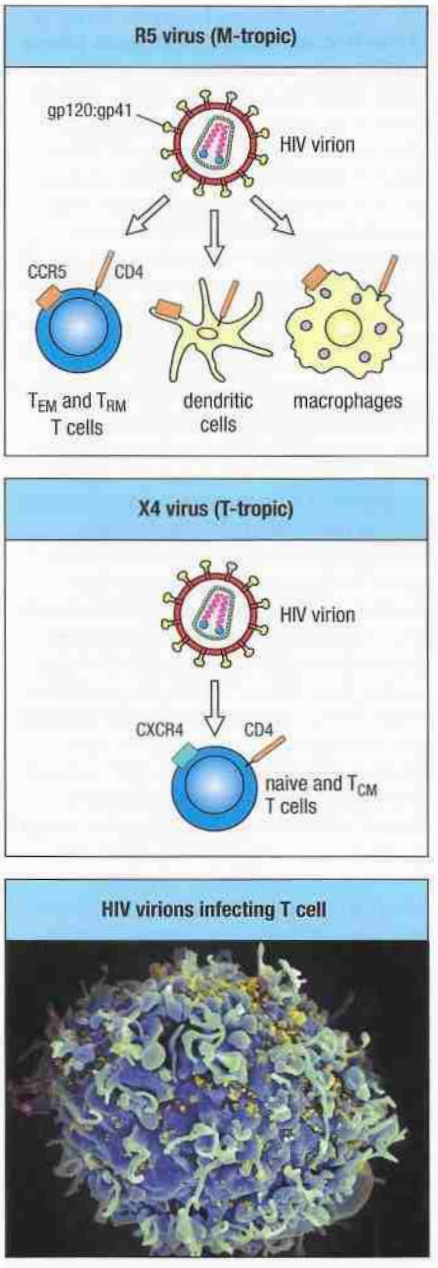

Fig. 13.35 HIV virions target different co-receptors expressed by distinct cell targets. In addition to the CD4 molecule, HIV virions must bind a chemokine co-receptor to initiate viral entry and infection. HIV virions that bind the CCR5 chemokine receptor (so-called R5 variants) target effector memory (T_{EM}) and resident memory (T_{RM}) CD4 T cells, as well as dendritic cells and macrophages (hence, 'M-tropic')—all of which express the CCR5 co-receptor. R5 variants of HIV are thought to represent the major population of virus that establishes initial infection. HIV virions that bind the CXCR4 chemokine receptor (so-called X4 variants) target naive and central memory (T_{CM}) CD4 T cells. X4 variants of HIV emerge after initial infection to expand the pool of T-cell targets within the T-cell repertoire. The photographic image (bottom panel) shows a pseudocolored scanning electron micrograph of HIV virions (yellow) infecting a CD4 T cell (blue).

exposes a high-affinity site that is bound by the co-receptor (Fig. 13.36). This, in turn, causes gp41 to refold and insert a portion of its structure (fusion peptide) into the plasma membrane of the target cell, inducing fusion of the viral envelope with the cell's plasma membrane. This allows the viral nucleocapsid, composed of the viral genome and associated viral proteins, to enter the host-cell cytoplasm (Fig. 13.37). As will be discussed later, the particular chemokine co-receptor bound by a given viral particle is of importance in the transmission of HIV between individuals and its propagation within an infected person.

Once the virus has entered cells, it replicates similarly to other retroviruses. Reverse transcriptase transcribes the viral RNA into a complementary DNA (cDNA) copy. The viral cDNA, which encodes nine genes (Fig. 13.38), is then integrated into the host-cell genome by viral integrase, which recognizes and partially cleaves repetitive DNA sequences, called long terminal repeats (LTRs), that reside at each end of the viral genome. LTRs are required for the integration of the provirus into the host-cell DNA and contain binding sites for gene-regulatory proteins that control expression of the viral genes. The integrated cDNA copy is known as the **provirus**.

Like the genomes of other retroviruses, the HIV genome is small, with three major genes—*gag*, *pol*, and *env*. The gene *gag* encodes the structural proteins of the viral nucleocapsid core, *pol* encodes the enzymes involved in viral replication, and *env* encodes the viral envelope glycoproteins (see Fig. 13.38). The *gag* and *pol* mRNAs are translated to give polyproteins—long polypeptide chains that are then cleaved by the **viral protease** (encoded by *pol*) into individual functional proteins. Thus, *pol* alone encodes the three major enzymes that are required for viral replication: reverse transcriptase, integrase, and viral protease. The product of the *env* gene, gp160, has to be cleaved by a host-cell protease into gp120 and gp41, which are then assembled as trimers in the viral envelope. HIV has six other, smaller, regulatory genes encoding proteins that affect viral replication and infectivity in various ways. Two of these, Tat and Rev, perform regulatory functions that are essential early in the viral replication cycle. The remaining four—Nef, Vif, Vpr, and Vpu—are essential for efficient virus production *in vivo*.

HIV can complete its replication cycle in the host cell to produce progeny virus, or, like other retroviruses and herpesviruses, establish a latent infection in which the provirus remains quiescent. What determines whether infection of a cell results in latency or a productive infection is unclear, but it is thought to be related to the activation state of the cell infected. As we will discuss in the next section, transcription of the provirus after integration is initiated by host transcription factors, which are induced by immune-cell activation. Thus, infection of a cell that becomes dormant soon after infection might favor viral latency, whereas infection of activated cells favors productive viral replication. This has important consequences in the case of CD4 T cells, which, unlike macrophages and dendritic cells, are very long-lived and can provide a reservoir of latent HIV provirus that can be activated when the T cells are reactivated, even years after initial infection. Because macrophages and dendritic cells in tissues are short-lived cells that do not divide, latency in these host cells would be short-lived. Thus, long-lived latency of HIV is primarily a consequence of the tropism of the virus for CD4 T cells. The combined features of tropism for CD4

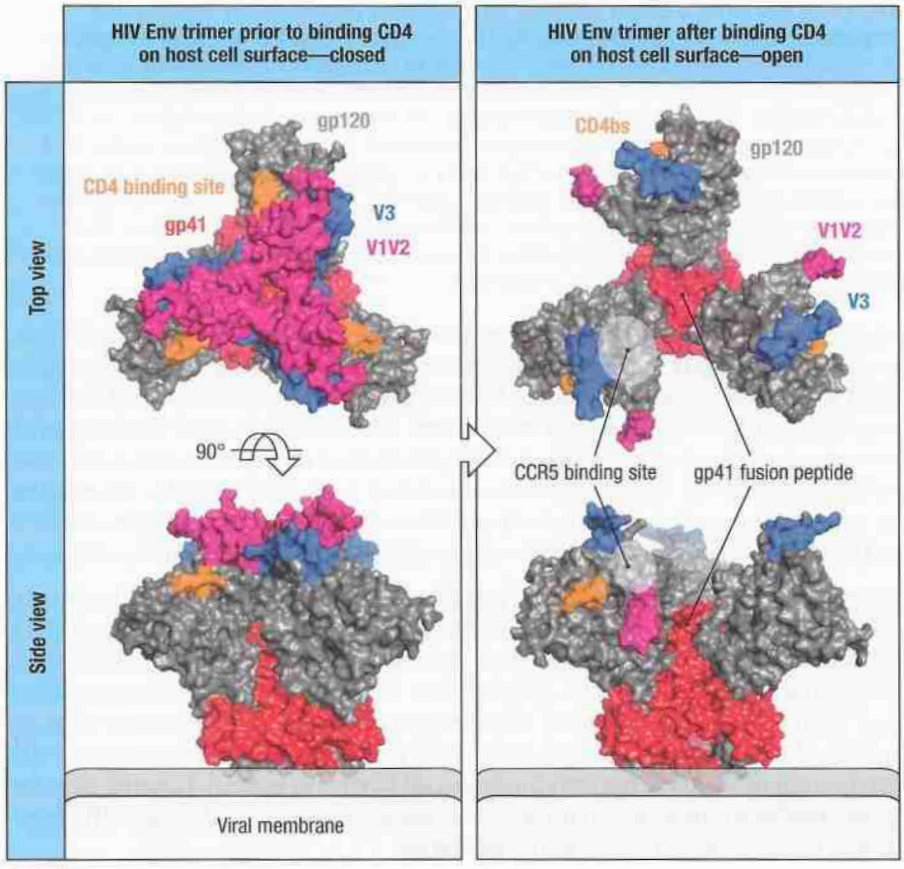

Fig. 13.36 Structural basis for binding of the HIV envelope gp120:gp41 trimer to CD4 and co-receptors. The ability of HIV to infect host cells requires sequential interactions between the viral envelope (Env) protein and CD4 and the CCR5 or CXCR4 co-receptors of the host. Shown are cryo-electron microscopy (cryo-EM) solved structures of the HIV Env trimer, composed of three heterodimers of gp120 (gray structures) and gp41 (red structures). Prior to binding CD4 on the host-cell surface (left panel), the HIV Env trimer is in a 'closed' conformation, with variable sequence loops (V1 and V2, purple; and V3, blue) arranged on the apical surface in a manner that occludes the co-receptor binding site for CCR5 or CXCR4. Upon binding of CD4 to its binding site on gp120 (orange patches), gp120 undergoes conformational changes that lead to an 'open' conformation (right panel) that results from peripheralization of the variable loops to expose co-receptor binding sites (highlighted by light gray ovals), allowing binding to CCR5 or CXCR4. Repositioning of gp120 domains induced by CD4 binding also relieves constraints on gp41 that results in the refolding of the gp41 subunit and exposure of its fusogenic domain. Current structural studies support a model in which co-receptor binding stabilizes CD4-induced gp120 conformational changes to expose the fusogenic domain of gp41 and bring it in close proximity to the target membrane to induce fusion.

T cells and activation-dependent transcription of the provirus are central to the pathogenesis of HIV and its characteristic progressive depletion of CD4 T cells that leads to AIDS.

13-31 Activated CD4 T cells are the major source of HIV replication.

HIV provirus requires activation of the host cell to complete its replication cycle and produce infectious virions that can infect other cells. This is due to a requirement for transactivation of proviral gene expression by transcription factors of the host cell. Two host transcription factors can initiate transcription of the viral genome: NFκB and nuclear factor of activated T cells (NFAT). Both of these factors require cellular activation for their translocation to the nucleus, where they bind DNA and induce gene transcription (see Sections 7-14 and 7-16). While NFκB is expressed in all of the immune cells infected by HIV, NFAT is primarily activated in CD4 T cells, enabling transactivation of the provirus by an additional factor in this cell host. This, coupled with the fact that CD4 T cells are long-lived and more abundant in immune tissues, contributes to CD4 T cells being the major cellular source for HIV replication. Here we consider the mechanism by which transcription of the HIV provirus is regulated in CD4 T cells.

As discussed in Sections 7-14 and 7-16, activation of T cells by antigen induces activation and nuclear translocation of NFAT and NFκB; activation of effector memory T cells by cytokines can also activate NFκB in the absence of antigen (see Fig. 13.37). Thus, in addition to antigen-dependent activation of HIV provirus transcription by NFAT and NFκB , provirus might be activated independently of TCR stimulation in memory CD4 T cells via NFκB alone, as it is in infected macrophages and dendritic cells. Binding of NFAT and NFκB initiates transcription of viral RNA by binding to promoters in the proviral LTR. The viral transcript is spliced in various ways to produce mRNAs for translation of viral proteins (see Fig. 13.38).

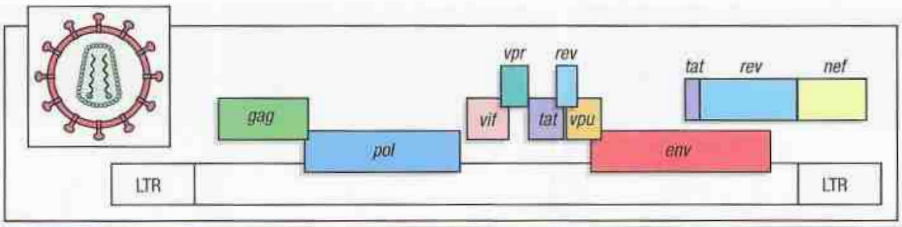
Fig. 13.37 The life cycle of HIV. Top row: The virus binds to CD4 using gp120, which is altered by CD4 binding so that it now also binds a chemokine receptor that acts as a co-receptor for viral entry. This binding releases gp41, which causes fusion of the viral envelope with the cell membrane and release of the viral core into the cytoplasm. Once in the cytoplasm, the viral core releases the RNA genome, which is reverse-transcribed into double-stranded complementary DNA (cDNA) using the viral reverse transcriptase. The double-stranded cDNA migrates to the nucleus in association with the viral integrase and the Vpr protein and is integrated into the cell genome, becoming a provirus. Bottom row: Activation of CD4 T cells induces the expression of the transcription factors NFκB and NFAT, which bind to the proviral long terminal repeat (LTR) and initiate transcription of the HIV genome. The first viral transcripts are extensively processed, producing spliced mRNAs encoding several regulatory proteins, including Tat and Rev. Tat both enhances transcription from the provirus and binds to the RNA transcripts, stabilizing them in a form that can be translated. Rev binds the RNA transcripts and transports them to the cytosol. As levels of Rev increase, less extensively spliced and unspliced viral transcripts are transported out of the nucleus. The singly spliced and unspliced transcripts encode the structural proteins of the virus, and unspliced transcripts, which are also the new viral genomes, are packaged with these proteins to form many new virus particles.

At least two of the viral proteins—Tat and Rev—serve to enhance production of the viral genome (see Fig. 13.37). Tat binds to a transcriptional activation region (TAR) in the 5′ LTR. This recruits cellular cyclin T1 and its partner, cyclin-dependent kinase 9 (CDK9), to form a complex that phosphorylates RNA polymerase and enhances its ability to generate full-length transcripts



Gene		Gene product/function
gag	Group-specific antigen	Core proteins and matrix proteins
pol	Polymerase	Reverse transcriptase, protease, and integrase enzymes
env	Envelope	Transmembrane glycoproteins. gp120 binds CD4 and CCR5; gp41 is required for virus fusion and internalization
tat	Transactivator	Positive regulator of transcription
rev	Regulator of viral expression	Allows export of unspliced and partially spliced transcripts from nucleus
vif	Viral infectivity	Affects particle infectivity
vpr	Viral protein R	Transport of DNA to nucleus. Augments virion production. Cell-cycle arrest
vpu	Viral protein U	Promotes intracellular degradation of CD4 and enhances release of virus from cell membrane
nef	Negative-regulation factor	Augments viral replication *in vivo* and *in vitro*. Decreases CD4, MHC class I and II expression

Fig. 13.38 The genomic organization of HIV. Like all retroviruses, HIV-1 has an RNA genome flanked by long terminal repeats (LTRs) involved in viral integration and in regulation of transcription of the viral genome. The genome can be read in three frames, and several of the viral genes overlap in different reading frames. This allows the virus to encode many proteins in a small genome. The three main protein products—Gag, Pol, and Env—are synthesized by all infectious retroviruses. The known functions of the different genes and their products are listed. The products of *gag*, *pol*, and *env* are known to be present in the mature viral particle, together with the viral RNA. The mRNAs for Tat, Rev, and Nef proteins are produced by splicing of viral transcripts, so their genes are split in the viral genome. In the case of Nef, only one exon, shown in yellow, is translated.

of the viral genome. In this way, Tat provides a positive feedback circuit for rapid amplification of productive viral replication. Rev is important for shuttling unspliced viral RNA transcripts out of the nucleus by binding to a specific viral RNA sequence, the Rev response element (RRE). Eukaryotic cells have mechanisms to prevent the export of incompletely spliced mRNA transcripts from the nucleus. This could pose a problem for the retrovirus, which is dependent on export of unspliced mRNA species that encode the full complement of viral proteins, as well as the viral RNA genome. While export of a fully spliced mRNA transcript that encodes Tat and Rev occurs early after viral infection by means of the normal host cellular mechanisms of mRNA export, the export of later, unspliced viral transcripts requires Rev to prevent their destruction by the host cell.

The success of viral replication also depends on the proteins Nef, Vif, Vpu, and Vpr. These viral products appear to have evolved to defeat host immune mechanisms of viral clearance, as well as antiviral restriction factors—host cellular proteins that function in a cell-autonomous manner to inhibit replication of retroviruses. Nef (negative-regulation factor) performs multiple critical functions in the viral life cycle. It acts early in the viral life cycle to sustain T-cell activation and the establishment of a persistent state of HIV infection, in part by lowering the threshold for T-cell receptor signaling and down-regulating expression of the inhibitory co-stimulatory receptor CTLA-4. Combined, these actions result in a greater and more sustained T-cell activation that promotes viral replication. Nef also contributes to immune evasion of infected cells by down-regulating expression of MHC class I and class II molecules, making actively infected cells less likely to induce an antiviral immune response or be killed by cytotoxic T cells. In addition, Nef promotes the clearance of surface CD4 molecules, which otherwise would bind to the virion during budding and interfere with virion release. Vif (viral infectivity factor) acts to overcome a cytidine deaminase called APOBEC, which catalyzes the conversion of deoxycytidine to deoxyuridine in reverse-transcribed viral cDNA, thereby destroying its ability to encode viral proteins. Vpu (viral protein U) is unique to HIV-1 and

variants of SIV and is required to overcome a cellular factor called tetherin, which inserts into both the plasma membrane of the host cell and the envelope of the mature virion to block its release. The function of Vpr (viral protein R) is not fully understood, but it may target the restriction factor SAMHD1, a cellular protein that inhibits HIV-1 infection by limiting the intracellular pool of deoxynucleoside triphosphate (dNTP) molecules available for viral cDNA synthesis by reverse transcriptase.

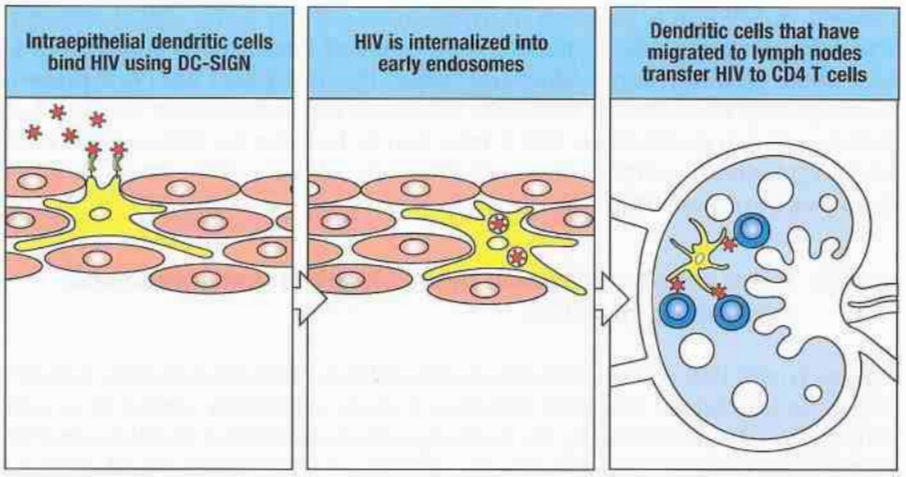
13-32 There are several routes by which HIV is transmitted and establishes infection.

Infection with HIV occurs after the transfer of body fluids from an infected person to an uninfected one. HIV infection is most commonly spread by sexual intercourse. Transmission by the exchange of contaminated needles used for intravenous drug delivery or by the therapeutic use of infected blood or blood products also occurs, although the latter route of transmission has largely been eliminated in countries where blood products are routinely screened for HIV. An important route of virus transmission is from an infected mother to child, which can occur *in utero*, during birth, or through breast milk. Rates of transmission from an untreated infected mother to her child vary (from about 15 to 45%), depending on the viral load in the mother and whether the mother breast-feeds the child, as breast-feeding increases the risk of transmission. The use of antiretroviral drugs to decrease maternal viral load during pregnancy dramatically reduces the transmission rate to the child (see Section 13-41).

The virus can be transmitted as free infectious particles or via infected cells for which the virus has tropism (for example, CD4 T cells and dendritic cells). Infected cells are found in blood, but can also be present in semen or vaginal secretions, as well as breast milk; free virus is present in blood, semen, vaginal fluid, or mother's milk. As we discuss in the next section, HIV virions can differentially express gp120 variants that bind either CCR5 or CXCR4, thereby influencing the cell types infected. In the genital and gastrointestinal mucosae, which are the dominant sites of primary infection by sexual transmission, HIV virions establish infection initially in a small number of mucosal immune cells that express CCR5—effector memory CD4 T cells, dendritic cells, and macrophages (see Fig. 13.35). The virus replicates locally in these cells before spreading via T cells or dendritic cells (mucosal macrophages are nonmigratory) to lymph nodes draining the mucosa. The lymphoid compartment of mucosal tissues is enriched for T_H1 and T_H17 cells, which express CCR5 (naive T cells and T_H2 cells do not), so initial viral replication is favored in these subsets of CD4 T cells. After accelerated replication in regional lymph nodes, where there is a high concentration of CD4 T cells, the virus disseminates widely via the bloodstream and gains broader access to the gut-associated lymphoid tissue (GALT), where the highest number of CD4 T cells in the body reside.

13-33 HIV variants with tropism for different co-receptors play different roles in transmission and progression of disease.

To establish infection in a new host, the HIV virion must contact a CD4-expressing immune cell. The cell type targeted is determined by the affinity of the virion's gp120 variant for the different chemokine co-receptors: CCR5 or CXCR4. Accordingly, the two major tropism variants of HIV are referred to as R5 and X4, respectively (see Fig. 13.35). Because CCR5 dominates on CD4-expressing immune cells resident at the major sites of viral transmission—sites that are constantly exposed to commensal microbes and thus harbor large numbers of activated immune cells (mucosal tissues of the female and male genital tracts or rectum for sexual transmission; upper gastrointestinal tract for



Intraepithelial dendritic cells bind HIV using DC-SIGN
HIV is internalized into early endosomes
Dendritic cells that have migrated to lymph nodes transfer HIV to CD4 T cells

Fig. 13.39 Dendritic cells can initiate infection by transporting HIV from mucosal surfaces to lymphoid tissue. HIV adheres to the surface of intraepithelial dendritic cells by the binding of viral gp120 to DC-SIGN (left panel). It gains access to dendritic cells at sites of mucosal injury or possibly to dendritic cells that have protruded between epithelial cells to sample the external world; HIV can also bind directly to some epithelial cells and is transported across them to subepithelial dendritic cells (not shown). Dendritic cells internalize HIV virions into mildly acidic early endosomes and migrate to lymphoid tissue (center panel). HIV virions are translocated back to the cell surface, and when the dendritic cell encounters CD4 T cells in a secondary lymphoid tissue, the HIV is transferred to the T cell (right panel).

mother-to-child transmission)—CCR5-tropic, R5 strains of virus are typically required for transmission and dominate early in infection.

Before HIV can contact CD4-expressing immune cells in the genital and intestinal mucosae, it must traverse the epithelium of these tissues. Here, the CCR5-tropic variants of the virus also have an advantage. Infection occurs across two types of epithelium: the stratified, or multilayered, squamous epithelium that lines the mucosae of the vagina, foreskin of the penis, ectocervix, oropharynx, and esophagus; or the single-layered columnar epithelium lining the endocervix, rectum, and upper GI tract. Epithelial cells of the rectum and endocervix can express CCR5 and have been shown to selectively translocate R5, but not X4, HIV variants through the epithelial monolayer. Other molecules expressed by epithelial cells also participate; gp120-binding glycosphingolipids expressed by epithelial cells of the vaginal or ectocervical mucosae also foster transcytosis of virus across the epithelium. The rate at which virus can cross epithelial barriers to establish infection is fast. SIV virus has been shown to penetrate the cervicovaginal epithelium within 30–60 minutes of exposure.

In addition to direct transcytosis across epithelial cells, the interdigitating processes of dendritic cells that ramify between epithelial cells provide an avenue for HIV to traverse the epithelium. A complex ferrying mechanism seems to transfer HIV picked up by dendritic cells to CD4 T cells in lymphoid tissue. HIV can attach to dendritic cells by the binding of viral gp120 to C-type lectin receptors such as langerin (CD207), the mannose receptor (CD206), and DC-SIGN. A portion of the bound virus is rapidly taken up into vacuoles, where it can remain for days in an infectious state. In this way the virus is protected and remains stable until it encounters a susceptible CD4 T cell, whether in the local mucosal environment or after being carried to draining lymphoid tissue (Fig. 13.39). Finally, at some mucosal sites, CCR5-expressing CD4 T cells reside within the epithelium (intraepithelial T cells) and have been shown to be sites of early viral replication. Thus, HIV can infect CD4 T cells either directly or via dendritic cells that interact with CD4 T cells.

During the **acute phase** of infection, which typically lasts for several weeks and is characterized by an influenza-like illness in about half of those infected (the rest remaining asymptomatic), there is rapid replication of the virus, primarily in CCR5-expressing CD4 T cells (Fig. 13.40). This period is marked by an abundance of virus circulating in the blood (viremia) and the rapid decline of CCR5-expressing CD4 T cells, the latter due primarily to the extensive death of CD4 T cells in the GALT that are killed by viral cytopathic effects (macrophages and dendritic cells appear more resistant to lysis by replicating virus). The depletion of immune cells in the gut might compound the rapid production of virus in the GALT by fostering increased immune-cell activation because of barrier breakdown and translocation of constituents of the microbiota. Because of

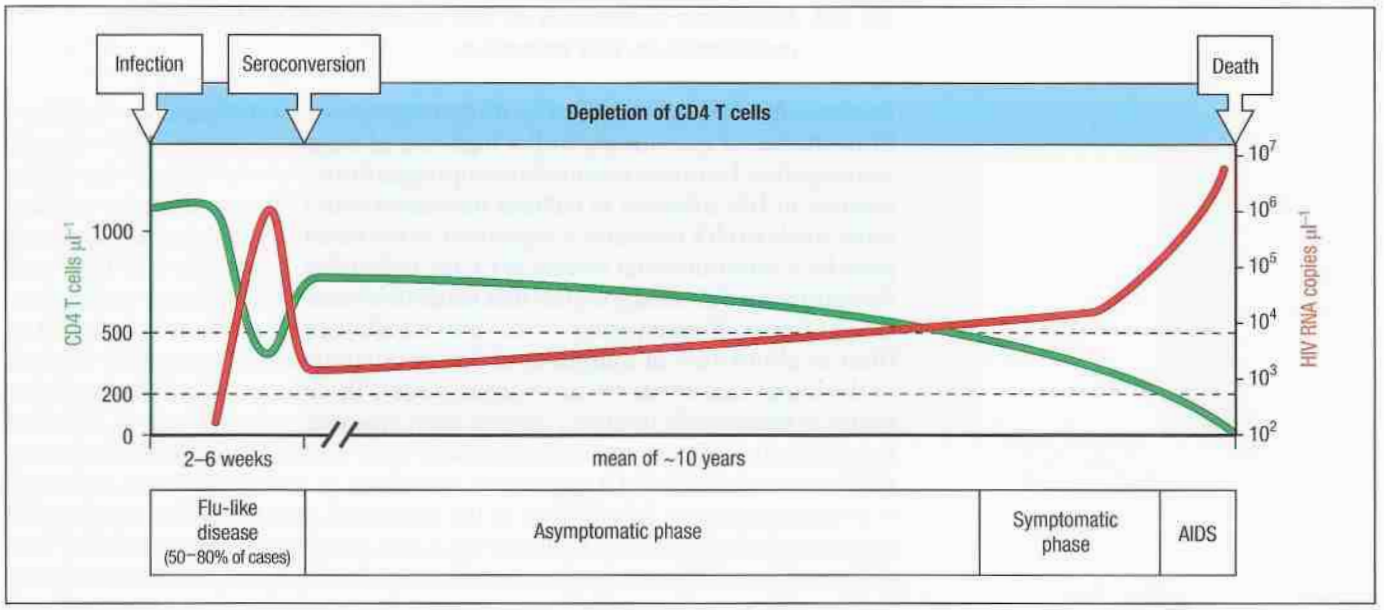


Fig. 13.40 The typical course of untreated infection with HIV. The first few weeks are typified by an acute influenza-like viral illness, sometimes called seroconversion disease, with high titers of virus in the blood. An adaptive immune response follows, which controls the acute illness and largely restores levels of CD4 T cells but does not eradicate the virus. This is the asymptomatic phase, which typically lasts 5–10 years without treatment. Opportunistic infections and other symptoms become more frequent as the CD4 T-cell count in peripheral blood falls, beginning at about 500 cells μl^{-1}. The disease then enters the symptomatic phase. When CD4 T-cell counts fall below 200 cells μl^{-1}, the individual is said to have AIDS. Note that CD4 T-cell counts are measured for clinical purposes in cells per microliter (cells μl^{-1}), rather than cells per milliliter (cells ml^{-1}), the unit used elsewhere in this book.

the high viral titers and preponderance of R5 strains during the acute phase of infection, the risk of viral transmission to uninfected contacts during this time is especially high.

The acute phase and its high viremia reside in virtually all individuals once an adaptive immune response is established (see Fig. 13.40). Cytolytic CD8 T cells specific for viral antigens develop and kill HIV-infected cells, and virus-specific antibodies become detectable in the serum of those infected (**seroconversion**). The development of a CTL response results in early control of the virus, resulting in a sharp drop in viral titers and a rebound of CD4 T-cell counts. The level of virus that persists in blood plasma at this stage of infection, referred to as the **viral set point**, is usually a good indicator of future disease progression. At this point, the disease transitions to a clinically latent phase, or **asymptomatic phase**, marked by low viremia and slowly declining CD4 T-cell numbers, typically over several years. During this time the virus continues to actively replicate, but it is held in check, principally by HIV-specific CD8 T cells and antibodies.

Under strong selective pressure brought by the antiviral antibody response, there is selection for HIV **escape mutants** that express altered envelope variants no longer neutralized by existing anti-envelope antibodies. This gives rise to many different viral variants in a single infection and to even broader variation within the population as a whole. Late in infection, in approximately 50% of cases, the dominant viral type switches from R5 to X4 variants that infect T cells via CXCR4 co-receptors. This is followed by a rapid decline in CD4 T-cell count and progression to AIDS. The exact mechanism by which this shift in viral tropism leads to accelerated loss of CD4 T cells is not completely understood, although the expression of the CXCR4 co-receptor by both naive and memory CD4 T cells may play a role by expanding the pool of HIV-susceptible T cells. On balance, then, R5 variants appear critical for transmission of the virus from infected to uninfected individuals, whereas X4 variants that emerge under selective pressure exerted by the antiviral immune response contribute to the progression of disease within an infected individual.

13-34 A genetic deficiency of the co-receptor CCR5 confers resistance to HIV infection.

Evidence for the importance of CCR5 in transmission of HIV infection has come from studies of individuals with a high risk of exposure to HIV-1 who remain seronegative. Lymphocytes and macrophages from these individuals are highly resistant to HIV infection in cultures inoculated with HIV. The resistance of these individuals to HIV infection is explained by the discovery that they are homozygous for a nonfunctional variant of CCR5, called Δ32, caused by a 32-base-pair deletion from the coding region that leads to a frameshift mutation and a truncated protein. The frequency of this mutant allele in Caucasians is high at 0.09 (that is, about 10% of members of this population are heterozygous carriers of the allele and about 1% are homozygous). The mutant allele has not been found in Japanese or in black Africans from Western or Central Africa. Whether heterozygous deficiency of CCR5 provides some protection against infection by HIV is controversial, but it appears to contribute to a modest, if any, reduction in progression rates. In addition to the structural polymorphism of the gene, variations in the promoter region of the CCR5 gene have been associated with different rates of disease progression. The high incidence of the *CCR5Δ32* allele in Caucasians predating the HIV pandemic suggests selection for this variant in a past epidemic. Both smallpox and bubonic plagues have been put forward as possible selective agents, but this is as yet unproven.

13-35 An immune response controls but does not eliminate HIV.

Infection with HIV generates an immune response that contains the virus but only very rarely, if ever, eliminates it. A time course of the response of various adaptive immune elements to HIV in adults is shown in Fig. 13.41, together with the levels of infectious virus in plasma. As was noted earlier, in the acute phase, virus-mediated cytopathicity results in a substantial depletion of CD4 T cells, particularly in mucosal tissues. There is a good initial recovery of T-cell numbers outside mucosal tissues and transition to the asymptomatic phase of disease as the immune response develops and curbs viral replication (see Fig. 13.40). However, replication of the virus persists and, after a variable period lasting from a few months to more than 20 years, the CD4 T-cell numbers fall too low to maintain effective immunity, and AIDS develops (defined as less than 200 CD4 T cells per microliter in peripheral blood) (see Fig. 13.40). Several factors conspire to progressively deplete CD4 T cells until they can no longer maintain immunity: destruction by cytotoxic lymphocytes directed against HIV-infected cells, immune activation (direct and indirect) that induces activation of latent virus, ongoing viral cytopathic effects, and insufficient T-cell regeneration in the thymus. In this section we consider the roles of cytotoxic

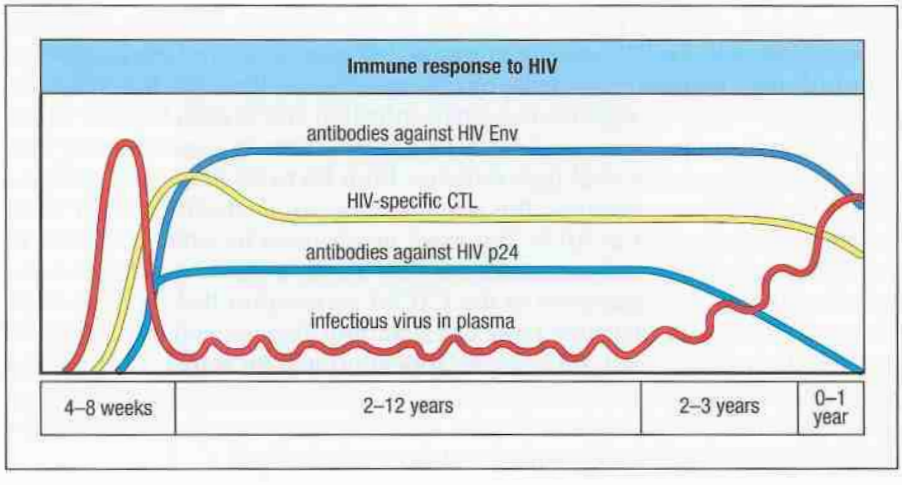

Fig. 13.41 The immune response to HIV. Infectious virus is present at relatively low levels in the peripheral blood of infected individuals during a prolonged asymptomatic phase, during which the virus is replicated persistently in lymphoid tissues. During this period, CD4 T-cell counts gradually decline (see Fig. 13.40), although antibodies and cytotoxic CD8 T cells directed against the virus remain at high levels. Two different antibody responses are shown in the figure, one to the envelope protein (Env) of HIV, and one to the core protein p24. Eventually, the levels of antibody and HIV-specific cytotoxic T lymphocytes (CTLs) also decline, and there is a progressive increase in infectious HIV in the peripheral blood.

CD8 T cells, CD4 T cells, antibodies, and other immune factors in mounting the immune response to HIV infection that initially contains the infection, but ultimately fails.

Studies of peripheral blood cells from infected individuals reveal cytotoxic T cells specific for viral peptides that can kill infected cells *in vitro*. *In vivo*, cytotoxic T cells are recruited to sites of HIV replication, where they are thought to kill many productively infected cells before any infectious virus is released, thereby containing viral load at the quasi-stable levels that are characteristic of the asymptomatic period. Evidence for the clinical importance of the control of HIV-infected cells by cytotoxic CD8 T cells comes from studies relating the numbers and activity of CD8 T cells to viral load. There is also direct evidence from experiments in macaques infected with SIV that cytotoxic CD8 T cells control retrovirus-infected cells; treatment of infected animals with monoclonal antibodies that remove CD8 T cells is rapidly followed by a large increase in viral load.

In addition to direct cytotoxicity mediated by recognition of cells infected with virus, a variety of factors produced by CD4, CD8, and NK cells are important in antiviral immunity. Chemokines that bind CCR5, such as CCL5, CCL3, and CCL4, are released at the site of infection by CD8 T cells and inhibit virus spread by competing with R5 strains of HIV-1 for the engagement of co-receptor CCR5, whereas CXCL12 can compete with R4 strains for binding to CXCR4. Cytokines such as IFN-α and IFN-γ may also be involved in controlling virus spread.

Evidence shows that in addition to being a major target for HIV infection, CD4 T cells also have an important role in the host response to HIV-infected cells. An inverse correlation is found between the strength of CD4 T-cell proliferative responses to HIV antigen and viral load. In addition, the type of effector CD4 T-cell response mounted against the virus appears to be important. There is an inverse correlation with viral load and control of acute infection in individuals whose CD4 T cells express greater T_H1 type activity, including production of IFN-γ and granzyme B. Like CD8 T cells, HIV-specific T_H1 cells can have lytic activity that contributes to clearance of HIV-infected targets. Moreover, CD4 T cells from individuals who do not progress to AIDS long after infection by HIV show strong antiviral proliferative responses. Finally, early treatment of acutely infected individuals with antiretroviral drugs is associated with a recovery in CD4 proliferative responses to HIV antigens. If antiretroviral therapy is stopped, the CD4 responses persist in some of these individuals and are associated with reduced levels of viremia. However, infection continues to persist in these individuals, and immunological control of the infection will ultimately fail. If CD4 T-cell responses are essential for the control of HIV infection, then the fact that HIV is tropic for these cells and kills them may explain the inability of the host immune response to control the infection in the long term.

Antibodies against HIV proteins are generated early in the course of infection, but, like T cells, are ultimately unable to clear the virus. As for viral T-cell epitopes, the virus shows a high capacity for generating escape mutants under the selective pressure of the antibody response. Two aspects of the antibody response appear to be important: (1) generating neutralizing antibodies against gp120 and gp41 envelope viral antigens in order to block viral attachment or entry into CD4-positive target cells, and (2) generating non-neutralizing antibodies that, like some neutralizing antibodies, target infected cells for antibody-dependent cell-mediated cytotoxicity (ADCC). Although neutralizing antibodies are eventually produced in nearly all who are HIV-infected, the relative inaccessibility of viral epitopes on the gp120 protein that bind CD4 and chemokine co-receptors (see Fig. 13.36) hampers the development of such antibodies for a prolonged period (typically months); this buys the virus time to generate escape mutants before the neutralizing antibodies can be produced. Indeed, the generation of so-called **broadly neutralizing antibodies**,

which can block infection by multiple viral strains, is typically found in those with high viral titers, emphasizing the fact that these antibodies cannot significantly modify established disease. Analyses of effective neutralizing antibodies to HIV indicate that they have undergone extensive somatic hypermutation that is rarely induced before the first year after infection. Nevertheless, analysis of these antibodies has identified a number of 'vulnerable' sites on the HIV gp120:gp41 envelope trimer that interfere with viral attachment and entry into target cells. The passive administration of some broadly neutralizing antibodies against HIV can protect experimental animals from mucosal infection by HIV, offering hope that a vaccine that can induce broadly neutralizing antibodies might be developed that could prevent new infections.

In contrast to neutralizing antibodies, which develop late in infection and appear to play a modest role in restraining viral replication, there is growing evidence that non-neutralizing antibodies that recruit ADCC by NK cells, macrophages, and neutrophils develop early in infections and are important in restraining viral replication in concert with the actions of cytolytic CD8 T cells. Again, however, the high rate of mutability of the virus allows it to stay a step ahead and persist. The mutations that occur as HIV replicates can allow resulting virus variants to escape recognition by CTLs or antibodies and are important in contributing to the long-term failure of the immune system to contain the infection. An immune response is often dominated by T or B cells specific for particular epitopes—**immunodominant** epitopes—and mutations in immunodominant HIV peptides presented by MHC class I molecules have been found, as have mutations in the epitopes targeted by neutralizing and non-neutralizing antibodies. Mutant peptides have been found to inhibit T cells responsive to the wild-type epitope, thus allowing both the mutant and wild-type viruses to survive.

While the immune response to HIV is ultimately unsuccessful, its importance in restraining disease progression is clear. This is perhaps best exemplified in the tragic case of children infected with HIV perinatally, in whom the course of disease is much more fulminant than in adults. This reflects a poor immune response to the virus in the acute phase of infection due to immaturity of the neonatal immune system, as well as infection by a viral strain that has already evaded an immune system that is genetically close to that of the child. In essence, the poor immune response results in the lack of a latent phase, leading rapidly to AIDS.

13-36 Lymphoid tissue is the major reservoir of HIV infection.

In view of the active, ongoing immune response to HIV infections and the advent of antiretroviral therapies that efficiently blunt viral replication (see Section 13-39), it is important to identify the reservoirs that allow the virus to persist. Although HIV load and turnover are usually measured in terms of the RNA present in virions in the blood, the major reservoir of HIV infection appears to be lymphoid tissue. Here, in addition to infected CD4 T cells, macrophages, and dendritic cells, HIV is also trapped in the form of immune complexes on the surface of follicular dendritic cells in germinal centers. These cells are not themselves infected but may act as a reservoir of infective virions that can persist for months, if not longer. Although tissue macrophages and dendritic cells seem able to harbor replicating HIV without being killed by it, these cells are short-lived and are not thought to be major reservoirs of latent infection. However, they appear to be important in spreading virus to other tissues, such as the brain, where infected cells in the central nervous system may contribute to the virus's long-term persistence.

From studies of patients receiving antiretroviral treatment, it is estimated that more than 95% of the virus that can be detected in the plasma is derived from productively infected CD4 T cells that have a very short half-life—about 2 days.

Virus-producing CD4 T cells are found in the T-cell areas of lymphoid tissues, and these T cells are thought to succumb to infection while being activated in an immune response. Latently infected memory CD4 T cells that become reactivated by antigen also produce virus that can spread to other activated CD4 T cells. In addition to cells that are productively or latently infected, a further large population of cells is infected by defective proviruses, which do not produce infectious virus. Unfortunately, latently infected memory CD4 T cells have an extremely long mean half-life of around 44 months. This means drug therapy that effectively eliminates viral replication would have to be administered for more than 70 years to completely clear the virus. Practically, then, infected patients will never be able to eliminate an HIV infection and require treatment for life.

13-37 Genetic variation in the host can alter the rate of HIV disease progression.

It became clear early in the HIV/AIDS pandemic that the course of the disease could vary widely. Indeed, while nearly all untreated HIV-infected individuals progress to AIDS and ultimately die from opportunistic infections or cancer, not all do. A small percentage of people exposed to the virus seroconvert, but do not seem to have progressive disease. Their CD4 T-cell counts and other measures of immune competence are maintained for decades without antiretroviral therapy. Among these are **long-term nonprogressors**, who, despite detectable viral loads, fail to progress to AIDS over many years, and **elite controllers**, who have unusually low levels of circulating virus (undetectable by some clinical assays despite ongoing low-level viral replication) and represent less than 1% of infected individuals. These individuals have been the subjects of a number of studies to determine how they are able to control their infection without therapy. Another group consists of individuals who engage in high-risk behaviors that repeatedly expose them to infection yet remain virus- and disease-free. Although evidence of prior HIV infection has been reported in such individuals, it is unclear whether these individuals were ever truly infected with infectious virus or were exposed to highly attenuated or defective strains unable to successfully establish infection. In any case, study of these individuals is of considerable interest as it could provide a better understanding of how the host immune response might better control the virus and define what genetic factors might predispose to a protective host response. It might also provide mechanistic insights that could guide development of better vaccines.

Although genetic variation in the virus itself can affect the outcome of infection, a growing number of host gene variants are being defined that impact the rate of progression of HIV infection toward AIDS. The implementation of genome-wide association studies (GWASs) and, more recently, better high-throughput tools to define individual genetic variation (for example, exome and whole-genome sequencing) are accelerating discovery of genetic variations that distinguish highly susceptible and resistant individuals (Fig. 13.42). As discussed in Section 13-34, one of the clearest cases of host genetic variation affecting HIV infection is a mutant allele of *CCR5*, *CCR5Δ32*, that when homozygous effectively blocks HIV-1 infection and when heterozygous may slow AIDS progression. Genetic polymorphisms in the HLA class I locus, particularly in the genes *HLA-B* and *HLA-C*, are another major factor in determining disease progression and are currently the strongest predictors of HIV control. Evidence from GWASs has mapped polymorphisms to the peptide-binding groove of HLA class I molecules as key determinants defining disease progression. Polymorphisms outside of the peptide-binding groove as well as those in noncoding regions that control the expression levels of HLA molecules are also implicated. The HLA class I alleles HLA-B57, HLA-B27, and HLA-B13, among others, are

Genes that influence progression to AIDS				
Gene	**Allele**	**Mode**	**Effect**	**Mechanism of action**
HIV entry				
CCR5	Δ32	Recessive	Prevents infection	Knockout of CCR5 expression
		Dominant	Prevents lymphoma (L)	Decreases available CCR5
			Delays AIDS	
	P1	Recessive	Accelerates AIDS (E)	Increases CCR5 expression
CCR2	I64	Dominant	Delays AIDS	Interacts with and reduces CXCR4
CCL5	In1.1c	Dominant	Accelerates AIDS	Decreases CCL5 expression
CXCL12	3′A	Recessive	Delays AIDS (L)	Impedes CCR5–CXCR4 transition (?)
CXCR6	E3K	Dominant	Accelerates *P. jirovecii* pneumonia (L)	Alters T-cell activations (?)
CCL2-CCL7-CCL11	H7	Dominant	Enhances infection	Stimulates immune response (?)
Cytokine anti-HIV				
IL10	5′A	Dominant	Limits infection	Decreases IL-10 expression
			Accelerates AIDS	
IFNG	−179T	Dominant	Accelerates AIDS (E)	
Acquired immunity, cell mediated				
HLA	A, B, C	Homozygous	Accelerates AIDS	Decreases breadth of HLA class I epitope recognition
	B*27	Codominant	Delays AIDS	Delays HIV-1 escape
	B*57			
	B*35-Px		Accelerates AIDS	Deflects CD8-mediated T-cell clearance of HIV-1
Acquired immunity, innate				
KIR3DS1	3DS1	Epistatic with HLA-Bw4	Delays AIDS	Clears HIV^+, HLA^- cells (?)

Fig. 13.42 Genes that influence progression to AIDS in humans.

associated with a better prognosis, whereas HLA-B35 and HLA-B07 are associated with more rapid disease progression. Homozygosity of HLA class I genes (*HLA-A, HLA-B,* and *HLA-C*) is also associated with more rapid progression, presumably because the T-cell response to infection is less diverse. Remarkably, one of the strongest associations with viral control is a single-nucleotide polymorphism (SNP) 35 kb upstream of the *HLA-C* locus; this polymorphism confers greater immune control that correlates with increased expression levels of HLA-C—with the greater control presumably being due to enhanced presentation of viral peptides to CD8 T cells. Certain polymorphisms of the killer cell immunoglobulin-like receptors (KIRs) present on NK cells (see Section 3-26), in particular the receptor KIR-3DS1 in combination with certain alleles of *HLA-B*, also delay the progression to AIDS. Mutations that affect the production of cytokines such as IFN-γ and IL-10 have also been implicated in the restriction of HIV progression.

Infections	
Parasites	*Toxoplasma* spp. *Cryptosporidium* spp. *Leishmania* spp. *Microsporidium* spp.
Intracellular bacteria	*Mycobacterium tuberculosis* *Mycobacterium avium intracellulare* *Salmonella* spp.
Fungi	*Pneumocystis jirovecii* *Cryptococcus neoformans* *Candida* spp. *Histoplasma capsulatum* *Coccidioides immitis*
Viruses	Herpes simplex Cytomegalovirus varicella-zoster
Malignancies	
Kaposi's sarcoma – (HHV8) Non-Hodgkin's lymphoma, including EBV-positive Burkitt's lymphoma Primary lymphoma of the brain	

Fig. 13.43 A variety of opportunistic pathogens and cancers can kill individuals with AIDS. Infections are the major cause of death in AIDS, with respiratory infection with *P. jirovecii* and mycobacteria being the most prominent. Host defense against most of these pathogens requires effective macrophage activation by CD4 T cells or effective cytotoxic T cells. Opportunistic pathogens are present in the normal environment but cause severe disease primarily in immunocompromised hosts, such as individuals with AIDS or individuals with cancer. Individuals with AIDS are also susceptible to several rare cancers, such as Kaposi's sarcoma [associated with human herpesvirus 8 (HHV8)] and various lymphomas, suggesting that immune surveillance of the causative herpesviruses by T cells can normally prevent such tumors (see Chapter 16).

13-38 The destruction of immune function as a result of HIV infection leads to increased susceptibility to opportunistic infection and eventually to death.

When CD4 T-cell numbers decline below a critical level, cell-mediated immunity is lost, and infections with a variety of opportunistic microbes appear (Fig. 13.43). Typically, resistance is lost early to oral *Candida* species and to *Mycobacterium tuberculosis*, which cause thrush (oral candidiasis) and tuberculosis, respectively. Later, individuals suffer from shingles (caused by the activation of latent varicella-zoster virus), from aggressive EBV-induced B-cell lymphomas, and from Kaposi's sarcoma, a tumor of endothelial cells that probably results both from a response to cytokines produced in the infection and a herpesvirus called Kaposi's sarcoma herpesvirus (KSHV, or HHV8). Since the earliest recognition of AIDS, pneumonia caused by *Pneumocystis jirovecii* (previously called *P. carinii*) has been the most common opportunistic infection; it was typically fatal before effective antifungal therapy was introduced. Co-infection by hepatitis C virus is common and associated with more rapid progression of hepatitis. In the final stages of AIDS, infection with cytomegalovirus or a member of the *Mycobacterium avium* group of bacteria is more prominent. It is important to note that not all individuals with AIDS get all of these infections or tumors, and there are other tumors and infections that are less prominent but still significant. Figure 13.43 lists the most common opportunistic infections and tumors, which are typically controlled until the CD4 T-cell counts drop toward zero.

13-39 Drugs that block HIV replication lead to a rapid decrease in titer of infectious virus and an increase in CD4 T cells.

Studies with drugs that block HIV replication indicate that the virus is replicating rapidly at all phases of infection, including the asymptomatic phase. Three viral proteins in particular have been the target of drugs aimed at arresting viral replication. These are viral reverse transcriptase, which is required for synthesis of the provirus; viral integrase, which is required for insertion of the viral provirus into the host genome; and viral protease, which cleaves viral polyproteins to produce virion proteins and viral enzymes. Reverse transcriptase is inhibited by nucleoside analogs such as zidovudine (ZDV; also known as azidothymidine, or AZT), which was the first anti-HIV drug to be licensed in the United States. Inhibitors of reverse transcriptase, integrase, and protease prevent infection of uninfected cells; cells that are already infected can continue to produce virions because, once the provirus is established, reverse transcriptase and integrase are not needed to make new virus particles, and while the viral protease acts at a very late maturation step of the virus, inhibition of the protease does not prevent virus from being released. However, in all cases, further cycles of infection by released virions are blocked, and replication is therefore prevented.

The introduction of combination therapy with a cocktail of viral protease inhibitors and nucleoside analogs, also known as combination antiretroviral therapy, or cART (previously referred to as highly active antiretroviral therapy, or HAART), has dramatically reduced mortality and morbidity in patients with HIV infection (Fig. 13.44). Patients treated with cART show a rapid and

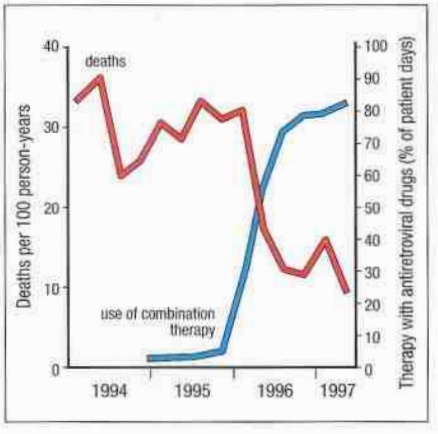

Fig. 13.44 The mortality in advanced HIV infection fell in the United States in parallel with the introduction of combination antiretroviral therapy. The graph shows the number of deaths, expressed each calendar quarter as the deaths per 100 person-years. Figure based on data from F. Palella.

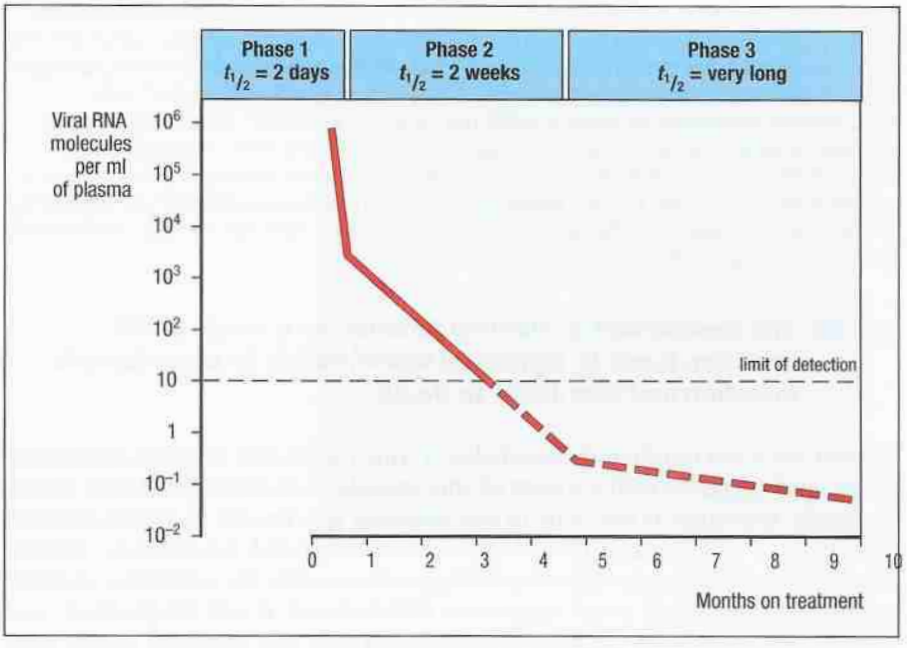

Fig. 13.45 The time course of reduction of HIV circulating in the blood during drug treatment. The production of new HIV particles can be arrested for prolonged periods by treatment using combinations of protease inhibitors and viral reverse-transcriptase inhibitors. After the initiation of such treatment, virus production is curtailed as the infected cells die and no new cells are infected. The half-life of virus decay occurs in three phases. The first phase has a half-life ($t_{1/2}$) of about 2 days, reflecting the half-life of productively infected CD4 T cells, and lasts for about 2 weeks, during which time viral production declines as the lymphocytes that were productively infected at the onset of treatment die. Released virus is rapidly cleared from the circulation, where it has a half-life of 6 hours, and there is a decrease in virus levels in plasma of more than 95% during this first phase. The second phase typically lasts for about 4 months, and the virus has a half-life of about 2 weeks. During this phase, virus is released from infected macrophages and from resting, latently infected CD4 T cells stimulated to divide and develop productive infection. It is thought that there is then a third phase of unknown length that results from the reactivation of integrated provirus in memory T cells and other long-lived reservoirs of infection. This reservoir of latently infected cells might remain present for many years. Measurement of this phase of viral decay is impossible at present because viral levels in plasma are below detectable levels (dotted line).

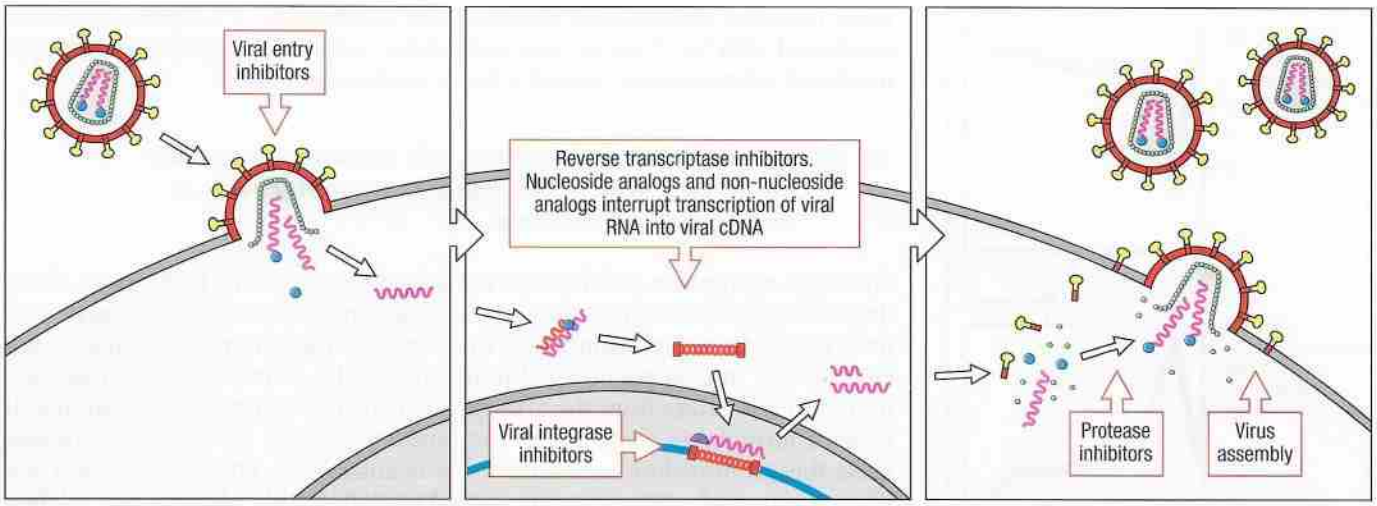
dramatic reduction in viremia, eventually maintaining levels of HIV RNA close to the limit of detection (50 copies per milliliter of plasma) for extended periods with continual therapy—in most cases, indefinitely (Fig. 13.45). It is unclear how the virus particles are removed so rapidly from the circulation after the initiation of cART. It seems most likely that they are opsonized by specific antibody and complement and removed by cells of the mononuclear phagocyte system. Opsonized HIV particles may also be trapped in lymphoid follicles on the surface of follicular dendritic cells.

cART is also accompanied by a slow but steady increase in CD4 T cells, despite the fact that many other compartments of the immune system remain compromised. Three complementary mechanisms have been established for the recovery in CD4 T-cell numbers. One is a redistribution of memory CD4 T cells from lymphoid tissues into the circulation as viral replication is controlled; this occurs within weeks of starting treatment. A second one is a reduction in the abnormal levels of immune activation as HIV infection is controlled; this mechanism is associated with reduced killing of infected CD4 T cells by cytotoxic T lymphocytes. The third mechanism is much slower and is caused by the emergence of new naive T cells from the thymus, which is indicated by the presence of T-cell receptor excision circles (TRECs) in these later-arriving cells (see Section 5-10).

Although cART is effective at inhibiting HIV replication, thereby preventing the progression to AIDS and greatly decreasing transmission by those infected, it is ineffective at eradicating all viral stores. Cessation of cART therefore leads to a rapid rebound of virus multiplication, so that patients require treatment indefinitely. This, coupled with the side effects and high cost of cART, has stimulated investigation into other targets to block viral replication (Fig. 13.46), as well as ways of eliminating viral reservoirs to eradicate infection permanently. New classes of anti-HIV replication drugs include **viral entry inhibitors**, which block the binding of gp120 to CCR5 or block viral fusion by inhibiting gp41, and **viral integrase inhibitors**, which block the insertion of the reverse-transcribed viral genome into the host DNA. Other approaches under development include efforts to enhance the activity of HIV restriction factors, such as APOBEC (see Section 13-31), which causes extensive mutation of newly formed HIV cDNA to destroy its ability to replicate.



Viral entry inhibitors
Reverse transcriptase inhibitors. Nucleoside analogs and non-nucleoside analogs interrupt transcription of viral RNA into viral cDNA
Viral integrase inhibitors
Protease inhibitors
Virus assembly

Fig. 13.46 Possible targets for interference with the HIV life cycle. In principle, HIV could be attacked by therapeutic drugs at multiple points in its life cycle: virus entry, reverse transcription of viral RNA, insertion of viral cDNA into cellular DNA by the viral integrase, cleavage of viral polyproteins by the viral protease, and assembly and budding of infectious virions. As yet, only drugs that inhibit reverse transcriptase and protease action have been developed. Combination therapy using different kinds of drugs is more effective than using a single drug.

Given the success of cART in blocking active viral replication, the inability of existing therapies to purge reservoirs of latently infected cells has become the greatest barrier to a cure. To overcome this, strategies are being considered that would induce viral replication in latently infected cells in combination with measures to enhance immune clearance of virus and infected cells. Examples of ways to activate latent virus include the administration of cytokines that activate viral transcription and replication (for example, IL-2, IL-6, and TNF-α) and the use of agents that target epigenetic modifiers, such as histone deacetylase (HDAC) inhibitors, to activate latent provirus. To date, however, no clinical trial using agents that target latent viral reservoirs has shown a significant reduction in viral load over that gained from cART treatment alone. Indeed, it was recently discovered that the activation of viral replication in latently infected cells is intrinsically stochastic, so that many immune cells harboring latent provirus will fail to activate viral replication in any given cycle of cellular activation. This adaptation of HIV to avoid elimination of latently infected cells could represent a formidable barrier to strategies aimed at 'flushing out' latent virus so that it can be eliminated.

An alternative strategy for cure has been highlighted by an American HIV patient, Timothy Ray Brown, who underwent hematopoietic stem-cell transplantation (HSCT) for treatment of leukemia while studying in Berlin (hence, referred to as the **Berlin patient**). By identifying a stem-cell donor who was homozygous for the *CCR5Δ32* co-receptor mutation, Brown's doctor was able to reconstitute him with immune cells resistant to viral propagation. Brown's CD4 T-cell counts rebounded, and he was found to be free of any evidence of HIV infection after cessation of antiretroviral therapy post-transplant. He remained virus-free for more than 10 years, suggesting that he was the first person to be cured of infection via HSCT. He ultimately died from recurrence of the leukemia for which he originally received HSCT. In view of the large number of infected individuals worldwide, the risk of complications with HSCT, and the rarity of HLA-matched CCR5-deletant donors, it is unlikely that this will be a practical approach for cure at the population level. And although the advent of gene-therapy approaches to effectively delete the CCR5 co-receptor in patients' own hematopoietic stem cells has raised the possibility of HSCT using autologous CCR5-deficient stem cells, the relative risk of HSCT compared to cART remains unfavorable. Moreover, there is a risk of progression or reinfection post-transplant by CXCR4-tropic viral variants. This outcome

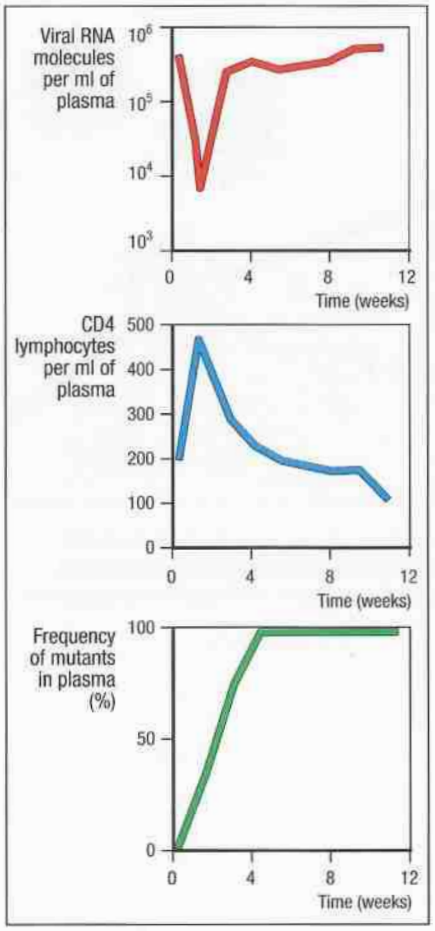


Fig. 13.47 Resistance of HIV to protease inhibitors develops rapidly. After the administration of a single protease inhibitor drug to a patient with HIV, there is in plasma a precipitous fall in levels of viral RNA, with a half-life of about 2 days (top panel). This is accompanied by an initial rise in the number of CD4 T cells in peripheral blood (center panel). Within days of starting the drug, mutant drug-resistant variants can be detected in plasma (bottom panel) and in peripheral blood lymphocytes. After only 4 weeks of treatment, viral RNA levels and CD4 lymphocyte levels have returned to their original pre-drug levels, and 100% of plasma HIV is present as the drug-resistant mutant.

does, however, dramatically establish that eradication of a latency reservoir combined with blockade of viral replication—whether by genetic or therapy-mediated interventions—might achieve a permanent cure.

13-40 In the course of infection, HIV accumulates many mutations, which can result in the outgrowth of drug-resistant variants.

The rapid replication of HIV, with the generation of 10^9 to 10^{10} virions every day, is coupled with a mutation rate of approximately 3×10^{-5} per nucleotide base per cycle of replication, and thus leads to the generation of many variants of HIV in a single infected individual in the course of a day. This high mutation rate arises from the error-prone nature of retroviral replication and poses a formidable challenge to the immune system. Reverse transcriptase lacks the proofreading mechanisms of cellular DNA polymerases, and the RNA genomes of retroviruses are copied into DNA with relatively low fidelity. Thus, although primary infection is typically established by a single founder virus, numerous variants of HIV, called **quasi-species**, rapidly develop within an infected individual. This phenomenon was first recognized in HIV and has since proved to be common to all lentiviruses.

As a consequence of its high variability, HIV rapidly develops resistance to antiviral drugs, much as it develops escape mutants that evade T-cell recognition (see Sections 13-33 and 13-35). When a drug is administered, viral variants with mutations that confer resistance emerge and multiply until the previous levels of virus are regained. Resistance to some viral protease inhibitors requires only a single mutation and appears after only a few days (Fig. 13.47); resistance to some inhibitors of reverse transcriptase develops in a similarly short time. In contrast, resistance to the nucleoside analog zidovudine takes months to develop, as it requires three or four mutations in the viral reverse transcriptase. Because of the relatively rapid appearance of resistance to anti-HIV drugs, successful drug treatment has typically depended on combination therapy, where the chance of simultaneous resistance mutations in multiple HIV proteins is virtually nil. Nevertheless, monotherapy with newer-generation antiretroviral agents has proven effective in patients with low viral loads at the onset of treatment.

13-41 HIV treatment and prophylaxis are leading to a decline in the spread of HIV and AIDS.

It is now well established that the spread of HIV can be prevented if antiretroviral drugs are taken regularly by those already infected and those who are uninfected but at risk for exposure. The advent of cART represented a major advance in blocking the transmission of HIV from infected people because of its ability to greatly reduce viral titers in body fluids—so-called treatment as prevention. Moreover, the prophylactic use of antiretroviral drugs (referred to as pre-exposure prophylaxis, or **PrEP**) by individuals at high risk for contracting HIV has demonstrated considerable effectiveness in preventing infection by the virus. When taken daily, the combination of two orally administered reverse transcriptase inhibitors has demonstrated more than 90% reduction in the risk of sexually transmitted HIV infection in at-risk populations. Moreover, use of antiretroviral therapy immediately post-exposure—for example, in hospital workers exposed to contaminated blood by accidental needlestick—substantially reduces the risk of acquiring HIV. Although an early concern with PrEP was the risk of developing drug resistance in those who do contract HIV while on PrEP, particularly in individuals with poor adherence to the dosing regimen, the experience to date has shown that this risk is quite modest. Current trials of new PrEP strategies that are based on long-acting

formulations administered monthly instead of daily may further reduce the risk of poor compliance and increase efficacy.

However, not everyone infected with or at risk of contracting HIV has access to cART, as it is expensive and requires ongoing treatment. Further, many of those infected are unaware that they carry the virus. Even where cART is unavailable, access to regular screening for those at risk is critical to inform those infected so they can take measures to avoid passing the virus to others. This, in turn, requires strict confidentiality and mutual trust. A barrier to the control of HIV is the reluctance of individuals to find out whether they are infected, especially as one of the consequences of a positive HIV test is stigmatization by society. Here, education becomes an important component of the prevention strategy, both to remove the stigma and provide guidance on how transmission of the virus can be prevented.

In addition to cART, precautions that can be taken by uninfected individuals are relatively inexpensive and involve measures to protect against contact with body fluids, such as semen, blood, blood products, or breast milk, from people who are infected. It has been repeatedly demonstrated that this is sufficient to prevent infection, as exemplified by health-care workers who care for AIDS patients for long periods without seroconversion or signs of infection. The routine use of condoms greatly reduces the risk of HIV transmission, as does restraint from breast-feeding by infected mothers of newborns. Male circumcision also reduces transmission rates, as the foreskin is a major site of viral entry in uncircumcised males. Additional measures that have been considered include the use of microbicidal gels or suppositories, improvements in which have led to products that show promise in recent trials. Some of these agents can also reduce the transmission of other sexually transmitted diseases (for example, genital herpes) that increase the risk of HIV transmission.

13-42 Vaccination against HIV remains an attractive solution but poses many difficulties.

The effectiveness of cART both in preventing transmission from those infected with HIV and as prophylaxis for those uninfected but at risk has profoundly altered the natural history and transmission rates of HIV infection (Fig. 13.48). Nevertheless, a safe and effective vaccine for the prevention of HIV infection and AIDS remains a major goal. Ideally, an effective vaccine would elicit both broadly neutralizing antibodies that block viral entry into target cells (that is, anti-gp120) and effective cytolytic T-cell responses to prevent and control HIV infection. However, no such vaccine has yet been developed, and its attainment is fraught with difficulties that have not been faced in the development of vaccines against other diseases.

The main problem is the nature of the infection itself, featuring a virus that directly undermines the central component of adaptive immunity—the CD4 T cell—and that proliferates and mutates extremely rapidly to cause sustained infection in the face of strong cytotoxic T-cell and antibody responses. The development of vaccines that could be administered to individuals already infected, to boost immune responses and prevent progression to AIDS, has been considered, as have prophylactic vaccines that would prevent initial infection. The development of therapeutic vaccination in those already infected would be extremely difficult. As discussed earlier (see Section 13-40), HIV evolves in individuals by the selective proliferation of mutant viruses that escape recognition by antibodies and cytotoxic T cells. The ability of the virus to persist in latent form as a transcriptionally silent provirus invisible to the immune system might also prevent even an immunized person from clearing an infection once it has been established.

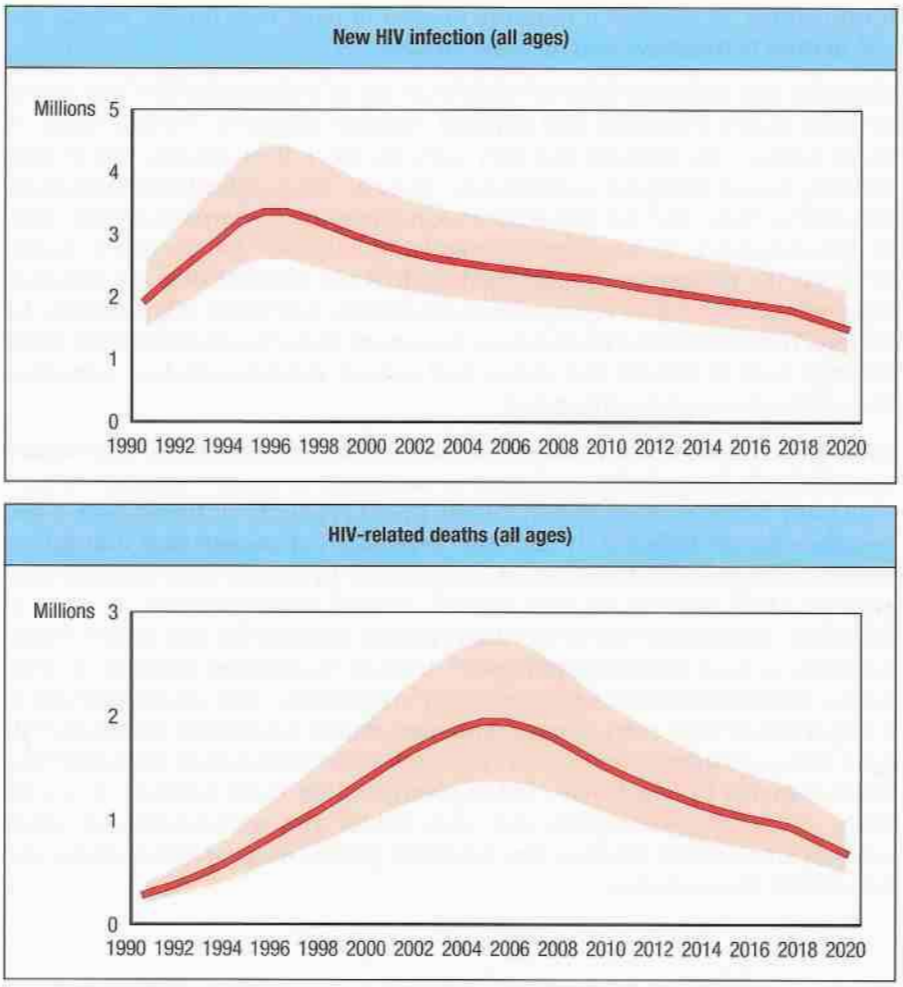

Fig. 13.48 The incidence of new HIV infections and HIV-related deaths worldwide is declining due to effective nonvaccine prevention and antiretroviral therapy. The introduction of effective antiretroviral drugs and their more widespread use, both for treatment of infected individuals and prevention of infection in those at high risk, has begun to stem the tide of the HIV pandemic.

There has been more hope for prophylactic vaccination to prevent new infection. But even here, the lack of protection of the normal immune response and the sheer scale of sequence diversity among HIV strains in the infected population—there are currently thousands of different HIV strains circulating in the human population—remain significant challenges. Individuals infected with one strain of virus do not seem to be resistant to closely related strains, and cases of superinfection, where two strains simultaneously infect the same cell, have also been described. This is compounded by the intrinsic difficulty in generating broadly neutralizing antibodies against HIV envelope glycoproteins (see Section 13-35). Further, there remains uncertainty over what form protective immunity to HIV might take. It is now believed that induction of both effective antibody and T-cell responses will be required to achieve protective immunity, although which epitopes might provide the best targets and how best to induce them remain undefined. Finally, the time from conception to design to performance of complete clinical trials of vaccines against HIV takes years, slowing the rate of progress; to date, few major clinical vaccine trials have been completed, and those have failed.

However, against this discouraging background, progress has been made, and there remains hope that successful vaccines might yet be developed. Various

strategies are being tried in an attempt to develop vaccines against HIV, varying from delivery of recombinant HIV proteins, plasmid DNA vaccination with HIV genes (see Section 16-9), delivery of HIV genes in viral vectors, to combinations thereof. Many successful vaccines against other viral diseases contain a live attenuated strain of the virus, which raises an immune response but does not cause disease (see Section 16-4). There are substantial difficulties in the development of live attenuated vaccines against HIV, not least the worry of recombination between vaccine strains and wild-type viruses that would lead to a reversion to virulence. An alternative approach is the use of other viruses, such as vaccinia or adenovirus, to deliver and express HIV genes that elicit B- and T-cell responses against HIV antigens. Because these viral vectors have already demonstrated safety in other human vaccination studies, they have been obvious choices for initial trials. Recently, there has been encouraging, albeit limited, success with this type of approach in combination with boosts using recombinant gp120. Delivery of HIV *gag*, *pol*, and *env* genes via a canarypox viral vector followed by boosts with HIV gp120 were shown to reduce the risk of infection in a modest but significant number of high-risk vaccine recipients. This represents the first demonstration of any degree of efficacy in a large HIV vaccine trial to date, and a confirmatory study is ongoing. Perhaps as important, data from this study have provided insights into the type of immune response that correlates with protection, indicating that the induction of non-neutralizing antibodies that elicit ADCC (for example, IgG3 isotype) might provide protection. Because neutralizing antibodies against HIV have proven so difficult to elicit, this provides encouragement that they might not be required. Further, a study that used a cytomegalovirus (CMV) vector to deliver SIV genes to rhesus monkeys showed that potent CTL responses were induced. Although these CTL responses did not prevent infection by a pathogenic SIV strain, they did result in clearance of virus in about half of the monkeys vaccinated after its systemic spread. This unprecedented result suggests that the viral vector used for delivery of HIV genes—in this case a vector that produces HIV antigens for prolonged periods after vaccination—might play an important role in the type and amplitude of the antiviral CD8 T-cell response elicited, and protection might be achieved by an effective T-cell response alone. Additional studies will be needed to determine whether combination vaccines that elicit the appropriate non-neutralizing antibodies and robust CD8 T-cell responses might achieve protection even in the absence of neutralizing antibodies.

In addition to the biological obstacles to developing effective HIV vaccines, there are difficult ethical issues. It would be unethical to conduct a vaccine trial without concurrent efforts to minimize the exposure of a population to HIV. In view of rapid adaptation worldwide of pre-exposure prophylaxis (PrEP) as the standard of care for preventing viral spread, future vaccine trials will have difficulty determining efficacy in the face of active cART use. The effectiveness of a vaccine can be assessed only in a population in which the exposure rate to the virus is high enough to assess whether vaccination protects against infection. Given the dramatic successes of cART as a transmission blocker and a prophylactic, it is conceivable that HIV/AIDS could be eradicated without the successful development of a vaccine, assuming there was universal screening for HIV and universal availability and use of cART.

Summary.

Infection with the human immunodeficiency virus (HIV) is the cause of acquired immune deficiency syndrome (AIDS). Although substantial gains in curbing the rate of spread of HIV have been made, this worldwide epidemic continues to spread, especially through heterosexual contact in less-developed countries. HIV is an enveloped retrovirus that replicates in cells of the immune

system. Viral entry requires the presence of CD4 and a particular chemokine receptor, and the viral cycle is dependent on transcription factors found in activated T cells. Infection with HIV causes a loss of CD4 T cells and an acute viremia that rapidly subsides as cytotoxic T-cell responses develop, but HIV infection is not eliminated by this immune response. HIV establishes a state of persistent infection in which the virus is continually replicating in newly infected cells. Current treatment consists of combinations of antiviral drugs that block viral replication and cause a rapid decrease in virus levels and a slow increase in CD4 T-cell counts. The main effect of HIV infection is the destruction of CD4 T cells, which occurs through the direct cytopathic effects of HIV infection and through killing by cytotoxic CD8 T cells. As the CD4 T-cell counts wane, the body becomes progressively more susceptible to opportunistic infection. Eventually, most untreated HIV-infected individuals develop AIDS and die; however, a small minority, so-called long-term nonprogressors, remain healthy for many years with no apparent ill effects of infection. From these individuals we hope to be able to learn how infection with HIV can be controlled. The existence of these individuals, and of others who seem to have been naturally immunized against infection, gives hope that it will be possible to develop effective vaccines against HIV.

Summary to Chapter 13.

Whereas most infections elicit protective immunity, successful pathogens have developed some means of at least partly resisting the immune response and can cause serious, sometimes persistent, disease. Some individuals have inherited deficiencies in different components of the immune system, making them highly susceptible to certain classes of infectious agents. Persistent infections and inherited immunodeficiency diseases illustrate the importance of innate and adaptive immunity in effective host defense and present ongoing challenges for immunological research. The human immunodeficiency virus (HIV), which leads to acquired immune deficiency syndrome (AIDS), combines the characteristics of a persistent infectious agent with the ability to create immunodeficiency in its human host, a combination that is usually slowly lethal to the individual. The key to fighting new pathogens such as HIV is to increase our understanding of the basic properties of the immune system and its role in combating infection.

Discussion Questions

13.1 Why do some primary immunodeficiency diseases preferentially affect males? List the most common examples.

13.2 How are primary immunodeficiencies that affect either the complement system or B-cell development similar and different?

13.3 What do people with inherited and acquired immunodeficiencies teach us about the normal mechanism of host protection against opportunistic infections?

13.4 List examples of immunodeficiencies that primarily affect T lymphocytes. Why do these generally affect immune responses more severely than do deficiencies involving B cells only?

13.5 Compare and contrast the host response to intracellular versus extracellular bacterial pathogens.

13.6 List the different ways in which viruses can evade the immune system. Which of these strategies leads to chronic infection, and why?

13.7 Compare antigenic drift and antigenic shift in the context of influenza infections and pandemics. How do these different types of antigenic variation occur?

13.8 How do HIV accessory proteins (Nef, Vif, Vpu, and Vpr) protect the virus from immune clearance?

13.9 How does infection by HIV cause AIDS?

13.10 Why can HIV infection not be cured by current drug therapies? Why is it difficult to make an HIV vaccine?

Allergic Diseases and Hypersensitivity Reactions

14

IN THIS CHAPTER

IgE and IgE-mediated allergic diseases.

Effector mechanisms in IgE-mediated allergic reactions.

Non-IgE-mediated allergic diseases.

Although the adaptive immune response is critical for defense against infections, antigens not associated with infectious agents can sometimes elicit adaptive immune responses and cause disease. In one circumstance in which this happens, inherently harmless 'environmental' antigens such as pollen, food, and drugs induce hypersensitivity reactions known generally as **allergic reactions**.

In the early 1960s, the British pathologists P. G. H. Gell and R. R. A. Coombs classified hypersensitivity reactions due to immunological responses into four broad types. Type I hypersensitivity reactions represented immediate-type allergic reactions mediated by plasma 'reagin,' later identified as **IgE** antibodies, accompanied by mast-cell activation as the major final effector mechanism. Type II and type III hypersensitivity reactions were driven by antigen-specific IgG antibodies with the final effector mechanism being by cytotoxicity (type II) or by formation of immune complexes (type III). Finally, type IV hypersensitivity reactions were depicted as being driven by cellular effectors, including lymphocytes and a variety of myeloid cell types. The Gell and Coombs classification system is still in widespread use, particularly in the clinic, but we now understand that immune responses usually involve both humoral and cellular components. The classification of responses described in Chapter 11 in terms of the four types of immune-response modules is also a useful system for understanding disease pathogenesis, including allergic responses (see Fig. 11.5).

Most allergic reactions occur because the individual has become **sensitized** to an innocuous antigen—the **allergen** (such as those in food, pollen, or house dust)—by producing IgE antibodies against it. Subsequent exposure to the allergen triggers the activation of IgE-binding cells, chiefly mast cells and basophils, in the exposed tissue, leading to a series of characteristic responses. In hay fever (allergic rhinoconjunctivitis), symptoms occur when allergenic proteins derived from grass or weed pollen grains come in contact with the mucous membrane of the nose and eyes. In contrast, some hypersensitivity disorders, such as allergic contact dermatitis, serum sickness, or celiac disease, are not dependent on IgE antibodies and represent unwanted immune responses driven by IgG antibodies and/or cellular immune responses.

We are all exposed regularly to potential environmental allergens, but most of us do not develop clinically significant allergic reactions to them. However, some surveys suggest that more than half of the population shows allergic response to at least one substance in the environment. Some individuals manifest allergic responses to multiple common antigens. A predisposition to become IgE-sensitized to environmental allergens is called **atopy**; such individuals are said to be **atopic**. In this chapter, we discuss the genetic and environmental factors that may contribute to this predisposition. Genetic factors appear to play a role. If both parents are atopic, a child has a 40–60% chance of developing an IgE-mediated allergy, whereas the risk is much lower, of the order 10%, if neither parent is atopic.

IgE is prominent in the defense against extracellular parasites such as helminths and protozoa (see Section 11-10), which are prevalent in developing nations. But in developed nations, most serum IgE is directed against innocuous antigens, sometimes causing allergies (Fig. 14.1). Although rarely

Fig. 14.1 IgE-mediated reactions to extrinsic antigens. All IgE-mediated responses involve mast-cell degranulation, but the symptoms experienced by the individual can be very different depending, for example, on whether the allergen is injected directly into the bloodstream, is eaten, or comes into contact with the mucosa of the ocular or respiratory tract.

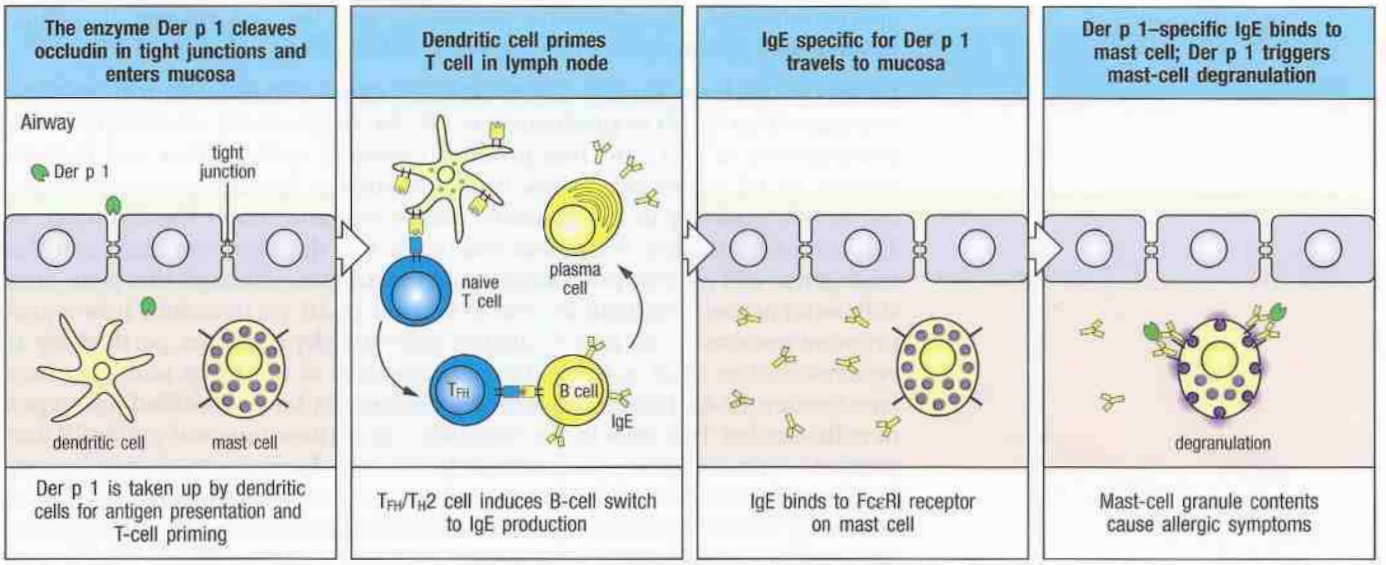
IgE-mediated allergic reactions			
Reaction or disease	**Common stimuli**	**Route of entry**	**Response**
Systemic anaphylaxis	Drugs Venoms Food, e.g., peanuts Serum	Intravenous (either directly or following absorption into the blood after oral intake)	Edema Increased vascular permeability Laryngeal edema Circulatory collapse Death
Acute urticaria (wheal-and-flare)	Post-viral Animal hair Bee stings Allergy testing	Through skin Systemic	Local increase in blood flow and vascular permeability Edema
Seasonal rhinoconjunctivitis (hay fever)	Pollens (ragweed, trees, grasses) Dust-mite feces	Contact with conjunctiva of eye and nasal mucosa	Edema of conjunctiva and nasal mucosa Sneezing
Asthma	Dander (cat) Pollens Dust-mite feces	Inhalation leading to contact with mucosal lining of lower airways	Bronchial constriction Increased mucus production Airway inflammation Bronchial hyperreactivity
Food allergy	Peanuts Tree nuts Shellfish Fish Milk Eggs Soy Wheat	Oral	Vomiting Diarrhea Pruritus (itching) Urticaria (hives) Anaphylaxis (rarely)

life-threatening, allergic diseases can cause much distress and lost time from school and work, and their prevalence is increasing. Consequently, most clinical and scientific attention paid to IgE has been directed toward its pathologic roles in allergic disease rather than its protective capacity.

Here we first consider the mechanisms that favor the **sensitization** of an individual to an allergen, resulting in the production of antigen-specific IgE. We then describe the IgE-mediated allergic reaction itself, originally called the type I hypersensitivity response in a clinical classification scheme that was developed before the identification of IgE. We will also describe the pathological consequences of the interaction between an allergen and the IgE bound to the high-affinity Fcε receptor on mast cells and basophils. Finally, we consider the causes and consequences of other types of immunological hypersensitivity reactions, primarily type II and type III hypersensitivity responses.

IgE and IgE-mediated allergic diseases.

Immediate hypersensitivity reactions are those allergic reactions caused by activation of mast cells and basophils. This activation occurs when antigen binds to IgE that is already bound to the high-affinity IgE receptor **FcεRI** (see Section 10-24) expressed by these cells. IgE differs from other antibody isotypes in being predominantly localized in the tissues, where it is tightly bound to the surface cells expressing FcεRI. Binding of antigen to IgE causes cross-linking of FcεRI and the release of chemical mediators from the mast cells (Fig. 14.2). How an initial antibody response to environmental antigens comes to be dominated by IgE production in atopic individuals is still being worked out. In this part of the chapter, we describe the current understanding of the factors that contribute to this process.



The enzyme Der p 1 cleaves occludin in tight junctions and enters mucosa
Airway
Der p 1

IgE binds to FcεRI receptor on mast cell
Der p 1–specific IgE binds to mast cell; Der p 1 triggers mast-cell degranulation
degranulation
Mast-cell granule contents cause allergic symptoms

Fig. 14.2 Sensitization to an inhaled allergen. Der p 1 is a common respiratory allergen that is found in fecal pellets of the house dust mite. When an atopic individual first encounters Der p 1, subepithelial dendritic cells ingest the allergenic protein and traffic to the draining lymph node, where T cells specific for Der p 1 are activated (first and second panels). Interaction of T_{FH} cells (producing T_H2 cytokines such as IL-4) with Der p 1–specific B cells leads to the production of class-switched plasma cells producing Der p 1–specific IgE, which travels back to the mucosa (third panel). Here, the IgE is bound to Fc receptors on resident submucosal mast cells. On a subsequent encounter with Der p 1, the allergen binds to the mast cell–bound IgE, triggering mast-cell activation and the release of mast-cell granule contents, which cause the symptoms of the allergic reaction (last panel). Der p 1 is a protease that cleaves occludin, a protein that helps to maintain epithelial tight junctions; the enzymatic activity of Der p 1 is thought to help it pass through the epithelium.

14-1 Sensitization involves class switching to IgE production on first contact with an allergen.

To produce an allergic reaction, an individual must first be exposed to the allergen under conditions that lead to the production of IgE antibodies. Allergic symptoms occur when this individual experiences a subsequent exposure to that antigen. The different symptoms can depend on what tissues are involved. In developed countries, the most common exposure is to airborne allergens, which predominantly affect the nasal passages (allergic rhinitis), eyes (allergic conjunctivitis), or lower airways and lungs (asthma). Ingested allergens can lead to food allergy, sometimes affecting only the gastrointestinal tract, but not infrequently involving locations distant from the site of antigen entry. Reactions can occur at sites distant from the allergen entry point by transport through the blood circulation and can be limited to a single distant organ. Hives (also called urticaria) occur when allergens target the skin, wheezing (or bronchospasms) occurs when they target the lungs, and life-threatening lowering of the blood pressure (shock) occurs when they target the vascular system. Serious systemic reactions are termed **anaphylaxis**. It is not known why sensitization with a particular allergen in one individual leads to local reactions at the time of allergen challenge, whereas sensitization with the same allergen can yield anaphylaxis in another individual.

Atopic individuals often develop sensitization to many different antigens and may have many types of allergic symptoms depending on the route and quantity of allergen. Frequently, a progression can occur; for example, from atopic eczema in childhood to include allergic rhinitis and eventually asthma in later life. This progression has been termed the **atopic march**. Allergic reactions in non-atopic people, in contrast, are predominantly due to sensitization to one specific allergen, such as to bee venom or a drug such as penicillin, and can develop at any time of life. However, not all encounters with a potential

allergen will lead to sensitization, and not all sensitizations will lead to a symptomatic allergic response, even in atopic individuals.

Recall that we have already described many of the signals leading to immune responses that result in production of IgE. In Section 9-15, we described the development of T_H2 cells that produce cytokines such as IL-4 and IL-5. In Section 10-12, we described how cytokines such as IL-4 can promote switching to IgE, typically in the germinal center reaction under the influence of T_{FH} cells. Presumably, conditions that favor T_H2 development also favor the emergence of T_{FH} cells producing similar cytokines, although this is an area still under active investigation. And in Section 11-10, we described how type 2 immune responses can protect against infections by parasites, particularly at vulnerable sites such as the mucosal epithelium of the lungs and intestines (see Section 12-4). Further, very recent discoveries have identified new types of cells—called Tuft cells in the intestine—in various mucosal epithelia that promote type 2 immune responses. These cells function as chemosensory cells and are sensitive to various signals that are still being identified. When activated, Tuft cells produce cytokines that enhance type 2 immune responses; one mechanism is their production of IL-25 (Section 11-3), which acts on T cells and type 2 innate lymphoid cells (ILC2 cells) to produce IL-13. IL-33, which can be produced by activated mast cells and by damaged or injured epithelial cells, also contributes to amplification of type 2 immune responses. IL-33 can act directly on T_H2 cells and ILC2 cells, augmenting their cytokine production.

Normally, allergic responses against common environmental antigens may be controlled because of the lack of signals that typically accompany infections. Dendritic cells that encounter and process antigens in the absence of 'danger' signals, such as those provoked by microbial infection, generally do not drive the development of CD4 T cells into an effector cell, such as a T_H2 cell. Instead, such dendritic cells can induce the development of antigen-specific regulatory T cells (T_{reg} cells) that contribute to a state of tolerance to the antigen (see Section 12-10). Despite a great deal of molecular understanding, it is still unknown why some individuals become strongly sensitized to particular allergens, but others do not.

14-2 Although many types of antigens can cause allergic sensitization, proteases are common sensitizing agents.

Most airborne allergens are small, highly soluble proteins carried on dry particles such as pollen grains or dust-mite feces (Fig. 14.3). On contact with the mucus-covered epithelia of the eyes, nose, or airways, the allergen is eluted from the particle and is picked up by dendritic cells to provoke sensitization (see Fig. 14.2). At mucosal surfaces, allergens are typically presented to the immune system at low concentrations. It has been estimated that the maximum exposure of a person to the common pollen allergens in ragweed (*Ambrosia* species) does not exceed 1 μg per year.

However, not all allergens involve such low doses. Bee venom is a frequent cause of allergic sensitization, and individual bee stings result in the injection into the skin of 20–75 μg of bee venom. This is 1–2 orders of magnitude more than the dose of ragweed antigen that is inhaled into the airways. In the case of food allergy, ingestion of many grams of an allergenic food into the gastrointestinal tract over prolonged periods of time can lead to sensitization. Sensitization can also occur in response to injected antigens in either small or large doses. For example, before the introduction of recombinant human insulin, individuals with diabetes could develop allergy to porcine insulin, usually administered in small doses of 1–2 mg per injection. In contrast, penicillin-type drugs (including cephalosporins and other β-lactam–containing antibiotics) can lead to sensitization when administered by intramuscular or intravenous injection in the range of 1–2 g per injection.

Features of airborne allergens that may promote the priming of T_H2 cells that drive IgE responses	
Protein, often with carbohydrate side chains	Protein antigens induce T-cell responses
Low dose	Favors activation of IL-4–producing CD4 T cells
Low molecular mass	Allergen can diffuse out of particles into the mucosa
Highly soluble	Allergen can be readily eluted from particle
Stable	Allergen can survive in desiccated particle
Contains peptides that bind host MHC class II	Required for T-cell priming

Fig. 14.3 Properties of inhaled allergens. The typical characteristics of inhaled allergens are described in this table.

While no physical, chemical, or functional feature has been found that is common to all allergens, many clinically significant allergens are proteases. One ubiquitous protease allergen is the cysteine protease **Der p 1**, which is present in the feces of the house dust mite, *Dermatophagoides pteronyssinus*. Der p 1 provokes allergic reactions in about 20% of the North American population. This enzyme has been found to cleave occludin, a protein component of intercellular tight junctions in the airway mucosa. The destruction of the integrity of the tight junctions between epithelial cells may allow Der p 1 to gain access to the subepithelial antigen-presenting cells such as dendritic cells, thereby inducing an immune response (see Fig. 14.2). Although still an area of active research, other activities of proteases include the activation of **nociceptors**, which are neuropeptide-producing sensory neurons present in the skin. House dust mites that have cysteine protease activity can activate these sensory neurons and induce their secretion of substance P, which can activate nearby mast cells. Cytokines secreted from mast cells can promote type 2 immune responses.

The cysteine protease papain, derived from the papaya fruit, can cause allergic reactions in workers preparing the enzyme. Allergies caused by environmental allergens present in the workplace are called **occupational allergies**. Although Der p 1 and papain are potent allergens, not all allergens are enzymes. In fact, two allergens identified from filarial worms are enzyme inhibitors, and in general, most allergenic pollen-derived proteins do not seem to possess enzymatic activity.

Some associations between allergies and proteases are indirect and somewhat coincidental. For example, high levels of IgE and multiple allergies are seen in individuals with Netherton syndrome (Fig. 14.4), an autosomal recessive condition caused by a mutation in the gene *SPINK5* (serine protease inhibitor Kazal-type 5). *SPINK5* encodes the serine protease inhibitor LEKTI (lymphoepithelial Kazal type–related inhibitor), which is expressed in the most differentiated viable layer of the skin (the granular cell layer), just internal to the cornified cell layer of the epidermis. Absence of LEKTI results in overly active epidermal **kallikreins**, which are proteases that can cleave desmosomes in the skin, leading to keratinocyte shedding and disturbed barrier function of the skin. It is the disturbance of the skin's barrier function—not the direct action of the protease—that leads to the production of IgE and allergies by allowing entry of antigen directly into the skin and underlying dermis, where immune responses can be initiated. A major component driving the T_H2 and IgE response is the production by the damaged epidermis of thymic stromal lymphopoietin (TSLP), which acts on T cells and dendritic cells to promote a type 2 immune response through mechanisms that are not precisely understood but are still being investigated. Mice with skin-specific deletions in the gene *Notch1* (see Section 8-14) also develop a failure in the barrier function of the skin, due to the requirement for Notch signaling for terminal keratinocyte differentiation. These mice also produce high amounts of TSLP and develop allergic manifestations in the skin.

Fig. 14.4 Netherton syndrome illustrates the association between disruption of the skin barrier and development of high levels of IgE and allergy. This 26-year-old man with Netherton syndrome, caused by a deficiency in the protease inhibitor SPINK5, had persistent erythroderma (redness of the skin), recurrent infections of the skin and other tissues, and multiple food allergies associated with high serum IgE levels. In the photograph, large erythematous plaques covered with scales and erosions are visible over the upper trunk. The epidermis in these regions is thickened and contains a perivascular infiltrate of neutrophils and mononuclear cells.

14-3 Genetic factors contribute to the development of IgE-mediated allergic disease.

For more than a decade, the genetic causes of allergy and asthma have been investigated predominantly using genome-wide association studies (GWASs). These studies examine the association of common genetic variations in the genome with a variety of clinical manifestations. The genetic variations that are mapped are typically **single-nucleotide polymorphisms, or SNPs**, which are frequently present in two forms at a genomic site. SNPs can be located in a coding region of a gene, where they may change the sequence of the encoded protein, but more frequently they are located in the intragenic regions of

Asthma susceptibility loci
Genes expressed in airway epithelial cells

Fig. 14.5 Susceptibility loci for asthma. Loci that have shown linkage on the basis of GWASs or targeted gene analysis are listed, separated into genes that are expressed in epithelial cells of the airways, genes that regulate the differentiation and/or function of CD4 T cells and ILC2 cells, and genes with other miscellaneous or unknown functions.

unknown function or in gene-regulatory regions. The medical conditions examined in GWASs have included asthma, total IgE levels, allergic sensitization, atopic dermatitis, allergic rhinitis, and food allergies. These studies have identified more than 40 loci associated with these conditions and have examined large numbers of individuals, a process that allows the discovery of SNPs with weak, but statistically significant, associations (Fig. 14.5). The strength of such associations is defined by the **odds ratio**. For example, an odds ratio of 10 means that the chance of having asthma is 10 times higher when a person has a particular SNP compared to individuals who have a common variant. The large size of GWASs for allergic conditions has allowed the identification of risk alleles with odds ratios less than 1.2, despite having very high statistical significance (p values). For example, a recent study into risk loci for asthma included nearly 24,000 asthma cases, more than 100,000 controls, and identified 5 new risk loci, with the largest odds ratio being 1.11. In other words, having that risk allele increases a person's chance of having asthma by a factor of 1.11 compared with a person with the common allele. Thus, their risk is increased only by 11% over normal.

Many of the risk alleles identified for allergic disorders are near genes with recognizable immunological function (see Fig. 14.5), but how any particular SNP contributes to susceptibility is frequently unknown. For example, specific alleles at the IL-33 receptor and IL-13 loci show strong association with both allergic asthma and atopic eczema. This sharing of genetic risk alleles by allergic asthma and atopic eczema is consistent with the finding that these two disorders are commonly found together in atopic families, with some family members manifesting both disorders, while other family members may manifest only atopic eczema or allergic asthma, but not both. But how this risk allele alters the biological activity of IL-33 in immune responses is unclear.

Alleles of many genes, especially genes that regulate the skin's barrier function, show linkage to atopic eczema without enhancing the risk for allergic asthma or allergic rhinoconjunctivitis, suggesting that other genetic factors can contribute to allergic responsiveness. In addition, there are differences among various ethnic groups for which susceptibility genes are most associated with a given allergic disease. Several of the chromosome regions associated with allergy or asthma are also associated with the inflammatory disease psoriasis and with autoimmune diseases, suggesting that these loci contain genes that are involved in exacerbating inflammation.

One candidate susceptibility gene for both allergic asthma and atopic eczema resides at 11q12–13 and encodes the β subunit of the high-affinity IgE receptor FcεRI. Another region associated with allergic disease, 5q31–33, contains at least four types of candidate genes that might be responsible for increased susceptibility. First, there is a cluster of tightly linked genes encoding the cytokines IL-3, IL-4, IL-5, IL-9, IL-13, and granulocyte-macrophage colony-stimulating factor (GM-CSF), which enhance IgE class switching, eosinophil survival, and mast-cell proliferation. A genetic variation in the IL-4 gene promoter that is associated with increased IgE levels in atopic individuals exhibits increased transcriptional activity in experimental systems, and so conceivably produces increased IL-4 *in vivo*. Atopy has also been associated with a gain-of-function mutation of the α subunit of the IL-4 receptor, with the mutation causing increased signaling after ligation of the receptor.

The second set of candidate genes in this region of chromosome 5 belongs to the TIM family (for T cell, immunoglobulin domain, and mucin domain). These genes encode four surface proteins expressed on T cells (Tim-1, -2, -3) and antigen-presenting cells (Tim-3, -4). In mice, Tim-3 is expressed on T_H1 cells and inhibits T_H1 responses, whereas Tim-2 is preferentially expressed in and inhibits T_H2 cells. Mouse strains with different variants of the Tim genes differ both in their susceptibility to allergic inflammation of the airways and in the production of IL-4 and IL-13 by their T cells. The third and

fourth candidate genes in this part of the genome encode p40 and the β-adrenergic receptor. The p40 gene encodes the shared subunit of IL-12 and IL-23 (see Fig. 11.17) and could influence their production, while the β-adrenergic receptor gene could influence smooth muscle responsiveness to endogenous or pharmacological ligands. However, for the susceptibility locus at 5q31–33, we still do not understand how the different polymorphisms influence the complex genetics of atopy.

An inherited variation in IgE responses is linked to a particular HLA class II allele (the human MHC class II region) but affects responses to specific allergens rather than causing a general susceptibility to atopy. This results from the ability of certain HLA class II alleles to form a peptide:MHC complex with some allergens, which in atopic individuals will favor a T_H2 response. For example, IgE responses to several ragweed pollen allergens are associated with haplotypes containing the HLA class II allele DRB1*1501.

Allergic responses to drugs such as penicillin were originally thought to show no association with HLA class II or with the presence or absence of atopy. However, some drugs can interact with specific HLA alleles in a way that changes the structure of the peptide:MHC complex, and so elicit an autoimmune-type reaction. For example, a metabolite of the seizure medication carbamazepine, carbamazepine-10,11-epoxide (EPX), binds with HLA-B15:02 and the peptide bound in this HLA-B allele. The immune response to this EPX:peptide:HLA-B complex can lead to development of toxic epidermal necrolysis, a severe immune-mediated skin reaction in which widespread skin loss occurs due to necrosis, leaving the skin looking scalded.

Some genes may affect only particular aspects of allergic disease. In the skin, filaggrin contributes to normal skin barrier function by binding keratin molecules into the lipid envelope of cornifying keratinocytes. Loss-of-function mutations in the gene encoding filaggrin lead to the development of eczema. Through unknown mechanisms, filaggrin mutations also can contribute to the development of asthma. Almost half of the people in the United States who suffer from severe eczema have at least one mutated filaggrin allele. Between 7% and 10% of Caucasians carry a loss-of-function mutation in filaggrin, and the frequency of this mutation is considerably higher in individuals with asthma.

Allergic Asthma

14-4 Environmental factors may interact with genetic susceptibility to cause allergic disease.

Studies suggest that environmental factors and genetic variation each account for about 50% of the risk of developing atopy. In the past 50–60 years, atopic allergic diseases, and asthma in particular, have become more prevalent in economically advanced regions of the world, likely due to environmental changes that interact with an individual's genetic background. Although the incidence of asthma is lower in economically underdeveloped regions of Africa, Americans of African ancestry show increased asthma frequency and severity compared with Americans not of African ancestry. This shows a clear impact of environment on the expressivity of genetic influences.

One hypothesis suggests that this steady increase in allergic diseases is the result of a reduction in infectious diseases in early childhood that has occurred as populations have moved increasingly from rural into urban environments. The original proposition, first suggested in 1989 by David P. Strachan, was that infections in early life reduced atopy, and that less-hygienic environments, particularly those encountered in less-developed rural settings, predispose to more numerous infections early in childhood, which help to protect against the development of atopy and allergic asthma. Subsequently, this proposition

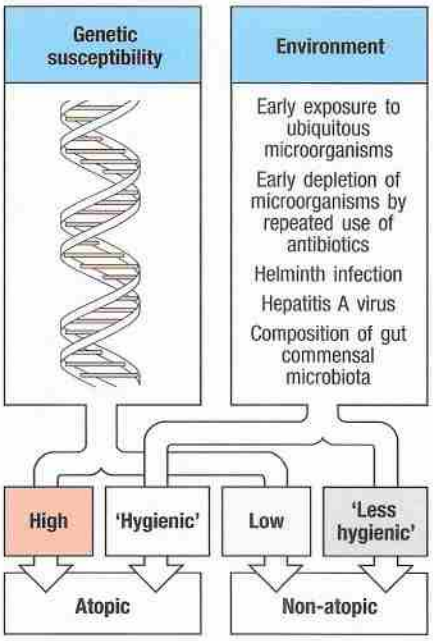

Fig. 14.6 Genes, the environment, and atopic allergic diseases. Both inherited and environmental factors are important determinants of the likelihood of developing allergic disease. Many genes are known to influence the development of asthma (see Fig. 14.5). The postulate of the 'hygiene hypothesis' is that exposure to some infections and to common environmental microorganisms in infancy and childhood drives the immune system toward a general state of non-atopy. In contrast, children who have a genetic susceptibility to atopy and who live in an environment with low exposure to infectious disease and environmental microorganisms or who received multiple courses of antibiotics in infancy and early childhood are thought not to develop efficient immunoregulatory mechanisms and to be most susceptible to the development of atopic allergic disease.

has evolved to become known as the **hygiene hypothesis** (Fig. 14.6) and has incorporated additional ideas. One idea was that reduced early-life exposure to microorganisms that were associated with farm animals and soil microorganisms led to changes in the intestinal microbiota, which performs an important immunomodulatory function (discussed in Chapter 12). But this idea seemed inconsistent with other evidence of a negative correlation between infection by helminths (such as hookworms and schistosomes) and the development of allergic disease. A study in Venezuela showed that children treated for a prolonged period with anti-helminthic agents had a higher prevalence of atopy than did untreated and heavily parasitized children. As helminths provoke a strong T_H2-mediated IgE response, this result was seemingly inconsistent with the original hygiene hypothesis.

This apparent inconsistency may suggest that many types of infection protect against the development of atopy. This protection could result from the production of cytokines such as IL-10 and TGF-β as part of the homeostatic responses during the infection. IL-10 and TGF-β suppress the formation of both T_H1 and T_H2 responses, and IL-10 suppresses T_H17 responses (see Sections 9-15 and 9-16). Most allergic reactions are initiated by antigens that enter through mucosal surfaces such as the respiratory or intestinal epithelium. The human mucosal immune system has evolved mechanisms of regulating responses to commensal flora and environmental antigens (such as food antigens) that involve the generation of IL-10 and TGF-β, thereby promoting the emergence of T_{reg} cells (see Chapter 12). Thus, decreased early exposure to common microbial pathogens and commensal bacteria could reduce the production of T_{reg} cells and increase the risk of an allergic response to common environmental antigens.

In support of a role for disturbed immunoregulatory pathways in susceptibility to asthma is circumstantial evidence that early exposures to certain types of childhood infections or to animals, with the important exception of the respiratory infection that we consider shortly, help to protect against the development of allergic disease. A history of infection with hepatitis A virus also may have a negative association with atopy. A possible explanation for this association is that the human counterpart of the murine Tim-1 protein (see Section 14-3) is the cellular receptor for hepatitis A virus (designated HAVCR1). The infection of T cells by hepatitis A virus could thus directly influence their differentiation and cytokine production, limiting the development of an IgE-generating response.

In contrast to these negative associations, there is a positive association between asthma in children and previous attacks of bronchiolitis associated with respiratory syncytial virus (RSV) infection. Children hospitalized with RSV infection have a skewed ratio of cytokine production away from IFN-γ toward IL-4, presumably increasing their likelihood of developing T_H2 responses and increased production of IgE. This effect of RSV appears to depend on age at first infection. But the basis for this association remains unclear. In a randomized clinical trial, prevention of RSV infection in the first year of life using an antibody to the virus (palivizumab) did not reduce the occurrence of asthma subsequently up to 6 years of age. Conceivably, some other common environmental factor may represent a significant cause of asthma or the association between RSV and asthma may be due to an underlying factor associated with both susceptibility to RSV and asthma.

Other environmental factors that might contribute to the increase in atopic disease are changes in diet, allergen exposure, atmospheric pollution, and tobacco smoke. There is evidence for an interaction between allergens and pollution, particularly in genetically susceptible individuals. Diesel exhaust particles are the best-studied pollutant in this context; they increase IgE production 20- to 50-fold when combined with allergen, with an accompanying shift to T_H2 cytokine production. Reactive oxidant chemicals such as ozone are

generated as a result of such pollution, and individuals less able to deal with this onslaught may be at increased risk of allergic disease. Genes that might be governing this aspect of susceptibility are *GSTP1* and *GSTM1*, members of the glutathione-*S*-transferase superfamily that are important in preventing oxidative stress. Individuals who were allergic to ragweed pollen and who carried particular variant alleles of these genes showed an increased airway hyperreactivity when challenged with the allergen-plus-diesel exhaust particles than when challenged with the allergen alone. A study in Mexico City on the effects of atmospheric ozone levels on atopic children with allergic asthma also found that the children carrying the null allele of *GSTM1* were more susceptible than noncarriers to airway hyperreactivity when exposed to given levels of ozone.

Summary.

Allergens are generally innocuous antigens that commonly provoke an IgE antibody response in susceptible individuals. Such antigens normally enter the body at very low doses by diffusion across mucosal surfaces and trigger a type 2 immune response. The differentiation of naive allergen-specific T cells into T_H2 cells and T_{FH} cells that produce cytokines such as IL-4 and IL-13 support the switching of allergen-specific B cells to the IgE isotype. The specific IgE produced in response to the allergen circulates and binds to the high-affinity receptor for IgE on mast cells and basophils, where it serves as the trigger to activate these cells upon future encounter with free allergen. The tendency for a person to overproduce IgE in response to exposure to innocuous allergens is influenced by both genetic and environmental factors. GWASs have revealed a large number of SNPs that identify alleles of many candidate genes associated with atopy and allergy. Most of these candidate genes have functions related to regulation of immune processes. However, most such alleles have a relatively weak odds ratio for their association, and in most cases the mechanism of their association is unclear. Nonetheless, once IgE has been produced in response to an allergen, subsequent exposure to the allergen triggers an allergic response, which we describe in the next part of the chapter.

Effector mechanisms in IgE-mediated allergic reactions.

Allergic reactions are triggered when allergens cross-link preformed IgE bound to the high-affinity receptor FcεRI on mast cells. Mast cells line external mucosal surfaces and serve to alert the immune system to local infection. Once activated, they induce inflammatory reactions by secreting pharmacological mediators such as **histamine** stored in preformed granules and by synthesizing prostaglandins, leukotrienes, and platelet-activating factor from the plasma membrane. Mast cells also release various cytokines and chemokines after activation and, in the case of an allergic reaction, provoke unpleasant reactions to innocuous antigens that are not associated with invading pathogens that need to be expelled.

14-5 Most IgE is cell-bound and engages effector mechanisms of the immune system by pathways different from those of other antibody isotypes.

Antibodies engage effector cells such as mast cells by binding to receptors specific for their Fc constant regions. Most antibodies engage Fc receptors only after their antigen-binding sites have bound specific antigen, forming an immune complex of antigen and antibody. IgE is an exception, because it

is captured by the high-affinity Fcε receptor (FcεRI) in the absence of bound antigen. This means that, unlike other antibodies, which are found mainly in body fluids, IgE is mostly found fixed on cells that carry this receptor—mast cells in tissues, and basophils in the circulation and at sites of inflammation. The ligation of the cell-bound IgE antibody by specific multivalent antigen triggers the activation of these cells at the sites of antigen entry into the tissues. The release from these activated mast cells of inflammatory lipid mediators, cytokines, and chemokines at sites of IgE-triggered reactions recruits eosinophils and basophils to augment the allergic response. It also recruits T_H2 cells, which can then mount a local type 2 cellular response.

There are two types of Fc receptors that bind IgE. The first, FcεRI, expressed on mast cells and basophils, is a high-affinity receptor of the immunoglobulin superfamily (see Section 10-24). High levels of IgE, such as those that exist in people with allergic diseases or parasite infections, can result in a marked increase in FcεRI on the surface of mast cells, an enhanced sensitivity of such cells to activation by low concentrations of specific antigen, and a markedly increased, IgE-dependent release of chemical mediators and cytokines. When IgE bound to this receptor is cross-linked by specific antigen, it transduces an activating signal through the receptor-bound Lyn tyrosine kinase (see Section 7-20), which phosphorylates ITAMs on the intracellular domain of the receptor (**Fig. 14.7**). The phosphorylated ITAMs recruit and activate the amplifying tyrosine kinase Syk, which in turn phosphorylates and activates a broad range of downstream effector pathways. One important target is the activation of the enzyme phospholipase C-γ (PLC-γ). As in the TCR signaling pathway, this leads to the generation of IP_3 and ultimately to an increase in cytosolic calcium (see Section 7-13 and Fig. 7.18), which activates the release of the preformed secretory granules in the cell into the surrounding tissues.

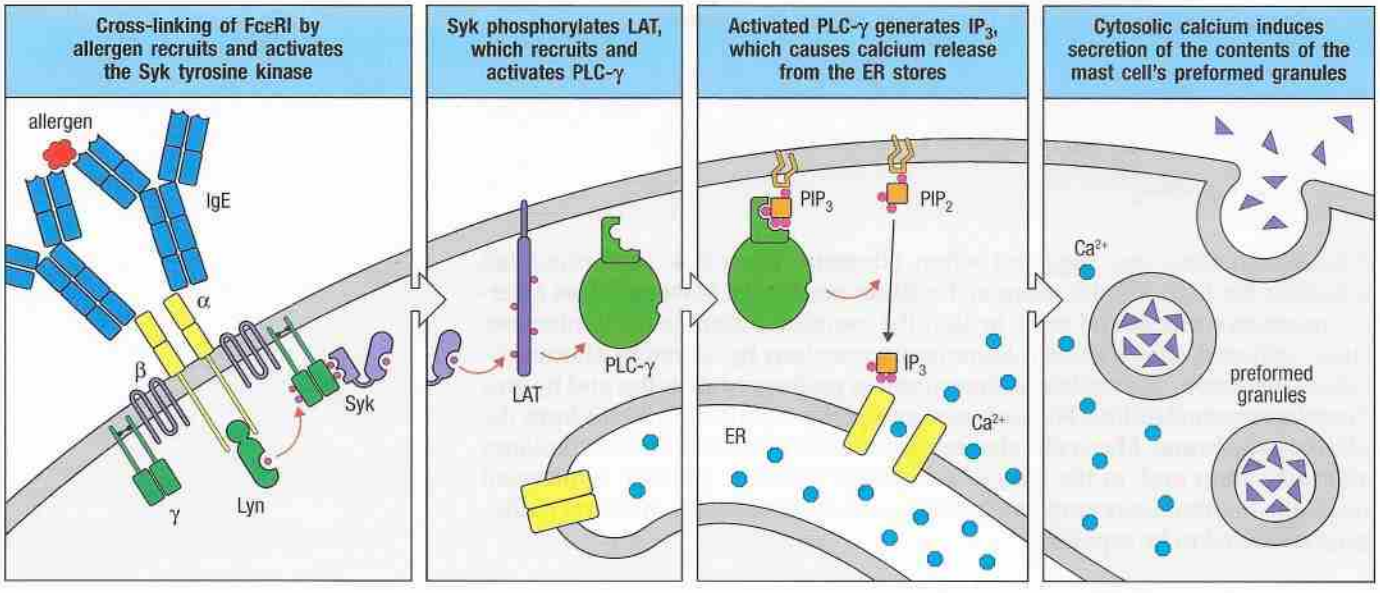

Fig. 14.7 Allergens induce signaling by the FcεRI receptor to cause degranulation of mast cells. First panel: IgE specific to an allergen is bound to the high-affinity IgE receptor, FcεRI. Binding of a multivalent allergen to this IgE induces receptor cross-linking, leading to the phosphorylation by the bound kinases Fyn (not shown) and Lyn of the ITAMs in the γ chain of FcεRI, which is similar in structure to the TCR γζ chain, thus recruiting the ITAM-binding kinase Syk. Second panel: Syk phosphorylates the signaling molecule LAT, which recruits signaling components that lead to the activation of phospholipase C-γ (PLC-γ) (see Fig. 7-17). Third panel: Activated PLC-γ cleaves phosphatidylinositol 4,5-bisphosphate (PIP_2), generating inositol 1,4,5-trisphosphate (IP_3), which acts on receptors in the membrane of the endoplasmic reticulum (ER) to induce the release of calcium ions (Ca^{+2}) into the cytosol. Fourth panel: This increase in cytosolic Ca^{+2} ions induces the fusion of membranes of the preformed secretory granules in the mast-cell cytoplasm with the cell's plasma membrane (mechanisms not shown) to release the granule's contents, such as histamine, into the extracellular space.

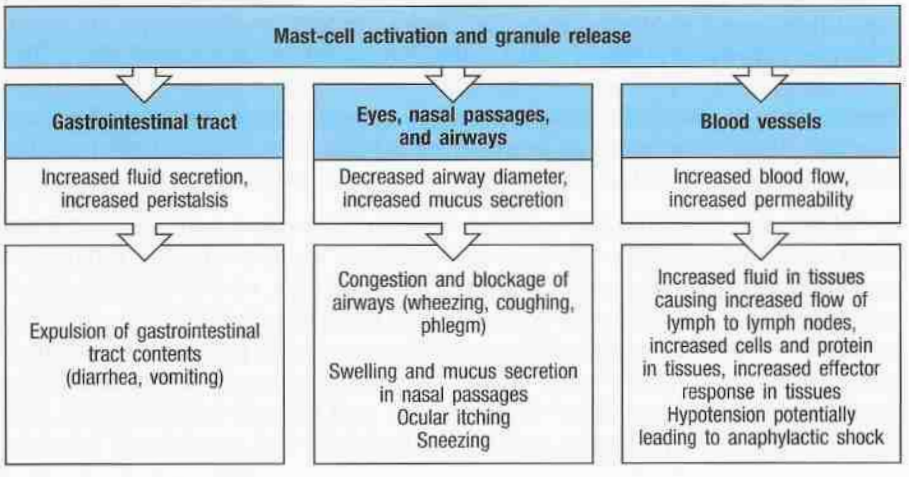
The second IgE receptor, FcεRII, usually known as **CD23**, is a C-type lectin and is structurally unrelated to FcεRI; it binds IgE with low affinity. CD23 is present on many cell types, including B cells, activated T cells, monocytes, eosinophils, platelets, follicular dendritic cells, and some thymic epithelial cells. This receptor was thought to be crucial for the regulation of IgE levels, but mouse strains in which the gene for CD23 has been inactivated still develop relatively normal polyclonal IgE responses. Nevertheless, CD23 does seem to be involved in enhancing IgE antibody levels in some situations. Responses against a specific antigen are known to be increased in the presence of the antigen complexed with IgE, but such enhancement fails to occur in mice that lack the gene for CD23. This has been interpreted to indicate that CD23 on antigen-presenting cells has a role in the capture of antigen that is complexed with IgE.

14-6 Mast cells reside in tissues and orchestrate allergic reactions.

When Paul Ehrlich described mast cells found in the mesentery of rabbits, he called them *Mastzellen* ('fattened cells'). Like basophils, mast cells contain granules rich in acidic proteoglycans that take up basic dyes. Mast cells are derived from hematopoietic stem cells but mature locally, often residing near surfaces exposed to pathogens and allergens, such as mucosal tissues and the connective tissues surrounding blood vessels.

The major factors for mast-cell growth and development include stem-cell factor (the ligand for the receptor tyrosine kinase Kit), IL-3, and T_H2-associated cytokines such as IL-4 and IL-9. Mice with defective Kit lack differentiated mast cells, and although they produce IgE, they cannot make IgE-mediated inflammatory responses. This shows that such responses depend almost exclusively on mast cells. There are many mast-cell precursors in tissues, and they can rapidly differentiate into mature mast cells in conditions of allergic inflammation, thus aiding the continuation of the allergic response. Mast-cell growth and survival depend on the activation of phosphatidylinositol 3-kinase (PI 3-kinase) in mast cells by Kit. Pharmacological inactivation of the p110δ isoform of PI 3-kinase has been shown to protect mice against allergic responses. Inhibitors of the amplifying tyrosine kinase Syk have also shown promise as blockers of IgE-dependent mast-cell responses.

The consequences of IgE-mediated mast-cell activation depend on the dose of antigen, its route of entry, and which tissues are affected (Fig. 14.8). Symptoms range from the swollen eyes and rhinitis associated with contact of pollen with the conjunctiva of the eye and the nasal epithelium to the life-threatening circulatory collapse that occurs in anaphylaxis. The immediate reaction caused by mast-cell degranulation is followed, to a greater or lesser extent depending on the disease, by a more sustained inflammation, which is due to the



Mast-cell activation and granule release
Gastrointestinal tract
Increased fluid secretion, increased peristalsis
Expulsion of gastrointestinal tract contents (diarrhea, vomiting)
Eyes, nasal passages, and airways
Decreased airway diameter, increased mucus secretion
Congestion and blockage of airways (wheezing, coughing, phlegm)
Swelling and mucus secretion in nasal passages
Ocular itching
Sneezing
Blood vessels
Increased blood flow, increased permeability
Increased fluid in tissues causing increased flow of lymph to lymph nodes, increased cells and protein in tissues, increased effector response in tissues
Hypotension potentially leading to anaphylactic shock

Fig. 14.8 Mast-cell activation has different effects on different tissues.

Class of product	Examples	Biological effects
Enzyme	Tryptase, chymase, cathepsin G, carboxypeptidase A	Remodel connective tissue matrix
Toxic mediator	Histamine, heparin	Toxic to parasites Increase vascular permeability Cause smooth muscle contraction Anticoagulation
Cytokine	IL-4, IL-13, IL-33	Stimulate and amplify T_H2 cell response
	IL-3, IL-5, GM-CSF	Promote eosinophil production and activation
	TNF-α (some stored preformed in granules)	Promotes inflammation Stimulates cytokine production by many cell types Activates endothelium
Chemokine	CCL3	Attracts monocytes, macrophages, and neutrophils
Lipid mediator	Prostaglandins D2, E2 Leukotrienes C4, D4, E4	Smooth muscle contraction Chemotaxis of eosinophils, basophils, and T_H2 cells Increase vascular permeability Stimulate mucus secretion Bronchoconstriction
	Platelet-activating factor	Attracts leukocytes Amplifies production of lipid mediators Activates neutrophils, eosinophils, and platelets

Fig. 14.9 Molecules released by activated mast cells. Mast cells release a wide variety of biologically active proteins and other chemical mediators. The enzymes and toxic mediators listed in the first two rows are released from the preformed granules. The cytokines, chemokines, and lipid mediators are mostly synthesized after activation.

recruitment of other effector leukocytes, notably T_H2 lymphocytes, eosinophils, and basophils.

Mast-cell degranulation begins within seconds of antigen binding, releasing an array of preformed and newly generated inflammatory mediators (Fig. 14.9). Granule contents include the short-lived vasoactive amine, histamine, serine esterases, and proteases such as chymase and tryptase. Histamine acts through four known receptors, H_1 through H_4, each a G protein–coupled receptor. Histamine acts via the H_1 receptor on local blood vessels to cause an immediate increase in local blood flow and vessel permeability. This leads to edema and local inflammation. Histamine is also a major stimulus for itching and sneezing, by virtue of its activation of neural receptors. By acting through H_2, H_3, and H_4 receptors on a variety of leukocytes and tissue cells, histamine participates in atopic dermatitis, chronic urticaria, and several autoimmune disorders.

Human mast cells are classified into subtypes on the basis of their protease content and tissue location. Mast cells in mucosal epithelia express tryptase as their primary serine protease. These cells are designated MC_T. Mast cells in the submucosa and other connective tissues predominantly express chymase, tryptase, carboxypeptidase A, and cathepsin G and are designated MC_{CT}. The proteases released by the mast cells activate matrix metalloproteinases, which break down extracellular matrix proteins, causing tissue disintegration and damage. These proteases can exert beneficial effects such as degrading snake and bee venoms, thus helping to suppress allergic responses to these agents.

In addition to secreting the contents of their preformed granules, activated mast cells also synthesize *de novo* and release a number of other inflammatory mediators. These include chemokines, cytokines, and lipid mediators—prostaglandins, leukotrienes, thromboxanes (collectively called eicosanoids), and platelet-activating factor. MC_T and MC_{CT} mast cells, for example, produce the cytokine IL-4, which helps perpetuate type 2 immune responses. These secreted products contribute to both acute and chronic inflammation. The lipid mediators, in particular, can act both rapidly and persistently to cause

smooth muscle contraction, increased vascular permeability, and the secretion of mucus, as well as induce the influx and activation of leukocytes, which contribute to allergic inflammation.

Eicosanoids derive mainly from the membrane-associated fatty acid arachidonic acid. This is cleaved from membrane phospholipids by phospholipase A_2, which is activated at the plasma membrane as a result of cell activation. Arachidonic acid can be modified by either of two pathways to give rise to lipid mediators. Modification via the cyclooxygenase pathway produces the prostaglandins and thromboxanes, whereas leukotrienes are produced via the lipoxygenase pathway. Prostaglandin D2 is the major prostaglandin produced by mast cells; it recruits T_H2 cells, eosinophils, and basophils, all of which express its receptor (PTGDR). Prostaglandin D2 is critical to the development of allergic diseases such as asthma; polymorphisms in the gene *PTGDR* have been linked to an increased risk of developing asthma. The leukotrienes, especially C4, D4, and E4, are also important in sustaining inflammatory responses in tissues. Nonsteroidal anti-inflammatory drugs such as aspirin and ibuprofen exert their effects by preventing prostaglandin production. They inhibit the cyclooxygenases that act on arachidonic acid to form the ring structure present in prostaglandins.

Large amounts of the cytokine tumor necrosis factor (TNF)-α are also released by mast cells after activation. Some comes from stores in the granules; some is newly synthesized by the activated mast cells. TNF-α activates endothelial cells, resulting in increased expression of adhesion molecules, which in turn promotes the influx of pro-inflammatory leukocytes and lymphocytes into the affected tissue (see Chapter 3). Additionally, mast-cell TNF-α contributes importantly to the influx of leukocytes into regional lymph nodes in response to microbial infection of peripheral tissues.

14-7 Eosinophils and basophils cause inflammation and tissue damage in allergic reactions.

The inflammatory cascade produced by mast-cell activation is amplified by the recruitment of eosinophils, basophils, T_H2 lymphocytes, and B cells. Normally this reaction is a defense against parasite infection (see Section 10-25), but in an allergic reaction, it represents a pathological response to environmental antigens.

Eosinophils are granulocytic leukocytes that originate in bone marrow. They are so called because their granules, which contain arginine-rich basic proteins, are colored bright orange by the acidic stain eosin. In healthy humans, these cells represent less than 6% of the leukocytes in the circulation; most eosinophils are found in tissues, especially in the connective tissue immediately underneath respiratory, gut, and urogenital epithelium, implying a likely role for these cells in defense against invading organisms at these sites. They possess numerous cell-surface receptors, including receptors for cytokines (such as IL-5), Fcγ and Fcα receptors, and the complement receptors CR1 and CR3, through which they can be activated and stimulated to degranulate. For example, parasites coated with IgG, C3b, or IgA can cause eosinophil degranulation. In allergic tissue reactions, the large concentrations of IL-5, IL-3, and GM-CSF that are typically present are likely to contribute to degranulation.

When activated, eosinophils express two kinds of effector function. First, they can release highly toxic granule proteins and free radicals, which can kill microorganisms and parasites but also can cause significant damage to host tissues in allergic reactions (Fig. 14.10). Second, they can synthesize chemical mediators, including prostaglandins, leukotrienes, and cytokines. These amplify the inflammatory response by activating epithelial cells and by recruiting and activating more eosinophils and leukocytes. In chronic inflammatory

Class of product	Examples	Biological effects
Enzyme	Eosinophil peroxidase	Toxic to targets by catalyzing halogenation Triggers histamine release from mast cells
	Eosinophil collagenase	Remodels connective tissue matrix
	Matrix metalloproteinase-9	Matrix protein degradation
Toxic protein	Major basic protein	Toxic to parasites and mammalian cells Triggers histamine release from mast cells
	Eosinophil cationic protein	Ribonuclease Toxic to parasites Neurotoxin
	Eosinophil-derived neurotoxin	Neurotoxin
Cytokine	IL-4, IL-13, IL-3, GM-CSF	Amplify eosinophil production by bone marrow Eosinophil activation
	TGF-α, TGF-β	Epithelial proliferation Myofibroblast formation
Chemokine	CXCL8 (IL-8)	Promotes influx of leukocytes
Lipid mediator	Leukotrienes C4, D4, E4	Smooth muscle contraction Increase vascular permeability Increase mucus secretion Bronchoconstriction
	Platelet-activating factor	Attracts leukocytes Amplifies production of lipid mediators Activates neutrophils, eosinophils, and platelets

Fig. 14.10 Eosinophils secrete a range of highly toxic granule proteins and other inflammatory mediators. As for mast cells (see Fig. 14.9), enzymes and toxic mediators released by eosinophils are largely stored preformed in granules. In contrast, cytokines, chemokines, and lipid mediators are largely synthesized after eosinophil activation.

responses, eosinophils can contribute to airway tissue remodeling. In allergic tissue reactions, eosinophils may accumulate in large numbers, and the continued presence of eosinophils is characteristic of chronic allergic inflammation, and they may be major contributors to tissue damage.

Because their inappropriate activation is harmful to the host, the activation and degranulation of eosinophils is strictly regulated, The first level of control acts on the production of eosinophils by the bone marrow. Few eosinophils are produced in the absence of infection or other immune stimulation. But when T_H2 cells are activated, the cytokines they produce, such as IL-5 and GM-CSF, increase the production of eosinophils in the bone marrow and their release into the circulation. However, transgenic animals overexpressing IL-5 have increased numbers of eosinophils (**eosinophilia**) in the circulation but not in their tissues, indicating that the migration of eosinophils from the circulation into tissues is regulated separately by a second set of controls.

The key molecule regulating the entry of eosinophils into tissues is the chemokine receptor CCR3. CCR3 is highly expressed on eosinophils and is also expressed on basophils, mast cells, and T_H2 cells. CCR3 is quite promiscuous and binds several CC chemokines. Three CC chemokines have been named **eotaxins** because of their specificity for eosinophils—CCL11 (eotaxin 1), CCL24 (eotaxin 2), and CCL26 (eotaxin 3)—and each binds to CCR3. In addition, the CC chemokines CCL5, CCL7, and CCL13 also bind CCR3 and will induce eosinophil chemotaxis and activation. Identical or similar chemokines stimulate mast cells and basophils. For example, eotaxins attract basophils and cause their degranulation. T_H2 cells also express CCR3 and will migrate toward eotaxins.

Basophils are also present at the site of an inflammatory reaction. Growth factors for basophils are very similar to those for eosinophils; they include IL-3,

IL-5, and GM-CSF. There is evidence for reciprocal control of the maturation of the stem-cell population into basophils or eosinophils. For example, TGF-β in the presence of IL-3 suppresses eosinophil differentiation and enhances that of basophils. Basophils are normally present in very low numbers in the circulation and seem to have a similar role to that of eosinophils in defense against pathogens. Like eosinophils, they are recruited to the sites of IgE-mediated allergic reactions. Basophils express high-affinity FcεRI on their cell surfaces and so have IgE bound. On activation by antigen binding to IgE or by cytokines, they release histamine from their granules and also produce IL-4 and IL-13.

Eosinophils, mast cells, and basophils can interact with each other. Eosinophil degranulation releases **major basic protein** (see Fig. 14.10), which in turn causes the degranulation of mast cells and basophils. This effect is augmented by any of the cytokines that affect eosinophil and basophil growth, differentiation, and activation, such as IL-3, IL-5, and GM-CSF.

14-8 IgE-mediated allergic reactions have a rapid onset but can also lead to chronic responses.

Under laboratory conditions, the clinical response of a sensitized individual to challenge by intradermal allergen or inhalation of allergen can be divided into an 'immediate reaction' and a 'late-phase reaction' (Fig. 14.11). The immediate reaction is due to IgE-mediated mast-cell activation and starts within seconds of allergen exposure. It is the result of the actions of histamine, prostaglandins, and other preformed or rapidly synthesized mediators released by mast cells. These mediators cause a rapid increase in vascular permeability,

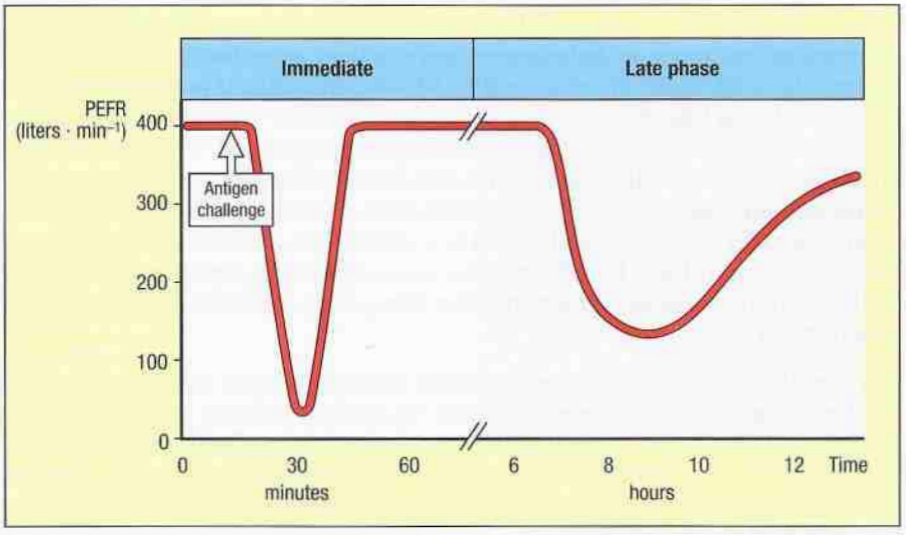


Fig. 14.11 Allergic reactions in response to test antigens can be divided into an immediate response and a late-phase response. Left panel: The response to an inhaled antigen can be divided into early and late responses. An asthmatic response in the lungs with narrowing of the airways caused by the constriction of bronchial smooth muscle and development of edema can be measured as a fall in the peak expiratory flow rate (PEFR). PEFR is a person's maximum ability to breathe out air and is a measure of the flow of air through the bronchi of the lungs. The immediate response peaks within minutes after antigen inhalation and then subsides, returning to near-baseline PEFR. Six to eight hours after antigen challenge, there can be a late-phase response that also results in a fall in the PEFR. The immediate response is caused by the direct effects on blood vessels, nerves, and smooth muscle of rapidly metabolized mediators such as histamine and lipid mediators released by mast cells. The late-phase response is caused by the continued production of these mediators, by the production of vasoactive compounds that dilate blood vessels, and by recruitment of lymphocytes and myeloid cells, which together lead to the production of edema. Right panel: A wheal-and-flare allergic reaction develops within a minute or two of intradermal injection of antigen and lasts for up to 30–60 minutes. The more widespread edematous response characteristic of the late phase develops approximately 6 hours later and can persist for up to 2 or 3 days. The photograph shows an intradermal skin challenge with allergen resulting in a wheal-and-flare (early-phase) reaction observed 15 minutes after allergen challenge (left) and a late-phase reaction occurring 6 hours after challenge (right). The allergen was grass pollen extract.

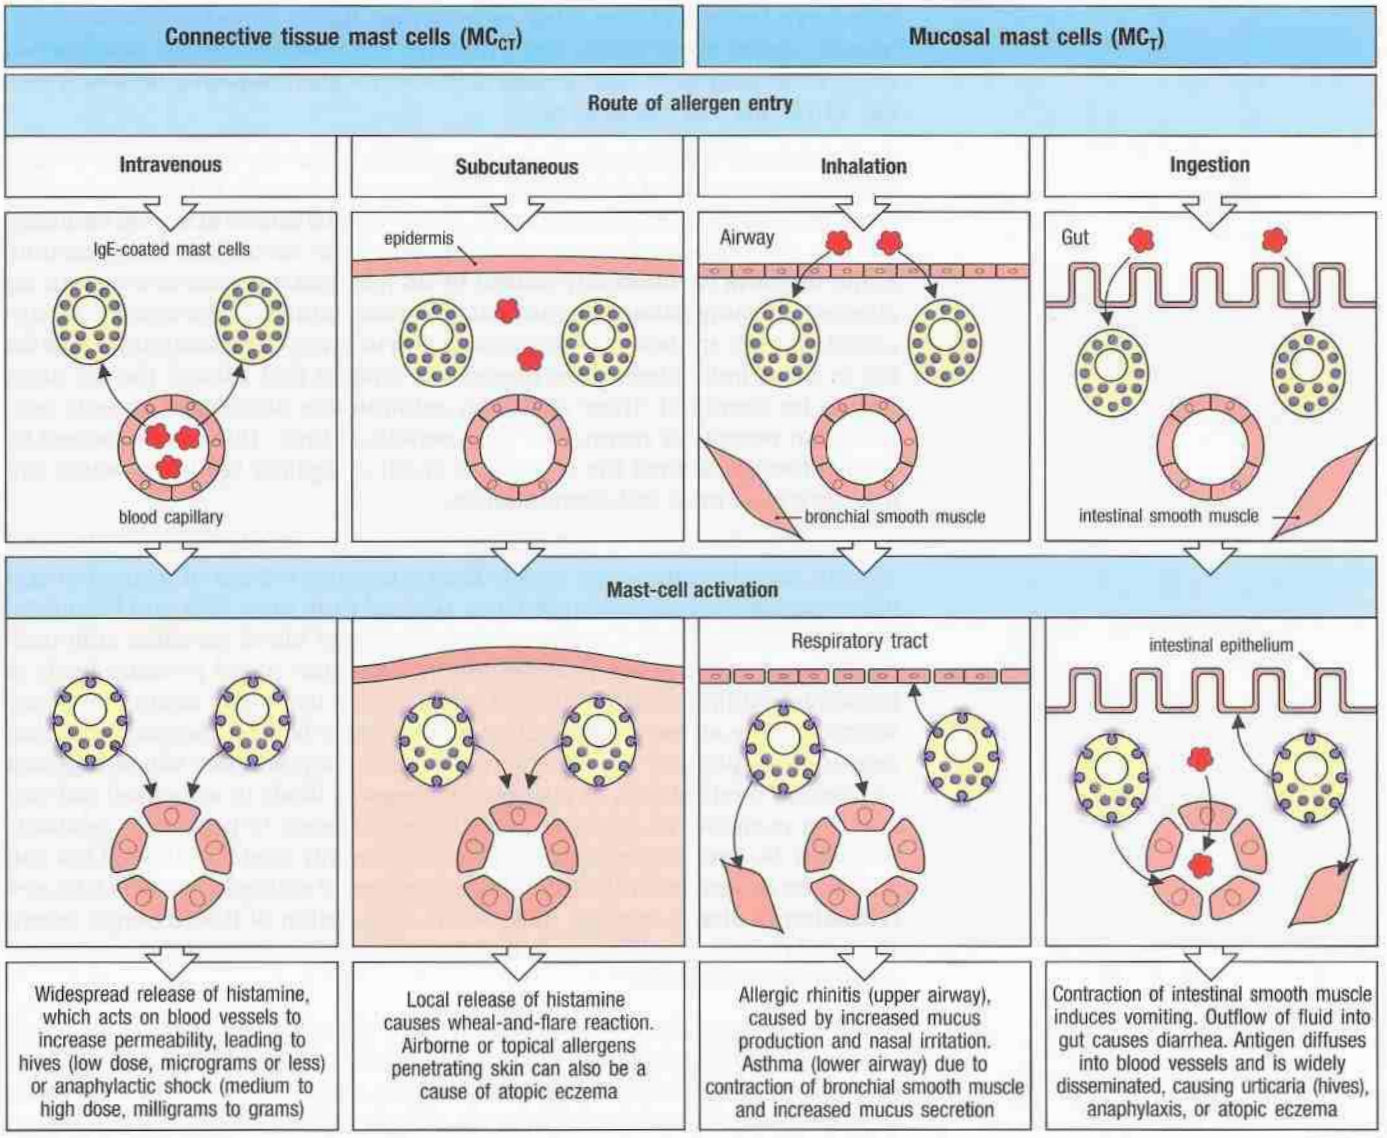
resulting in visible edema and reddening of the skin (in a skin response) and airway narrowing as result of edema and the constriction of smooth muscle (in an airway response). In the skin, histamine acting on H_1 receptors on local blood vessels causes an immediate increase in vascular permeability, which leads to extravasation of fluid and edema. Histamine also acts on H_1 receptors on local nerve endings, leading to reflex vasodilation of cutaneous blood vessels and local reddening of the skin. The resulting skin lesion is called a **wheal-and-flare reaction** (see Fig. 14.11, right panel).

Whether or not a **late-phase reaction** occurs depends on allergen dose and on aspects of the cellular immune activation that are difficult to quantify. At doses of intradermally administered allergen that are deemed safe for skin testing of subjects with allergic asthma, for example, a late reaction occurs in about 50% of individuals who show an immediate response (see Fig. 14.11, right panel). The late reaction peaks between 3 and 9 hours after antigen challenge, and in skin tests it becomes obvious as a much increased area and degree of edema that can persist for 24 hours or longer. The late-phase reaction is caused by the continued synthesis and release of inflammatory mediators by mast cells, especially vasoactive mediators such as calcitonin gene-related peptide (CGRP) and vascular endothelial growth factor (VEGF), which cause vasodilation and vascular leakage that result in edema and the recruitment of eosinophils, basophils, monocytes, and lymphocytes. The importance of this cellular influx is shown by the ability of glucocorticoid medications to block the late-phase response through their inhibition of cell recruitment, whereas glucocorticoids do not block the immediate response. A late-phase reaction can also occur after aerosol exposure to allergen and is characterized by a second phase of airway narrowing with sustained edema and cellular infiltration into the peribronchial spaces.

In individuals with a clinical history of allergic disease, allergists use the immediate response to help assess and confirm sensitization and to determine which allergens are responsible. Minute amounts of potential allergens are introduced into the skin by a skin prick—one site for each allergen—and if the individual is sensitive to any of the allergens tested, a wheal-and-flare reaction will occur at the site within a few minutes (see Fig. 14.11, right panel). Although the reaction after the administration of such small amounts of allergen is usually very localized, there is a small risk of inducing anaphylaxis. Another standard test for allergy is to measure the circulating concentration of IgE antibody specific for a particular allergen in an ELISA (see Appendix I, Section A-4).

IgE-mediated allergic diseases can cause chronic allergic inflammation with serious long-term consequences, such as chronic asthma. In long-standing asthma, for example, the cytokines and vasoactive mediators such as CGRP and VEGF result in persistent edema and narrowing of the airways. This can also lead to **airway tissue remodeling**, which changes the bronchial tissue via smooth muscle hypertrophy (an increase in the size of the muscle cells) and hyperplasia (an increase in the number of cells), subepithelial deposition of collagen, and often goblet-cell hyperplasia.

The clinical symptoms produced by an IgE-mediated allergic reaction depend on several variables: the dose of allergen, the amount of allergen-specific IgE present, the route by which the allergen is introduced, and probably some underlying defect in barrier function in the particular tissue or organ affected. The outcomes produced by different combinations of allergen dose and route of entry are summarized in Fig. 14.12. When exposure to allergen in a sensitized individual triggers an allergic reaction, both the immediate and the chronic effects are focused at the site at which mast-cell degranulation occurs, and they involve the recruitment of many soluble and cellular components of effector pathways.



Connective tissue mast cells (MC_{CT})
Mucosal mast cells (MC_T)
Route of allergen entry
Intravenous
Subcutaneous
Inhalation
Ingestion
IgE-coated mast cells
blood capillary
epidermis
Airway
bronchial smooth muscle
Gut
intestinal smooth muscle
Mast-cell activation
Respiratory tract
intestinal epithelium
Widespread release of histamine, which acts on blood vessels to increase permeability, leading to hives (low dose, micrograms or less) or anaphylactic shock (medium to high dose, milligrams to grams)
Local release of histamine causes wheal-and-flare reaction. Airborne or topical allergens penetrating skin can also be a cause of atopic eczema
Allergic rhinitis (upper airway), caused by increased mucus production and nasal irritation. Asthma (lower airway) due to contraction of bronchial smooth muscle and increased mucus secretion
Contraction of intestinal smooth muscle induces vomiting. Outflow of fluid into gut causes diarrhea. Antigen diffuses into blood vessels and is widely disseminated, causing urticaria (hives), anaphylaxis, or atopic eczema

Fig. 14.12 The route of administration of allergen determines the type of IgE-mediated allergic reaction that results. There are two main anatomic distributions of mast cells: those associated with vascularized connective tissues and called connective tissue mast cells (MC_{CT}) and those found in submucosal layers of the gut and respiratory tract and called mucosal mast cells (MC_T). In an allergic individual, all of these mast cells are coated through their cell-surface Fcε receptors with IgE directed against specific allergens. The response to an allergen then depends on which mast cells are activated. Allergen in the bloodstream (intravenous) activates connective tissue mast cells throughout the body, resulting in the systemic release of histamine and other mediators. Entry of allergen through the skin activates local connective tissue mast cells, leading to a local inflammatory reaction. After an experimental skin prick with allergen or a bite from an insect to which the individual is sensitized, this manifests as a wheal-and-flare reaction. In atopic individuals, airborne or topically applied allergens that penetrate the skin may lead to atopic eczema. Inhaled allergen that penetrates respiratory mucosal epithelia activates mainly mucosal mast cells, causing increased secretion of mucus by the mucosal epithelium and irritation in the nasal mucosa, leading to allergic rhinitis—or to asthma if constriction of smooth muscle in the lower airways occurs. Ingested allergen penetrates the gut epithelium, causing vomiting due to intestinal smooth muscle contraction and diarrhea due to outflow of fluid across the gut epithelium. Food allergens can also be disseminated in the bloodstream, causing widespread urticaria (hives) when the allergen reaches the skin, or they may cause eczema.

14-9 Allergen introduced into the bloodstream can cause anaphylaxis and urticaria.

If allergen is introduced directly into the bloodstream, for example, by a bee or wasp sting, or is rapidly absorbed into the bloodstream from the gut in a sensitized individual, connective tissue mast cells associated with blood vessels throughout the body can become immediately activated, resulting in a

widespread release of histamine and other mediators that causes the systemic reaction called anaphylaxis. The symptoms of a systemic allergic reaction can range in severity from mild **urticaria** (hives) to fatal **anaphylactic shock** (see Fig. 14.12, first and fourth panels).

Acute urticaria is a response to foreign allergens that are delivered to the skin via the systemic blood circulation. Activation of mast cells in the skin by allergen causes them to release histamine, which in turn causes itchy, red swellings all over the body—a disseminated version of the wheal-and-flare reaction. Acute urticaria is commonly caused by an IgE-mediated reaction against an allergen. In some patients, treatment with omalizumab (a therapeutic monoclonal anti-IgE antibody) leads to resolution of hives, demonstrating a role for IgE in these individuals, even though the antigen that elicited the IgE often cannot be identified. There is also an autoimmune disorder of chronic urticaria that persists or recurs over long periods of time. This can be caused by autoantibodies against the α chain of FcεRI or against IgE itself, which can directly trigger mast-cell degranulation.

In anaphylactic shock, a widespread increase in vascular permeability and smooth muscle contraction results from a massive release of histamine and other mediators, such as leukotrienes, derived from mast cells and basophils. The consequences are a catastrophic reduction of blood pressure, culminating in hypotensive shock (a condition in which low blood pressure leads to inadequate supply of blood to vital organs, often leading to death), and constriction of the airways, culminating in respiratory failure. The most common causes of anaphylaxis are allergic reactions to wasp and bee stings, ingested or injected medications, or allergic responses to foods in sensitized individuals. For example, anaphylaxis in individuals allergic to peanuts is relatively common. Severe anaphylactic shock can be rapidly fatal if untreated but can usually be controlled by the immediate injection of epinephrine, which causes relaxation of airway smooth muscles via stimulation of β-adrenergic receptors, and reverses the life-threatening cardiovascular effects via stimulation of α-adrenergic receptors.

Systemic allergic reactions can occur after repeated treatment with many classes of drugs, notably penicillin and related drugs. Allergic reaction to penicillin by injection can cause anaphylaxis and even result in death, while administration of oral penicillin to an allergic individual can cause anaphylaxis, but the reaction is usually less severe than that caused by injection. One of the reasons that penicillin is particularly prone to inducing allergic reactions is that it acts as a hapten (see Appendix I, Section A-1); it is a small molecule with a highly reactive β-lactam ring that is crucial for its antibacterial activity. This ring reacts with amino groups on host proteins to form covalent conjugates. Thus, when administered, penicillin can form conjugates with self proteins; it can be recognized as foreign by T cells by modifying self peptides and by B cells as a hapten. Most people treated with intravenous penicillin develop IgG antibodies against the drug, but these usually cause no symptoms. But in some individuals, IgE antibody is produced against the penicillin hapten. When penicillin is injected intravenously into these individuals, penicillin-modified proteins can cross-link IgE molecules on tissue mast cells and circulating basophils and cause anaphylaxis. Great care should be taken to avoid giving a drug to patients with a past history of allergy to that drug or to a close structural relative.

As is true for individuals with sensitivity to inhalant allergens, patients with a past history of anaphylactic-type reactions to penicillin or other β-lactam antibiotics can be evaluated by skin-prick testing. A positive skin test, which can occur when the antigen is delivered subcutaneously (see Fig. 14.12, second panel), is manifested by the formation of a wheal-and-flare reaction at the site of the test and can be associated with a substantial risk of developing an anaphylactic reaction during treatment with therapeutic doses of the drug.

14-10 Allergen inhalation is associated with the development of rhinitis and asthma.

The respiratory tract is an important route of allergen entry (see Fig. 14.12, third panels). Many atopic people react to airborne allergens with an IgE-mediated allergic reaction known as **allergic rhinitis**. This results from the activation of mucosal mast cells beneath the nasal epithelium caused by allergens that have diffused across the mucous membranes of the nasal passages. Allergic rhinitis is characterized by intense itching and sneezing; local edema leading to blocked nasal passages; a nasal discharge, which is typically rich in eosinophils; and irritation of the nasal mucosa as a result of histamine release. A similar reaction to airborne allergens deposited on the conjunctiva of the eye is called **allergic conjunctivitis**. Allergic rhinitis and conjunctivitis are commonly caused by environmental allergens that are present only during certain seasons of the year. For example, hay fever (known clinically as **seasonal allergic rhinoconjunctivitis**) is caused by a variety of allergens, including certain grass and tree pollens. Symptoms in the late summer or autumn are commonly caused by weed pollen, such as that of ragweed, or the spores of fungi such as *Alternaria*. Ubiquitous allergens such as Fel d 1 in cat dander, Der p 1 in the feces of house dust mites, and Bla g 1 in cockroaches can be a cause of year-round, or perennial, allergic rhinoconjunctivitis.

A more serious IgE-mediated respiratory disease is **allergic asthma**, which is triggered by allergen-induced activation of submucosal mast cells in the lower airways. This can lead within seconds to bronchial constriction and an increased secretion of fluid and mucus into the airways, making breathing more difficult by trapping inhaled air in the lungs. People with allergic asthma usually need treatment, and severe asthmatic attacks can be life threatening. The same allergens that cause allergic rhinitis and conjunctivitis commonly cause asthma attacks. For example, respiratory arrest caused by severe attacks of asthma in the summer or autumn has been associated with the inhalation of *Alternaria* spores.

Chronic allergen exposure leads to an important feature of asthma; namely, chronic inflammation of the airways, which is characterized by the continued presence of increased numbers of pathologic lymphocytes, eosinophils, neutrophils, basophils, and other leukocytes (Fig. 14.13). The concerted actions of these cells cause airway hyperreactivity and remodeling—a thickening of the airway walls due to hyperplasia and hypertrophy of the smooth muscle layer, with the eventual development of fibrosis. Fibrotic remodeling leads to a permanent narrowing of the airways and is responsible for many of the clinical manifestations of chronic allergic asthma. In chronic asthmatics, a general hyperreactivity of the airways to non-immunological stimuli such as perfumes or volatile irritants also often develops.

A rare but dramatic manifestation of chronic allergic inflammation is the formation of **Charcot–Leyden crystals** (CLCs) in inflamed tissues such as nasal passages (Fig. 14.14). CLCs form from crystallization of a highly abundant protein, galectin-10, which is produced by eosinophils and which presumably accumulates in tissues over time from the death of eosinophils in chronically inflamed tissues. Importantly, the crystalline form of galectin-10 is itself inherently inflammatory, possibly due to the direct activation of the NLRP3 inflammasome (see Section 3-11). This effect acts in a positive feedback loop that helps to perpetuate the chronically inflamed allergic state. Recently, a novel therapeutic approach was described in which monoclonal antibodies that recognize monomeric galectin-10 are able to dissolve CLCs and may be useful in reversing chronic allergic inflammation.

Individuals with asthma can vary greatly in their responsiveness to therapies, in the nature of their airway inflammatory cell infiltrates, and in inflammatory mediators present in the airways. Different patterns of asthma have been

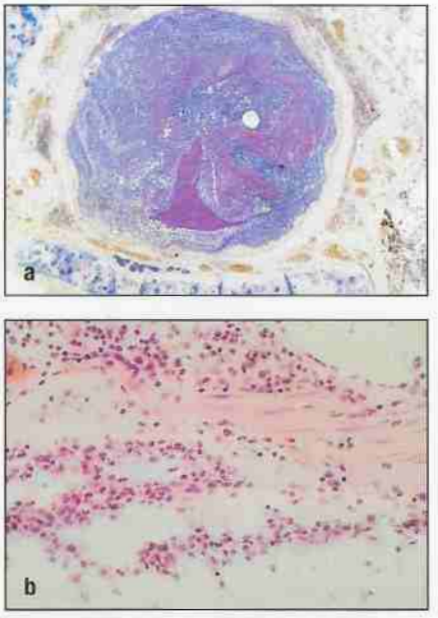


Fig. 14.13 Histologic evidence of chronic inflammation in the airways of an asthmatic individual. Panel a shows a section through a bronchus of an individual who died of asthma; there is almost total occlusion of the airway by a mucus plug, seen as the circular bluish area in the airway. In panel b, a close-up view of the bronchial wall shows injury to the epithelium lining the bronchus, accompanied by a dense inflammatory infiltrate, evident from the dense areas with numerous dark nuclei of various granulocytes. Although not discernible at this magnification, the infiltrate includes eosinophils, neutrophils, and lymphocytes.

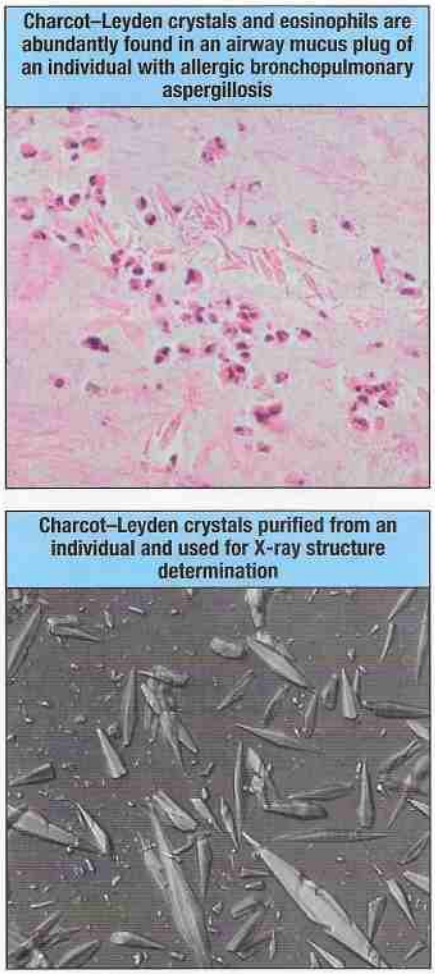
Allergic Asthma



Charcot–Leyden crystals and eosinophils are abundantly found in an airway mucus plug of an individual with allergic bronchopulmonary aspergillosis
Charcot–Leyden crystals purified from an individual and used for X-ray structure determination

Fig. 14.14 Charcot-Leyden crystals of galectin-10 made by eosinophils contribute to chronic allergic inflammation. Top panel: Severe allergic rhinitis is characterized by eosinophils and in some cases by crystals formed from the abundant protein galectin-10 produced by eosinophils, as visible in this tissue section stained with hematoxylin and eosin. These crystals become an irritant that helps to perpetuate chronic rhinitis, likely through activation of the NLRP3 inflammasome. Bottom panel: Crystals of galectin-10 were purified directly from individuals and used to determine their molecular structure. Monoclonal antibodies that bind to galectin-10 and block crystal formation can be used to dissolve crystals and may be useful in treating this condition.

called asthma 'endotypes.' Because different endotypes may result from different underlying disorders, it may be beneficial to consider an individual's endotype when selecting a therapy. The most common endotype is allergic asthma, but other endotypes include exercise-induced asthma, neutrophil-predominant (as opposed to eosinophil-predominant) asthma, and steroid-resistant severe asthma. The fundamental driver in allergic asthma is thought to be pathologically activated T_H2 cells, and eosinophils and basophils are prominent in the inflammatory infiltrates in the lungs. In severe, steroid-resistant asthma, T_H17 cells appear to play a larger role, and neutrophils are prominent in the inflammatory infiltrates. T_H17 cells also appear to be major inducers of the asthmatic syndrome allergic bronchopulmonary aspergillosis (ABPA).

In allergic asthma, allergens cause activation of mast cells leading to mast-cell mediator release and may also stimulate the airway epithelium directly through TLRs and other damage receptors to release IL-25 and IL-33, which activate submucosal ILC2 cells, which in turn release IL-4, IL-5, IL-9, and IL-13. Bronchial epithelial cells can produce the chemokines CCL5 and CCL11, which bind to CCR3 expressed on T_H2 cells, eosinophils, and basophils, further enhancing the response. Airway remodeling is induced in part by the production of TGF-β. A major feature of chronic allergic asthma is goblet-cell metaplasia, which is the differentiation of epithelial cells into goblet cells, and a consequent increase in mucus secretion, which occurs in response to T_H2-derived cytokines such as IL-9 and IL-13.

A disease resembling human asthma develops in mice deficient in Tbet, a transcription factor that is required for T_H1 differentiation (see Section 9-15). These mice have T-cell responses that are skewed toward the T_H2 phenotype and develop airway inflammation involving lymphocytes and eosinophils (Fig. 14.15). They also develop nonspecific airway hyperreactivity to non-immunological stimuli, similar to what is seen in human asthma. These changes occur in the absence of any exogenous inflammatory stimulus and show that, in extreme circumstances, a genetic imbalance toward T_H2 responses can cause allergic disease.

Chronic inflammation in asthma seems to be perpetuated even in the apparent absence of ongoing exposure to the inciting allergen. The airways become characteristically hyperreactive, and factors other than antigen can trigger asthma attacks. Asthmatics characteristically show hyperresponsiveness to environmental chemical irritants such as cigarette smoke and sulfur dioxide. Viral agents, especially rhinovirus, or, to a lesser extent, bacterial respiratory tract infections can also exacerbate the disease. Both irritant agents and the infectious agents can induce IL-25 and IL-33 release from airway epithelial cells, leading to activation of ILC2 cells and exacerbation of the chronic asthmatic inflammation. The significance of viral augmentation of the asthmatic response is evident from the fact that rhinovirus infection is one of the main causes of hospitalizations for asthma and is associated with the majority of deaths from asthma.

14-11 Allergy to particular foods causes systemic reactions as well as symptoms limited to the gut.

Adverse reactions to particular foods are common, but only some are due to an immune reaction. 'Food allergy' can be classified into IgE-mediated allergic reactions, non-IgE-mediated food allergy (celiac disease, discussed in Section 14-16), idiosyncrasies, and food intolerance. Idiosyncrasies are abnormal responses to particular foods whose cause is unknown but which can provoke symptoms resembling those of an allergic response. Food intolerances are non-immune adverse reactions due mainly to metabolic deficits, such as intolerance of cow's milk due to the inability to digest lactose.

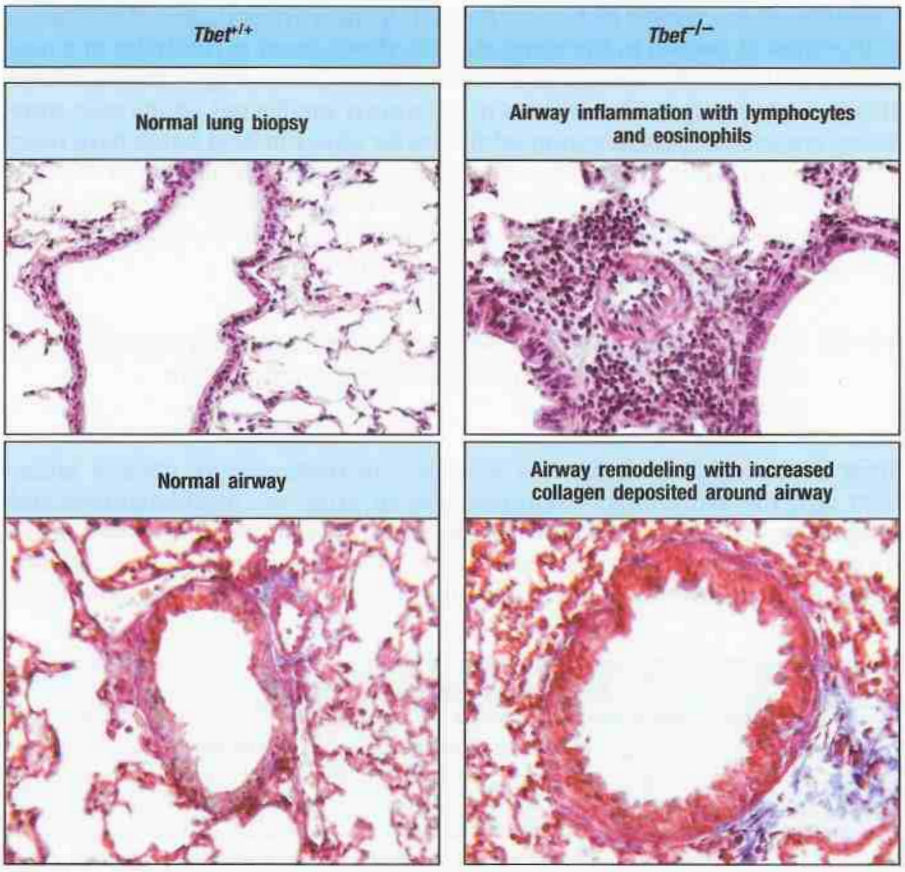


Fig. 14.15 Mice lacking the transcription factor Tbet develop allergic airway inflammation and T-cell responses polarized toward T_H2. Tbet binds to the promoter of the gene encoding IL-2 and is present in T_H1 but not T_H2 cells. Mice with a gene-targeted deletion of Tbet (*Tbet*$^{-/-}$) manifest impaired T_H1 responses and show spontaneous differentiation of T_H2 cells and development of an asthma-like phenotype in the lungs. Left panels: Lung and airways in normal mice. Right panels: Tbet-deficient mice show lung inflammation, with lymphocytes and eosinophils around the airway and blood vessels (top) and airway remodeling with increased collagen around the airway (bottom).

IgE-mediated food allergies affect about 1–4% of American and European adults and are slightly more frequent in children (around 5%). About 25% of food allergy in children is due to peanuts, and peanut allergy is increasing in incidence. Figure 14.16 lists risk factors for developing IgE-mediated food allergy. IgE-mediated food allergy can manifest itself in a variety of ways, ranging from a swelling of the lips and oral tissue on contact with the allergen to gastrointestinal cramping, diarrhea, or vomiting. Local gastrointestinal symptoms are due to activation of mucosal mast cells, leading to transepithelial fluid loss and smooth muscle contractions. Food allergens that subsequently reach the bloodstream can lead to urticaria, asthma, and, in the most severe cases, systemic anaphylaxis that can lead to cardiovascular collapse (see Section 14-9).

Certain foods, most importantly peanuts, tree nuts, and shellfish, are particularly associated with severe anaphylaxis. Around 150 deaths occur each year in the United States as a result of a severe allergic reaction to food, with peanut and tree nut allergies accounting for most of the deaths. Peanut allergy is a significant public health problem, especially in schools, where children may be unwittingly exposed to peanuts, which are present in many foods. Recent studies offer hope for reducing the incidence of severe food allergy. In one study, infants with severe eczema who were at high risk for developing peanut allergy were randomly assigned either to be fed peanuts regularly, starting between ages 4 and 11 months, or to be on a peanut-avoidance diet for 5 years. At the age of 5, the children who had consumed peanuts showed more than a threefold reduction in the frequency of peanut allergy; the reduction was associated with decreased production of peanut-specific IgE. This suggests deliberate introduction into the diet of allergen at the appropriate time to at-risk individuals may suppress the development of food allergy.

Risk factors for the development of food allergy
Immature mucosal immune system
Early introduction of solid food
Hereditary increase in mucosal permeability
IgA deficiency or delayed IgA production
Inadequate colonization of the intestinal immune system by commensal flora
Birth by cesarean section
Genetically determined bias toward a T_H2 environment
Polymorphisms of T_H2 cytokine or IgE receptor genes
Impaired enteric nervous system
Immune alterations (e.g., low levels of TGF-β)
Gastrointestinal infections

Fig. 14.16 Risk factors for the development of food allergy.

One of the characteristic features of food allergens is a high degree of resistance to digestion by pepsin in the stomach. This allows them to reach the mucosal surface of the small intestine as intact allergens. Cases of IgE-mediated food allergies arising in small numbers of previously unaffected adults who were taking antacids or proton-pump inhibitors for ulcers or acid reflux have been proposed to be due to impaired digestion of potential allergens in the less acidic stomach conditions produced by these medications. However, the ability to undergo digestion seems to be relevant for some, but not all, food allergens and is not a basis to predict the allergenicity of a food.

14-12 IgE-mediated allergic disease can be treated by inhibiting effector pathways or by desensitization to restore biological tolerance.

Most of the existing drugs that are used to treat allergic disease either treat only the symptoms—examples of such drugs are antihistamines and β-agonists—or are general anti-inflammatory or immunosuppressive drugs such as the corticosteroids (Fig. 14.17). Treatment is largely palliative, rather than curative, and the drugs often need to be taken throughout life.

Fig. 14.17 Approaches to the treatment of allergic disease. Examples of treatments in current clinical use for allergic reactions are listed in the top half of the table, with approaches under investigation listed below. mAb, monoclonal antibody against monomeric galectin-10.

Treatments for allergic disease		
Target	**Mechanism of treatment**	**Specific approach**
In clinical use		
Mediator action	Inhibit effects of mediators on specific receptors Inhibit synthesis of specific mediators	Antihistamines, β-agonists Leukotriene receptor blockers Lipoxygenase inhibitors
Chronic inflammatory reactions	General anti-inflammatory effects	Corticosteroids
T_H2 response	Induction of regulatory T cells	Desensitization therapy by injections of specific antigen
IgE binding to mast cell	Bind to IgE Fc region and prevent IgE binding to Fc receptors on mast cells	Anti-IgE antibodies (omalizumab)
Proposed or under investigation		
T_H2 activation	Induction of regulatory T cells	Injection of specific antigen peptides Administration of cytokines, e.g., IFN-γ, IL-10, IL-12, TGF-β Use of adjuvants such as CpG oligodeoxynucleotides to stimulate T_H1 response
Activation of B cell to produce IgE	Block co-stimulation Inhibit T_H2 cytokines	Inhibit CD40L Inhibit IL-4 or IL-13
Mast-cell activation	Inhibit effects of IgE binding to mast cell	Blockade of IgE receptor
Eosinophil-dependent inflammation	Block cytokine and chemokine receptors that mediate eosinophil recruitment and activation	Inhibit IL-5 Block CCR3
Charcot–Leyden crystals	Dissolution of crystal by mAb	Antibody to galectin-10

Anaphylactic reactions are treated with epinephrine, which stimulates the re-formation of endothelial tight junctions, promotes the relaxation of constricted bronchial smooth muscle, and stimulates the heart. Antihistamines that block the action of histamine at the H_1 receptor reduce symptoms in allergic rhinoconjunctivitis and IgE-triggered urticaria. In urticaria, for example, the relevant H_1 receptors include those on blood vessels and unmyelinated nerve fibers in the skin. Anticholinergic drugs, such as atropine, bronchodilate constricted airways and reduce respiratory secretions. Antileukotriene drugs act as antagonists of leukotriene receptors on smooth muscle, endothelial cells, and mucous-gland cells, and are also used to relieve the symptoms of allergic rhinoconjunctivitis and asthma. Inhaled bronchodilators that act on β-adrenergic receptors to relax constricted muscle relieve acute asthma attacks. In chronic allergic disease it is extremely important to treat and prevent the chronic inflammatory injury to tissues, and regular use of inhaled corticosteroids is recommended in persistent asthma to help suppress inflammation. Topical corticosteroids are used to suppress the chronic inflammatory changes seen in eczema.

Another type of allergy-suppressive therapy is the blockade of IgE function by using monoclonal anti-IgE antibodies. An example of this is omalizumab, which binds the Fc portion of IgE at the same site that binds FcεRI on basophils and mast cells. The portion of the Fc domain of IgE that binds to the low-affinity IgE receptor (FcεRII) that is expressed on a variety of leukocytes other than basophils and mast cells is different from the domain that binds the high-affinity FcεRI. Omalizumab blocks binding of IgE to the low-affinity receptor as well as to FcεRI. Prevention of binding of IgE to its receptors on basophils results in down-regulation of these receptors on these cells, making them less easily activated by exposure to allergens. The antibody is administered by subcutaneous injection once every 2–4 weeks and is highly effective for individuals with chronic urticaria and also appears to be effective in individuals with severe chronic asthma. Of special interest is that in studies of children with moderate to severe asthma who were treated for 4 years with omalizumab, most remained symptom free without any anti-asthma treatment, suggesting that the anti-IgE therapy modified the natural history of the disease.

Another, more routinely used approach that aims to permanently eliminate the allergic response is **allergen desensitization**. This form of immunotherapy aims to restore the patient's ability to tolerate exposure to the allergen. Patients are desensitized by injection with escalating doses of allergen, starting with tiny amounts. The mechanism by which desensitization occurs is not definitively established, but for most successfully desensitized patients, the procedure results in a change in the antibody response from one dominated by IgE to one dominated by an IgG. The exact mechanisms for this immunoregulatory effect are still obscure but may involve the induction of T_{reg} cells. Nonetheless, the procedure is associated with a reduction in the numbers of inflammatory cells at the site of the allergic reaction. Despite the extremely small doses of allergen used for desensitization, some patients can experience an IgE-mediated allergic response, including bronchospasms, and many physicians believe that this procedure is contraindicated in individuals with severe asthma. For patients who experience resolution of their allergy symptoms during allergen immunotherapy, weekly or every-other-week injections are continued for 3 years, and then the therapy is discontinued. In approximately half of patients treated in this fashion, symptoms do not recur after cessation of the injections.

When a patient is allergic to a drug that is essential for treatment of a disease (such as an antibiotic, insulin, or a chemotherapeutic agent), it is often possible to achieve a state of temporary **acute desensitization** by treating the patient with progressively increasing doses of the drug, starting at a very low

dose that causes no allergic symptoms and increasing the dose every half hour until the therapeutic dose is reached. It is common for patients undergoing drug desensitization to manifest mild to moderate allergic symptoms (itching, urticaria, mild wheezing) at some time during the procedure. If this occurs, the physician reduces the dose to the previous tolerated dose and then advances the dose again. This procedure is thought to lead to subclinical activation of mast cells and basophils that have been sensitized with IgE against the drug, inducing them to gradually release their intracellular mediators at a rate that does not cause severe symptoms; eventually, all of the cell-bound IgE is consumed by this process, leaving insufficient IgE available to cause an allergic reaction when subsequent therapeutic doses are administered. In order to maintain the desensitized state, the patient must receive daily therapeutic doses of the drug. If treatment is interrupted, then newly formed mast cells and basophils can be charged with newly secreted drug-specific IgE and can accumulate at levels sufficient to yield a new anaphylactic reaction.

A further approach to the treatment of allergic disease may be to block the recruitment of eosinophils to sites of allergic inflammation. The eotaxin receptor CCR3 is a potential target in this context. In experimental animals, the production of eosinophils in bone marrow and their exit into the circulation is reduced by blocking IL-5 action. Anti-IL-5 antibody (mepolizumab) is beneficial in treating patients who have **hypereosinophilic syndrome**, in which chronic overproduction of eosinophils causes severe organ damage. Clinical trials of anti-IL-5 treatment of asthma, however, show that, in practice, any beneficial effect is likely to be limited to a small subset of asthma patients who have prednisone-dependent eosinophilic asthma; in these patients, IL-5 blockade seems to reduce the number of asthma attacks when the corticosteroid dose is reduced.

Summary.

The allergic response to innocuous antigens reflects the pathophysiological aspects of a defensive immune response whose physiological role is to protect against helminth parasites. It is triggered by the binding of antigen to IgE antibodies that are bound to the high-affinity IgE receptor FcεRI on mast cells and basophils. Mast cells are strategically distributed beneath the mucosal surfaces of the body and in connective tissue. Antigen cross-linking the IgE on the surface of mast cells causes them to release large amounts of inflammatory mediators. The resulting inflammation can be divided into early events that are characterized by short-lived mediators, such as histamine, and later events that involve leukotrienes, cytokines, and chemokines, which recruit and activate eosinophils, basophils, and other leukocytes. This response can evolve into chronic inflammation, which is characterized by the presence of effector T cells and eosinophils and is most clearly seen in chronic allergic asthma.

Non-IgE-mediated allergic diseases.

In this part of the chapter we focus on immunological hypersensitivity responses involving IgG antibodies and type 1 or type 3 immune responses that involve antigen-specific T_H1 or T_H17 cells or CD8 T cells. These effector arms of the immune response occasionally react with noninfectious antigens to produce acute or chronic allergic reactions. Although the mechanisms initiating the various forms of hypersensitivity are different, much of the pathology is due to the same immunological effector mechanisms.

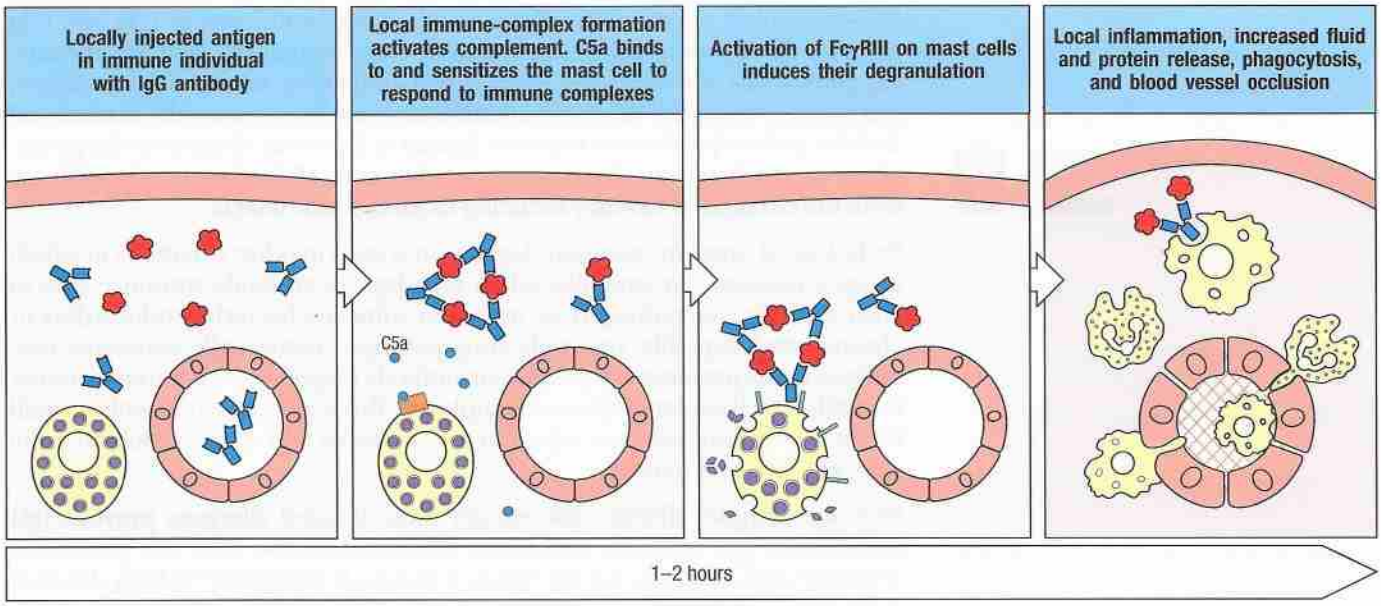
14-13 Non-IgE-dependent drug-induced hypersensitivity reactions in susceptible individuals occur by binding of the drug to the surface of circulating blood cells.

Antibody-mediated destruction of red blood cells (hemolytic anemia) or platelets (thrombocytopenia) can be caused by some drugs, including the β-lactam antibiotics penicillin and cephalosporin. Drug-induced hemolytic anemia (DIHA) is a very rare condition and in the Gell and Coombs classification is a type II hypersensitivity reaction, typically mediated by IgG or IgM and complement. In these reactions, the drug binds covalently to the cell surface and is a target for anti-drug antibodies that cause destruction of the cell. The anti-drug antibodies are made in only a minority of people, and it is not clear why these individuals make them. The cell-bound antibody triggers the clearance of the cell from the circulation, predominantly by tissue macrophages in the spleen, which bear Fcγ receptors.

14-14 Systemic disease caused by immune-complex formation can follow the administration of large quantities of poorly catabolized antigens.

Hypersensitivity reactions can arise after treatment with soluble antigens such as animal antisera. The pathology is caused by the deposition of antigen:antibody aggregates, or **immune complexes**, in particular tissues and sites. Immune complexes are generated in all antibody responses, but their pathogenic potential is determined, in part, by their size and by the amount, affinity, and isotype of the responding antibody. Larger aggregates fix complement and are readily cleared from the circulation by the mononuclear phagocyte system. However, the small complexes that form when antigen is in excess tend to be deposited in blood vessel walls. There they can ligate Fc receptors on leukocytes, leading to leukocyte activation and tissue injury.

A local hypersensitivity reaction called an **Arthus reaction** (Fig. 14.18) can be triggered in the skin of sensitized individuals who possess IgG antibodies



Locally injected antigen in immune individual with IgG antibody
Local immune-complex formation activates complement. C5a binds to and sensitizes the mast cell to respond to immune complexes
Activation of FcγRIII on mast cells induces their degranulation
Local inflammation, increased fluid and protein release, phagocytosis, and blood vessel occlusion
C5a
1–2 hours

Fig. 14.18 The deposition of immune complexes in tissues causes a local inflammatory response known as an Arthus reaction. In individuals who have already made IgG antibody against an antigen, the same antigen injected into the skin forms immune complexes with IgG antibody that has diffused out of the capillaries. Because the dose of antigen is low, the immune complexes are formed only close to the site of injection, where they activate mast cells bearing Fcγ receptors (FcγRIII). The immune complex induces activation of complement, and the complement component C5a contributes to sensitizing the mast cell to respond to immune complexes. As a result of mast-cell activation, inflammatory cells invade the site, and blood vessel permeability and blood flow are increased. Platelets also accumulate inside the vessel at the site, ultimately leading to vessel occlusion. If the reaction is severe, all these changes can lead to tissue necrosis.

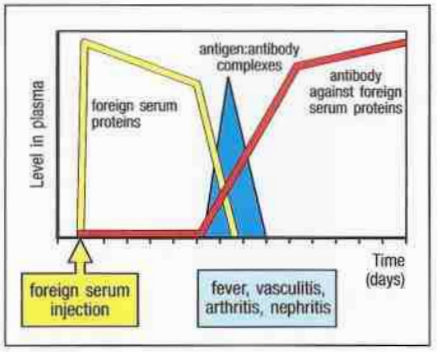


Fig. 14.19 Serum sickness is a classic example of a transient immune complex–mediated syndrome. An injection of a foreign protein, such as horse antitoxin, leads to an anti-horse serum antibody response. These antibodies form immune complexes with the circulating foreign proteins. The complexes are deposited in small blood vessels and activate complement and phagocytes, inducing fever and inflammatory lesions in blood vessels in the skin and connective tissues (vasculitis), in the kidney (nephritis), and in joints (arthritis). All these effects are transient and resolve when the foreign protein is cleared.

against the sensitizing antigen. When antigen is injected into the skin, circulating IgG antibody that has diffused into the skin forms immune complexes with the antigen locally and so in the Gell and Coombs classification is a type III hypersensitivity reaction. The immune complexes bind Fc receptors such as FcγRIII on mast cells and other leukocytes, generating a local inflammatory response and increased vascular permeability. Fluid and cells, especially neutrophils, enter from local blood vessels. The immune complexes also activate complement, generating complement fragment C5a, which activates C5a receptors on leukocytes to recruit them to the site of inflammation (see Section 2-13).

A systemic type III hypersensitivity reaction known as **serum sickness** can result from the injection of large quantities of a poorly catabolized foreign antigen. This illness was so named because it frequently followed the administration of therapeutic horse antiserum. In the pre-antibiotic era, antiserum made by immunizing horses with *Streptococcus pneumoniae* was used to treat pneumococcal pneumonia; the specific anti-pneumococcal antibodies in the horse serum would help the patient to clear the infection. In much the same way, **antivenin** (serum from sheep or horses immunized with snake venoms) is still used today as a source of neutralizing antibodies to treat people suffering from the bites of poisonous snakes.

Serum sickness occurs 7–10 days after the injection of horse serum, an interval that corresponds to the time required to produce an IgG-switched primary immune response against the foreign horse serum antigens (Fig. 14.19). The onset of disease occurs when these antibodies form immune complexes with their antigens, activate complement, and bind Fc receptors on leukocytes throughout the body, which in turn cause tissue damage. The clinical features of serum sickness are chills, fever, rash, arthritis, and sometimes glomerulonephritis (inflammation of the glomeruli of the kidneys). Formation of immune complexes causes clearance of the foreign antigen, so serum sickness is usually a self-limiting disease. Urticaria is a prominent feature of the rash, implying a role for histamine derived from mast-cell degranulation. In this case, the mast-cell degranulation is triggered by the ligation of cell-surface FcγRIII by IgG-containing immune complexes and by the anaphylatoxins C3a and C5a released due to complement activation by these complexes. With the increasing clinical use of humanized monoclonal antibodies, serum sickness is rare, but it can occur if the monoclonal antibody was not successfully humanized and the patient produces a reaction against it. However, symptoms are generally mild, resulting mainly in more rapid clearance of the therapeutic antibody from the circulation, thereby reducing its therapeutic effects.

Drug-Induced Serum Sickness

Pathological immune-complex deposition is seen in other situations in which antigen persists. For example, when an adaptive antibody response fails to clear the infecting pathogen, as occurs in subacute bacterial endocarditis or chronic viral hepatitis, the replicating pathogen continually generates new antigen in the presence of a persistent antibody response, with the consequent formation of abundant immune complexes. These are deposited within small blood vessels and result in injury in many tissues and organs, including the skin, kidneys, and nerves.

Immune-complex disease also occurs when inhaled allergens provoke IgG rather than IgE antibody responses, perhaps because they are present at relatively high levels in the air. When a person is reexposed to high doses of such allergens, immune complexes form in the walls of alveoli in the lungs. This leads to the accumulation of fluid, protein, and cells in the alveolar wall, slowing blood–air exchange of O_2 and CO_2 and compromising lung function. This type of reaction is more likely to occur in occupations such as farming, in which there is repeated exposure to hay dust or mold spores, and the resulting disease is known as **farmer's lung**. If exposure to antigen is sustained, the lining of the lungs can be permanently damaged.

14-15 Hypersensitivity reactions can be mediated by T_H1 cells and cytotoxic CD8 T cells.

Here we consider the hypersensitivity diseases caused by T_H1 and cytotoxic CD8 T cells (Fig. 14.20). Unlike the immediate hypersensitivity reactions, which are mediated by antibodies, **cellular hypersensitivity reactions** such as **delayed-type hypersensitivity (DTH)** reactions are mediated by antigen-specific effector T cells; in the Gell and Coombs classification, these are type IV hypersensitivity reactions. These cells function in hypersensitivity in essentially the same way as when they respond to a pathogen, and the responses can be transferred between experimental animals by purified T cells or cloned T-cell lines.

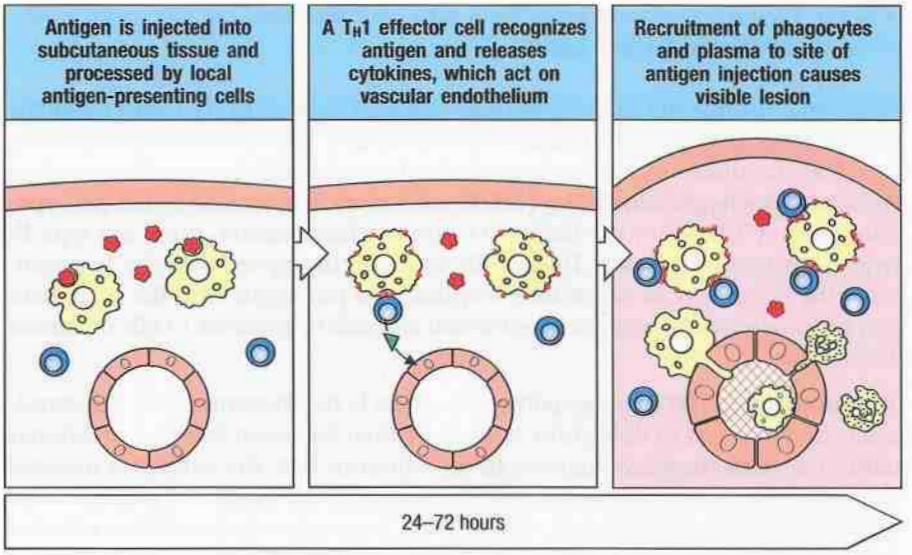
The prototypic DTH hypersensitivity reaction is the **Mantoux test**, the standard tuberculin test to determine if an individual has been infected previously with *Mycobacterium tuberculosis*. In the Mantoux test, the subject is injected intradermally with small amounts of tuberculin, an extract of peptides and carbohydrates derived from *M. tuberculosis*. In people who have been infected by the *M. tuberculosis* bacterium or immunized with BCG (bacillus Calmette-Guérin, a live-attenuated vaccine form of *Mycobacterium bovis*), a local T cell–mediated inflammatory reaction evolves over 24–72 hours. The response is caused by T_H1 cells, which enter the site of antigen injection, recognize complexes of peptide:MHC class II molecules on antigen-presenting cells, and release inflammatory cytokines such as IFN-γ, TNF-α, and lymphotoxin (LT). These cytokines stimulate the expression of adhesion molecules on endothelium and increase local blood vessel permeability, allowing plasma and accessory cells to enter the site, thus causing a visible swelling (Fig. 14.21). Each of these phases takes several hours and so the fully developed response only appears 24–72 hours after challenge. The cytokines produced by the activated T_H1 cells and their actions are shown in Fig. 14.22.

ANIMATION 14.1

Very similar reactions are observed in **allergic contact dermatitis** (also called contact hypersensitivity), which is an immune-mediated local inflammatory

Cellular hypersensitivity reactions are mediated by antigen-specific effector T cells		
Syndrome	**Antigen**	**Consequence**
Delayed-type hypersensitivity	Proteins: Insect venom Mycobacterial proteins (tuberculin, lepromin)	Local skin swelling: Erythema Induration Cellular infiltrate Dermatitis
Contact hypersensitivity	Haptens: Pentadecacatechol (poison ivy) DNFB Small metal ions: Nickel Chromate	Local epidermal reaction: Erythema Cellular infiltrate Vesicles Intraepidermal abscesses
Gluten-sensitive enteropathy (celiac disease)	α-Gliadin	Villous atrophy in small bowel Malabsorption

Fig. 14.20 Cellular hypersensitivity reactions. These responses are mediated by T cells and require 3–5 days or more to develop. They can be grouped into three syndromes, according to the route by which antigen passes into the body. In delayed-type hypersensitivity the antigen is injected into the skin; in contact hypersensitivity it is absorbed into the skin; and in gluten-sensitive enteropathy it is absorbed by the gut. In contact hypersensitivity, vesicles commonly form. They represent accumulations of fluid in small blisterlike lesions at the level of the basement membrane between the dermis and epidermis. Their formation at this location is probably the result of antigen penetrating the epidermis, accumulating at the basement membrane, and inducing a local inflammatory response with edema fluid. DNFB (dinitrofluorobenzene) is a sensitizing agent that can cause contact hypersensitivity.

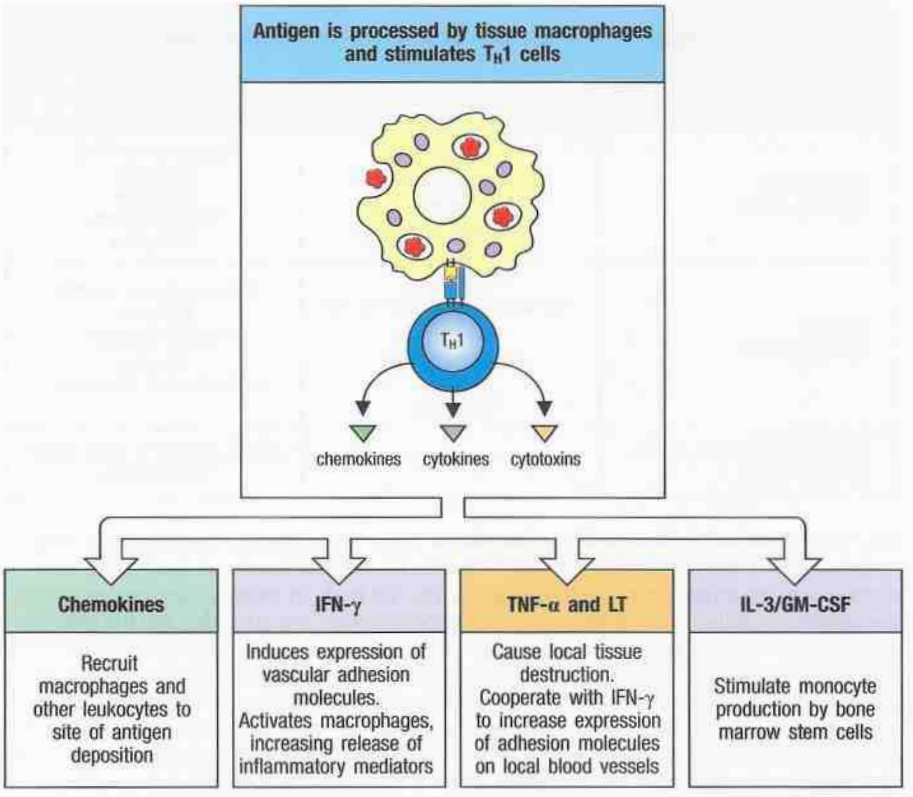


Antigen is injected into subcutaneous tissue and processed by local antigen-presenting cells
A T_H1 effector cell recognizes antigen and releases cytokines, which act on vascular endothelium
Recruitment of phagocytes and plasma to site of antigen injection causes visible lesion
24–72 hours

Fig. 14.21 The stages of a delayed-type hypersensitivity reaction. The first phase involves uptake, processing, and presentation of the antigen by local antigen-presenting cells. In the second phase, T_H1 cells that have been primed by a previous exposure to the antigen migrate into the site of injection and become activated. Because these specific cells are rare, and because there is little inflammation to attract cells into the site, it can take several hours for a T cell of the correct specificity to arrive. These cells release mediators that activate local endothelial cells, which recruit an inflammatory-cell infiltrate dominated by macrophages and cause the accumulation of fluid, serum proteins, and more leukocytes, thus producing a visible lesion.

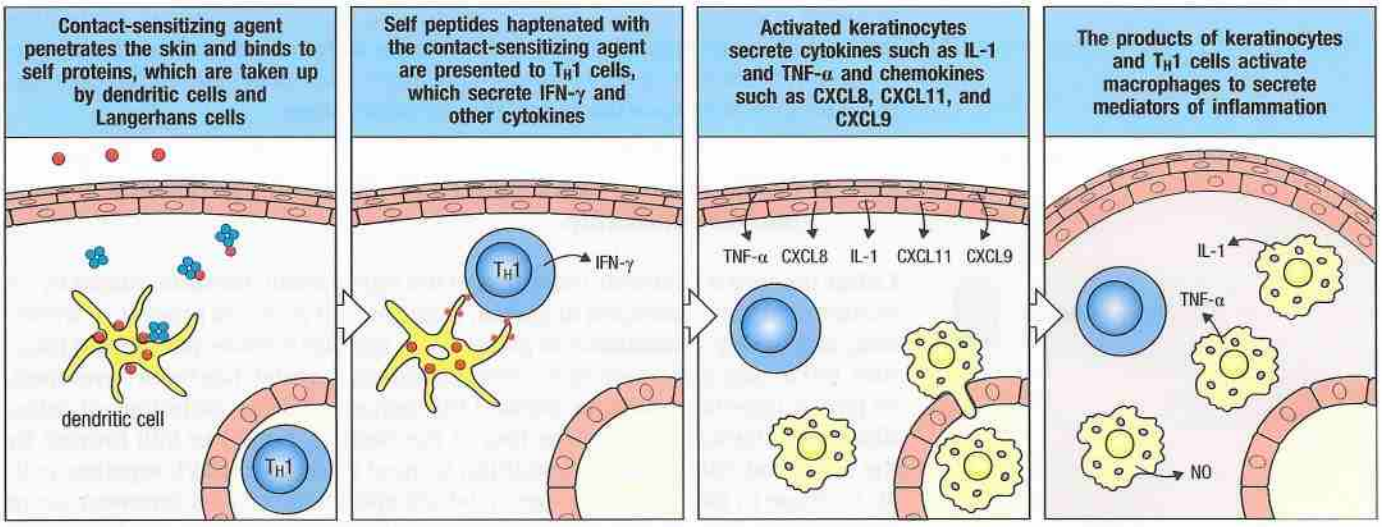
reaction in the skin caused by direct skin contact with certain antigens. Allergic contact dermatitis can be caused by the activation of CD4 or CD8 T cells, depending on the pathway by which the antigen is processed. Typically the antigens are highly reactive small molecules that penetrate intact skin, especially if they cause itching that leads to scratching and its consequent injury to the skin barrier. These chemicals then react with self proteins, creating haptenated proteins that can be processed for presentation as modified peptides bound to MHC molecules and recognized by T cells as foreign antigens.

As with other allergic responses, there are two phases to allergic contact dermatitis: sensitization and elicitation. During the sensitization phase,



Antigen is processed by tissue macrophages and stimulates T_H1 cells
T_H1
chemokines
cytokines
cytotoxins
Chemokines
Recruit macrophages and other leukocytes to site of antigen deposition
IFN-γ
Induces expression of vascular adhesion molecules. Activates macrophages, increasing release of inflammatory mediators
TNF-α and LT
Cause local tissue destruction. Cooperate with IFN-γ to increase expression of adhesion molecules on local blood vessels
IL-3/GM-CSF
Stimulate monocyte production by bone marrow stem cells

Fig. 14.22 The delayed-type hypersensitivity response is directed by chemokines and cytokines released by antigen-stimulated T_H1 cells. Antigen in the local tissues is internalized and processed by antigen-presenting cells and presented on MHC class II molecules. Antigen-specific T_H1 cells that recognize the antigen:MHC complexes locally at the site of antigen injection release chemokines and cytokines that recruit macrophages and other leukocytes to the site. Antigen presentation by the newly recruited macrophages then amplifies the response. T cells can also affect local blood vessels through the release of TNF-α and lymphotoxin (LT) and stimulate the production of macrophages through the release of IL-3 and GM-CSF. T_H1 cells activate macrophages through the release of IFN-γ and TNF-α and kill macrophages and other sensitive cells through the cell-surface expression of the Fas ligand.



Contact-sensitizing agent penetrates the skin and binds to self proteins, which are taken up by dendritic cells and Langerhans cells
Self peptides haptenated with the contact-sensitizing agent are presented to T_H1 cells, which secrete IFN-γ and other cytokines
Activated keratinocytes secrete cytokines such as IL-1 and TNF-α and chemokines such as CXCL8, CXCL11, and CXCL9

Fig. 14.23 Elicitation of a delayed-type hypersensitivity response to a contact-sensitizing agent. A contact-sensitizing agent is a small, highly reactive molecule that can penetrate intact skin. It binds covalently as a hapten to a variety of endogenous proteins, altering their structures so they become antigenic. These modified proteins are internalized, processed by Langerhans cells (the major antigen-presenting cells of skin), and presented to effector T_H1 cells (which were primed in lymph nodes as a result of prior antigen exposure). The activated T_H1 cells then secrete cytokines such as IFN-γ that stimulate keratinocytes to secrete additional cytokines and chemokines, which in turn attract monocytes and induce their maturation into activated tissue macrophages, further contributing to inflammatory lesions like those caused by poison ivy (see Fig. 14.24). NO, nitric oxide.

Langerhans cells in the epidermis and dendritic cells in the dermis take up and process antigen and migrate to regional lymph nodes, where they activate T cells (see Fig. 9.17). These eventually leave the lymph node and localize in the dermis as tissue-resident memory T cells. In the elicitation phase, a subsequent exposure to the sensitizing chemical leads to antigen presentation to these T cells, inducing the release of cytokines such as IFN-γ and IL-17. This stimulates the keratinocytes of the epidermis to release IL-1, IL-6, TNF-α, GM-CSF, the chemokine CXCL8, and the interferon-inducible chemokines CXCL11 (IP-9), CXCL10 (IP-10), and CXCL9 (Mig, a monokine induced by IFN-γ). These cytokines and chemokines enhance the inflammatory response by inducing the migration of monocytes into the lesion and their maturation into macrophages and by attracting more T cells (Fig. 14.23).

The rash produced by contact with the **poison ivy** plant (Fig. 14.24) is a common example of allergic contact dermatitis in the United States and is caused by a CD8 T-cell response to urushiol oil (a mixture of pentadecacatechols) in the plant. These chemicals are lipid-soluble and so can cross the cell membrane and attach to intracellular proteins, which are processed and presented on the cell surface by MHC class I molecules. CD8 T cells recognizing the peptides cause damage either by killing the eliciting cell or by secreting cytokines such as IFN-γ. Common clinical features of allergic contact dermatitis are erythema of the affected skin; development of a dermal and epidermal infiltrate consisting of monocytes, macrophages, lymphocytes, scant neutrophils, and mast cells; formation of intraepidermal abscesses; and vesicles (blisterlike collections of edema fluid between the dermis and epidermis).

Some insect proteins and metals can elicit a delayed-type hypersensitivity response. One example of this in the skin is a severe reaction to mosquito bites. Instead of a small itchy bump, people allergic to proteins in mosquito saliva can develop an immediate hypersensitivity reaction such as urticaria and swelling or, much more rarely, anaphylactic shock (see Section 14-9). Some allergic individuals subsequently develop a delayed reaction (consisting of a late-phase response) that can include profound swelling that can involve an entire limb. The divalent cation nickel can alter the conformation or peptide binding of MHC class II molecules and provoke a T-cell response. Sensitization

Fig. 14.24 Blistering skin lesions on the hand of an individual with allergic contact dermatitis caused by poison ivy.

Contact Sensitivity to Poison Ivy

to nickel is widespread as a result of prolonged contact with nickel-containing items such as jewelry, buttons, and clothing fasteners. Some countries now have standards that specify that such products must have non-nickel coatings in an attempt to reduce the prevalence of nickel allergy.

14-16 Celiac disease has features of both an allergic response and autoimmunity.

Celiac Disease

Celiac disease is a chronic condition of the upper small intestine caused by an immune response directed at gluten, a complex of proteins present in wheat, oats, and barley. Elimination of gluten from the diet restores normal gut function, but to date no approach for desensitization to gluten has been developed, so gluten ingestion must be avoided throughout life. The pathology of celiac disease is characterized by the loss of the slender, fingerlike villi formed by the intestinal epithelium (a condition termed villous atrophy), together with an increase in the size of the sites in which epithelial cells are renewed (crypt hyperplasia) (Fig. 14.25). These pathological changes result in the loss of the mature epithelial cells that cover the villi and normally absorb and digest food and are accompanied by severe inflammation of the intestinal wall, with increased numbers of T cells, macrophages, and plasma cells in the lamina propria, as well as increased numbers of lymphocytes in the epithelial layer. Gluten seems to be the only food component that provokes intestinal inflammation in this way, a property that reflects gluten's ability to stimulate both innate and specific immune responses in genetically susceptible individuals. The incidence of celiac disease has increased fourfold in the past 60 years, correlating with changes in baking practice that include adding large amounts of extra gluten to dough to decrease the time required for the dough to rise and to improve the texture.

Celiac disease shows an extremely strong genetic predisposition, with more than 95% of individuals expressing the HLA-DQ2 class II MHC allele. In

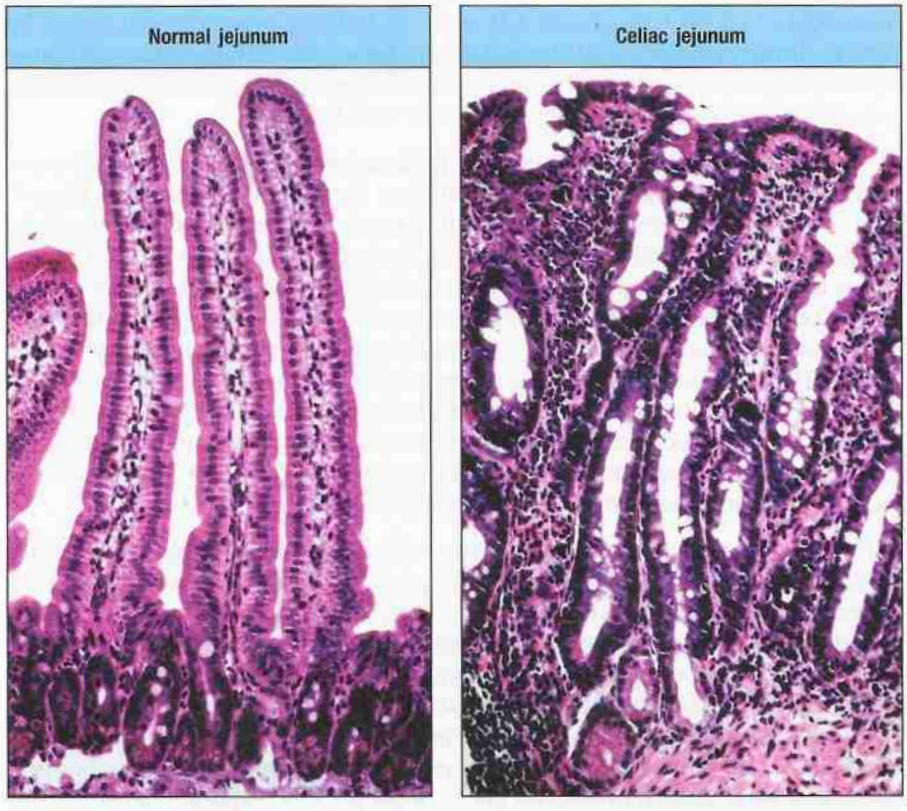

Fig. 14.25 The pathological features of celiac disease. Left panel: The surface of the normal small intestine is folded into fingerlike villi, which provide an extensive surface for nutrient absorption. Right panel: The local immune response against the food protein α-gliadin, a prominent component of wheat, oat, and barley gluten, leads to massive infiltration of the lamina propria (in the deeper, inner portion of the villi) by CD4 T cells, plasma cells, macrophages, and smaller numbers of other leukocytes, ultimately leading to destruction of the villi. In parallel, there is lengthening and increased mitotic activity in the underlying crypts, where new epithelial cells are produced. Because the villi contain all the mature epithelial cells that digest and absorb foodstuffs, their loss can result in life-threatening malabsorption and diarrhea.

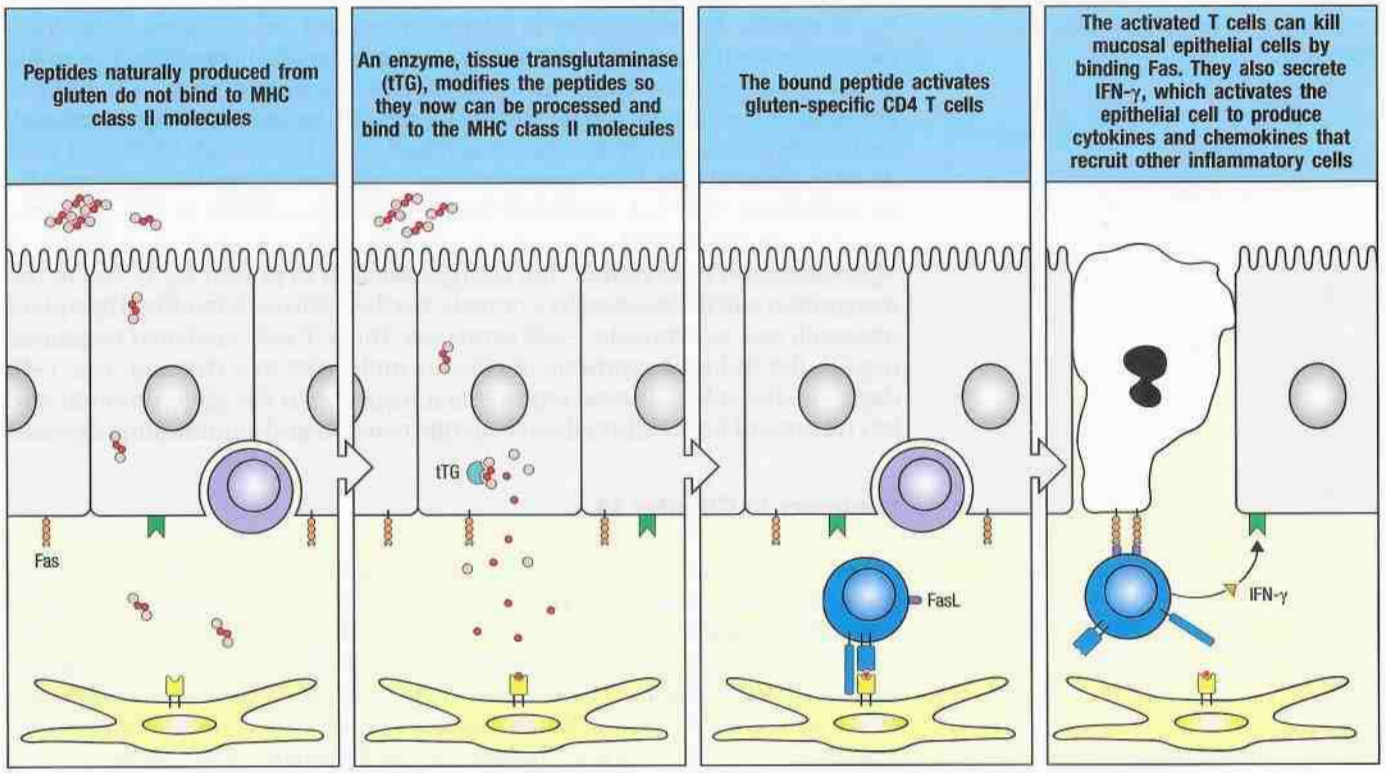
monozygotic twins, if one twin develops it, there is an 80% probability that the other will, but only a 10% concordance is observed in dizygotic twins. Nevertheless, most individuals expressing HLA-DQ2 do not develop celiac disease despite the almost universal presence of gluten in the Western diet. Thus, other genetic or environmental factors must make important contributions to susceptibility. Normally, food proteins induce oral tolerance, but it is unknown why this mechanism breaks down in people with celiac disease. The incidence of celiac disease is especially high in individuals with trisomy 21 (Down syndrome), approximately sixfold higher than in the normal population, underscoring the impact of genetic factors on disease prevalence.

Most evidence indicates that celiac disease requires the aberrant priming of IFN-γ–producing CD4 T cells by antigenic peptides present in α-gliadin, one of the major proteins in gluten. It is generally accepted that only a limited number of peptides can provoke an immune response leading to celiac disease. This is likely due to the unique structure of the peptide-binding groove of the HLA-DQ2 molecule. The key step in the immune recognition of α-gliadin is the deamidation of its peptides by the enzyme tissue transglutaminase (tTG), which converts selected glutamine residues to negatively charged glutamic acid. Only peptides containing negatively charged residues in certain positions bind strongly to HLA-DQ2, and thus the transamination reaction promotes the formation of peptide:HLA-DQ2 complexes, which can activate antigen-specific CD4 T cells (Fig. 14.26). Activated gliadin-specific CD4 T cells accumulate in the lamina propria, producing IFN-γ, a cytokine that when present in this location leads to intestinal inflammation.

Celiac disease is entirely dependent on the presence of the foreign antigen, gluten. It is not associated with a specific immune response against self antigens in the intestinal epithelium. Thus, celiac disease is not a classical autoimmune disease. But it does have some features of autoimmunity. Autoantibodies



Peptides naturally produced from gluten do not bind to MHC class II molecules
An enzyme, tissue transglutaminase (tTG), modifies the peptides so they now can be processed and bind to the MHC class II molecules
The bound peptide activates gluten-specific CD4 T cells
The activated T cells can kill mucosal epithelial cells by binding Fas. They also secrete IFN-γ, which activates the epithelial cell to produce cytokines and chemokines that recruit other inflammatory cells

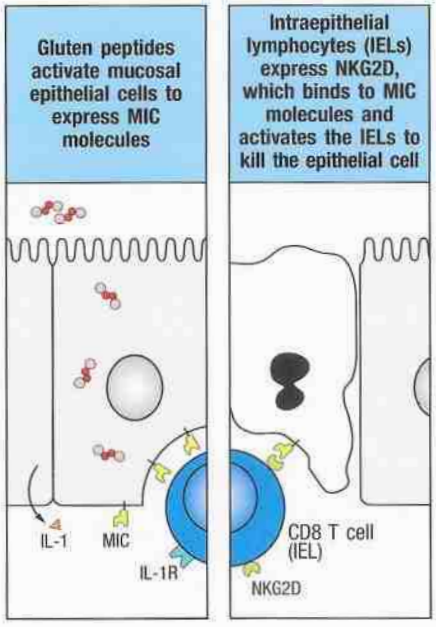
Fig. 14.26 Molecular basis of immune recognition of gluten in celiac disease. After the digestion of gluten by gut digestive enzymes, deamidation of epitopes by tissue transglutaminase renders the gluten more susceptible to being readily processed by local antigen-presenting cells, ultimately leading to its binding to HLA-DQ molecules and priming of the immune system.



Gluten peptides activate mucosal epithelial cells to express MIC molecules
Intraepithelial lymphocytes (IELs) express NKG2D, which binds to MIC molecules and activates the IELs to kill the epithelial cell

Fig. 14.27 The activation of cytotoxic T cells by the innate immune system in celiac disease. Gluten peptides can induce the expression of the MHC class Ib molecules MIC-A and MIC-B on gut epithelial cells and the synthesis and release of IL-1 from these cells. Intraepithelial lymphocytes (IELs), many of which are cytotoxic CD8 T cells, recognize the MIC proteins via the receptor NKG2D, which, together with the co-stimulator IL-1, activates the IELs to kill the MIC-bearing cells, leading to destruction of the gut epithelium.

against tissue transglutaminase are found in all individuals with celiac disease, but there is no evidence that they contribute directly to tissue damage. Indeed, the presence of serum IgA antibodies against this enzyme is used as a sensitive and specific test for the disease. Notably, no tTG-specific T cells have been found, but gluten-reactive T cells may provide help to tTG-reactive B cells that capture gluten in a complex with transglutaminase.

The gluten protein also seems to have several properties that contribute to pathogenesis. As well as its relative resistance to digestion, there is mounting evidence that some gliadin-derived peptides stimulate the innate immune system by inducing the release of IL-15 by intestinal epithelial cells. This process is antigen-nonspecific and involves peptides that cannot be bound by HLA-DQ2 molecules or recognized by CD4 T cells. IL-15 release leads to the activation of dendritic cells in the lamina propria, as well as the up-regulation of nonclassical MHC class Ib molecules MIC-A and MIC-B expression by epithelial cells (see Section 6-17). CD8 T cells in the mucosal epithelium can be activated via their NKG2D receptors, which recognize MIC-A, and they can kill MIC-A–expressing epithelial cells via these same NKG2D receptors (Fig. 14.27). Triggering of these innate immune responses by α-gliadin may create some intestinal damage on its own and also induce some of the co-stimulatory events necessary for initiating an antigen-specific CD4 T-cell response to other parts of the α-gliadin molecule. The ability of gluten to stimulate both innate and adaptive immune responses may thus explain its unique ability to induce celiac disease.

Summary.

Hypersensitivity reactions include several non-IgE-mediated conditions that reflect normal immune mechanisms that are inappropriately directed against innocuous antigens or inflammatory stimuli. These include both immediate and delayed-type reactions. Immediate-type reactions are due to the binding of specific IgG antibodies to allergen-modified cell surfaces, as in drug-induced hemolytic anemia (that is, type II hypersensitivity reactions), or to the formation of immune complexes of antibodies bound to poorly catabolized antigens, as occurs in serum sickness (type III hypersensitivity reactions). Cellular hypersensitivity reactions mediated by T_H1 cells and cytotoxic T cells develop more slowly than immediate-type reactions (type IV hypersensitivity reactions). The T_H1-mediated hypersensitivity reaction in the skin provoked by mycobacterial tuberculin is used to diagnose previous exposure to *Mycobacterium tuberculosis*. The allergic reaction to poison ivy is due to the recognition and destruction by cytotoxic T cells of skin cells modified by a plant molecule and to cytotoxic T-cell cytokines. These T cell–mediated responses require the induced synthesis of effector molecules and develop over 1–10 days. Finally, celiac disease represents a response to the gluten protein and has features of both cell-mediated allergic reaction and autoimmune disease.

Summary to Chapter 14.

In susceptible individuals, immune responses to otherwise innocuous antigens can produce allergic reactions upon reexposure to the same antigen. Most allergic reactions involve the production of IgE antibody against common environmental allergens. Some people are intrinsically prone to making IgE antibodies against many allergens, and such people are said to be atopic. IgE production is driven by cytokines produced in the type 2 immune responses, with T_H2/ILC2 cytokines and chemokines predominant, although the genetic and environmental factors causing this response are largely still unknown. Nonetheless, the IgE produced in this response binds to the high-affinity IgE receptor FcεRI on mast cells and basophils, and subsequent encounter

with the antigen sets the allergic response in motion. Specific effector T cells, mast cells, and eosinophils, in combination with T_H1 and T_H2 cytokines and chemokines, orchestrate chronic allergic inflammation, which is the major cause of the chronic morbidity of asthma. Failure to regulate these responses can occur at many levels of the immune system. Therapies to suppress allergic responses include blocking the effector pathways, with antihistamines for example, as well as elimination of circulating IgE using anti-IgE antibodies.

Discussion Questions

14.1 Explain the basis for the association between the IgE isotype antibody against an antigen and the triggering of an allergic reaction to that same antigen.

14.2 Using the typical example of a bee sting, describe the process leading to the rapid swelling at the site of injury. Describe how this process could lead to systemic shock and death.

14.3 Describe a way in which epithelial cells may promote the generation of an allergic response to an antigen.

14.4 In Netherton syndrome, what is the connection between a protease and the development of an allergic response?

14.5 Describe the mechanism underlying the rash caused by exposure to the poison ivy plant.

14.6 Celiac disease is caused by an immune response to gluten. In what way is celiac disease like an allergic response? In what ways is it like an autoimmune disease?

Autoimmunity and Transplantation

15

IN THIS CHAPTER

The making and breaking of self-tolerance.

Autoimmune diseases and pathogenic mechanisms.

The genetic and environmental basis of autoimmunity.

Responses to alloantigens and transplant rejection.

Chapter 14 described how environmental antigens can elicit allergic and atopic reactions. In contrast, this chapter will examine how self antigens can elicit immune responses against the body's own tissues. We will also describe how transplanted organs and even some commensal organisms can elicit undesirable immune responses. Responses to self antigens that lead to tissue damage and disease are broadly referred to as **autoimmunity**. Responses associated with the microbiota are called **xenoimmunity**, as these antigens are not encoded by the human genome, but we will consider these immune-mediated diseases as part of the spectrum of **autoimmune diseases**. Finally, the immune response to nonself antigens on transplanted organs is called an **alloimmune response**.

In Section 6-13, we introduced the basic features of alloreactive T cells. Such T cells from one individual react strongly to nonself MHC molecules because of both an inherent affinity of T-cell receptors to bind MHC molecules and the process of positive selection described in Chapter 8. Normal lymphocyte development generates a state of **self-tolerance**, in which an individual's immune system does not attack the normal tissues of the body. Autoimmunity represents a breakdown or failure of the mechanisms of self-tolerance. First, we will briefly review the mechanisms that regulate self-tolerance and see how these may fail. Then, we will describe several specific autoimmune diseases that illustrate various pathogenic mechanisms by which autoimmunity can damage the body. Next, we will discuss how genetic and environmental factors can predispose to or trigger autoimmunity. Finally, we will describe immune responses to the nonself tissue antigens that cause transplant rejection.

The making and breaking of self-tolerance.

Chapter 8 described the processes that generate the repertoire of B and T cells that form the adaptive immune system. For B cells, both deletion and the process of receptor editing contribute to the elimination of strongly self-reactive cells in the primary immune repertoire. For T cells, negative selection, as well as the development of T_{reg} cells, contribute to self-tolerance. Despite the operation of these mechanisms, some potentially self-reactive lymphocytes do populate the primary immune repertoire. Additional mechanisms act in the periphery of the body to keep these cells in check, but under some conditions, these can fail and allow autoimmunity to develop.

15-1 Multiple mechanisms normally contribute to prevent autoimmunity.

Chapter 8 described some of the mechanisms that contribute to the development of a self-tolerant repertoire of B and T lymphocytes (see Sections 8-7 and 8-20). After successful rearrangements in the various antigen receptor genes, B-cell or T-cell receptors are expressed on the surface of newly developing lymphocytes. Receptors that interact strongly with 'self' molecules expressed in the bone marrow or thymus can cause a change in a lymphocyte's development,

affecting either the lymphocyte's survival or, in some cases, the receptor that is expressed. Strongly self-reactive T cells and B cells may be eliminated entirely, whereas some self-reactive B cells may undergo receptor editing to allow replacement with a non-self-reactive receptor. Newly formed lymphocytes are especially sensitive to inactivation or deletion by strong signals through their antigen receptors, while the same signals may activate a mature lymphocyte in the periphery. Such tolerance induced during lymphocyte development is known as **central tolerance**.

However, we know that these processes are not perfect and that lymphocytes with potentially self-reactive antigen receptors do populate the peripheral repertoire. The term **peripheral tolerance** is sometimes used to refer collectively to a number of mechanisms that control the potentially self-reactive lymphocytes in the peripheral repertoire. This term originated well before there was an understanding of the mechanisms that control self-reactive lymphocytes. Some of these mechanisms have been described in earlier chapters, and we will only briefly recount them here. First, the system of innate recognition receptors, such as TLRs, that recognize the presence of pathogens (see Chapter 3) help to establish a threshold for lymphocyte activation in the periphery. They do this by providing a 'danger' signal needed to induce co-stimulatory molecules that are required to fully activate immune responses (see Section 9-6). As such, antigen recognition in the absence of such signals (that is, in a non-immunogenic context) may not lead to lymphocyte activation, but rather may induce a nonresponsive (anergic) state in lymphocytes. Also, we now recognize the importance of the subset of CD4 T cells called regulatory T cells (T_{reg} cells), which can inhibit responses to self antigens (see Sections 9-15 and 9-17). Some self antigens are expressed in locations that are not normally accessible to surveillance by immune cells, where there is a physical barrier to access of the antigen, leading to 'immunological ignorance.' Also, some tissues act as so-called 'immune-privileged sites' by using mechanisms to actively suppress lymphocyte activation. The various components of self-tolerance and peripheral tolerance are listed in Fig. 15.1.

Fig. 15.1 Self-tolerance depends on the concerted action of a variety of mechanisms that operate at different sites and stages of development. The different ways in which the immune system prevents activation of and damage caused by autoreactive lymphocytes are listed, along with the specific mechanism and the site where such tolerance predominantly occurs.

Layers of self-tolerance		
Type of tolerance	**Mechanism**	**Site of action**
Central tolerance	Deletion Editing	Thymus (T cells) Bone marrow (B cells)
Antigen segregation	Physical barrier to self-antigen access to lymphoid system	Peripheral organs (e.g., thyroid, pancreas)
Peripheral anergy	Cellular inactivation by weak signaling without co-stimulus	Secondary lymphoid tissue
Regulatory T cells	Suppression by cytokines, intercellular signals	Secondary lymphoid tissue and sites of inflammation; multiple tissues in steady state
Functional deviation	Differentiation of regulatory T cells that limit inflammatory cytokine secretion	Secondary lymphoid tissue and sites of inflammation
Activation-induced cell death	Apoptosis	Secondary lymphoid tissue and sites of inflammation
Immunological ignorance	Low-affinity interaction in absence of co-activation	Peripheral organs
Immunologically privileged sites	TGF-β Fas	Brain, eye, testis, uterus (fetus)

Disease	Disease mechanism	Consequence	Prevalence
Psoriasis	Autoreactive T cells against skin-associated antigens	Inflammation of skin with formation of scaly patches or plaques	1 in 50
Rheumatoid arthritis	Autoreactive T cells, autoantibodies against antigens localized to joint synovium, and rheumatoid factor.	Joint inflammation and destruction causing arthritis	1 in 100
Graves' disease	Autoantibodies against the thyroid-stimulating hormone (TSH) receptor	Hyperthyroidism: overproduction of thyroid hormones	1 in 100
Hashimoto's thyroiditis	Autoantibodies and autoreactive T cells against thyroid antigens	Destruction of thyroid tissue leading to hypothyroidism: underproduction of thyroid hormones	1 in 200
Systemic lupus erythematosus	Autoantibodies and autoreactive T cells against DNA, chromatin proteins, and ubiquitous ribonucleoprotein antigens	Glomerulonephritis, vasculitis, rash	1 in 200
Sjögren's syndrome	Autoantibodies and autoreactive T cells against ribonucleoprotein antigens	Lymphocyte infiltration of exocrine glands, leading to dry eyes and/or dry mouth; other organs may be involved, leading to systemic disease	1 in 300
Crohn's disease	Autoreactive T cells against intestinal flora antigens	Intestinal inflammation and scarring	1 in 500
Multiple sclerosis	Autoreactive T cells against brain and spinal cord antigens	Formation of sclerotic plaques in brain and spinal cord with destruction of myelin sheaths surrounding nerve cell axons, leading to muscle weakness, ataxia, and other symptoms	1 in 700
Type 1 diabetes mellitus (insulin-dependent diabetes mellitus; IDDM)	Autoreactive T cells against pancreatic islet cell antigens	Destruction of pancreatic islet β cells leading to nonproduction of insulin	1 in 800

Fig. 15.2 Some common autoimmune diseases. The diseases listed are among the most common autoimmune diseases and will be used as examples in this chapter. They are listed in order of prevalence.

The concept of autoimmunity was first presented at the beginning of the 20th century by Paul Ehrlich, who described it as '*horror autotoxicus*.' Autoimmune responses resemble normal immune responses to pathogens in being activated by specific antigens, but in this case by self antigens, or **autoantigens**. Like normal immune responses, autoimmune responses involve the generation of effector T cells and the production of antibodies, but these are directed against self antigens, or autoantigens. Such antibodies are called **autoantibodies**. Collectively, autoimmune disorders may affect as much as 5% of the populations of the United States, but individual types of autoimmunity are relatively rare. Figure 15.2 lists several of the more common autoimmune syndromes and illustrates the wide variety of effector mechanisms and tissue distributions that can arise.

Autoimmune Polyendocrinopathy–Candidiasis–Ectodermal Dystrophy (APECED)

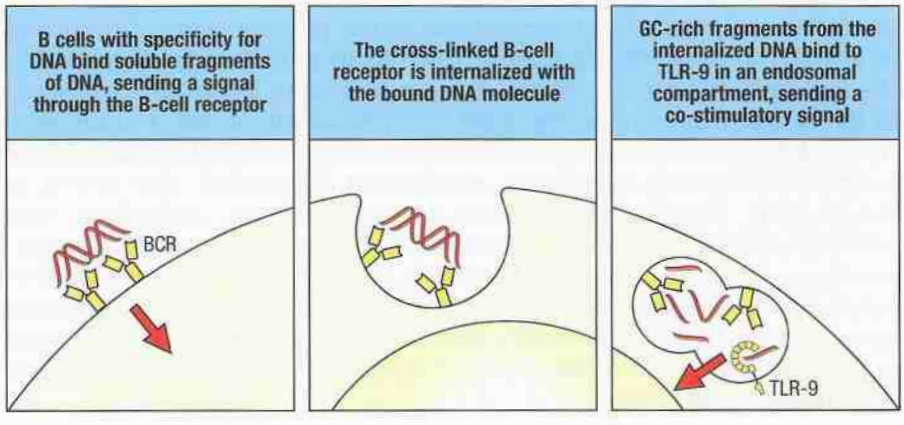
We have already described one situation in which central tolerance fails (see Section 8-25). Many self antigens are expressed in the thymus by either thymic epithelial cells in the medulla or a $CD8\alpha^+$ subset of dendritic cells to allow for the deletion of T cells that strongly react. Some 'peripheral genes' expressed in a highly tissue-restricted manner, such as insulin, are also expressed in the thymus because of the action of the transcription factor AIRE expressed in the thymic medulla (see Fig. 8.30). Individuals with a defect in the gene *AIRE* exhibit a rare inherited form of autoimmunity—**APECED (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy)**, also known as autoimmune polyglandular syndrome type I (APS-I). Individuals with APECED exhibit damage to multiple endocrine tissues, including insulin-producing pancreatic islets, and frequently acquire fungal infections, particularly candidiasis. Mice engineered to lack *AIRE* fail to express many peripheral genes in the thymus and develop a similar syndrome. The autoimmunity that accompanies AIRE deficiency takes time to develop and does not always affect all potential organ targets.

15-2 Lymphocytes that bind self antigens with relatively low affinity usually ignore them but in some circumstances become activated.

Another mechanism that prevents activation of potentially self-reactive lymphocytes is called **immunological ignorance**. This mechanism applies to lymphocytes that have a low affinity for self antigens and normally make no effector response against them. However, such 'ignorance' can be converted into an autoimmune response if the threshold for lymphocyte activation is sufficiently reduced; for example, by the induction of co-activating factors in antigen-presenting cells. This may occur during an infection, when naive T cells can encounter activated dendritic cells presenting the self antigen along with strong co-stimulatory signals and pro-inflammatory cytokines.

Immunological ignorance can also be broken when the autoantigen is also a ligand for a Toll-like receptor (TLR). These receptors recognize a variety of microbial-associated molecular patterns (see Section 3-5), but some such patterns can also be found among self molecules. For example, TLR-9 recognizes unmethylated CpG sequences in DNA. Normally much more common in bacterial than mammalian DNA, CpG sequences are enriched in mitochondrial DNA and in apoptotic mammalian cells. When extensive cell death occurs under conditions of inadequate clearance of apoptotic fragments, B cells with receptors that happen to bind chromatin components may internalize CpG sequences via their B-cell receptors. The internalized CpG can activate the intracellular TLR-9 (see Fig. 3.11), thereby activating the previously ignorant B cell (Fig. 15.3) and leading to the production of anti-chromatin autoantibodies. These B cells may also act as antigen-presenting cells for autoreactive T cells. Ribonucleoprotein complexes containing uridine-rich RNA have similarly been shown to activate naive B cells through binding by TLR-7 or TLR-8. Autoantibodies against DNA, chromatin, and ribonucleoproteins are produced in the autoimmune disease **systemic lupus erythematosus (SLE)**, and this appears to be one mechanism by which self-reactive B cells are stimulated to produce them.

Ignorant lymphocytes may also become activated by a change in the availability or form of self antigens. Antigens that are normally intracellular and not encountered by lymphocytes may be released as a result of tissue injury or inflammation. These antigens can then activate ignorant T and B cells, leading to autoimmunity. This can occur after myocardial infarction, when an autoimmune response is detectable some days after the release of cardiac antigens. Such reactions are typically transient and cease when the autoantigens have been removed; however, when clearance mechanisms are inadequate, they can continue, causing clinical autoimmune disease.



B cells with specificity for DNA bind soluble fragments of DNA, sending a signal through the B-cell receptor
The cross-linked B-cell receptor is internalized with the bound DNA molecule
GC-rich fragments from the internalized DNA bind to TLR-9 in an endosomal compartment, sending a co-stimulatory signal
BCR
TLR-9

Fig. 15.3 Self antigens that are recognized by Toll-like receptors can activate autoreactive B cells by providing co-stimulation. B cells that have a low affinity for DNA can escape deletion in the bone marrow and persist in the periphery but are not normally activated. Under some conditions and in genetically susceptible individuals, the concentration of DNA may increase, leading to the ligation of enough B-cell receptors to activate these B cells. When this occurs, B cells signal through their receptor (left panel). This will also result in the uptake of DNA (center panel) and its delivery to an endosomal compartment (right panel), where it may be recognized by TLR-9. DNA that is enriched in unmethylated CpG DNA sequences present in microbial DNA normally allows TLR-9 to distinguish pathogens from self. But unmethylated CpG DNA sequences are also enriched in mitochondrial DNA and can arise from apoptotic mammalian cells, which can be sufficient to activate TLR-9. This pathway can promote the activation of the DNA-specific B cells and lead to the production of autoantibodies against DNA.

Additionally, some autoantigens are present in great quantity but are usually in a non-immunogenic form. IgG is a good example, as there are large quantities of it in blood and extracellular fluids. B cells specific for the IgG constant region are not usually activated because IgG is monomeric and cannot cross-link the B-cell receptor. However, when immune complexes form after infection or immunization, enough IgG is in multivalent form to evoke a response from otherwise ignorant B cells. The anti-IgG autoantibody they produce is called **rheumatoid factor** because it is often present in rheumatoid arthritis. Again, this response is normally short-lived, as long as the immune complexes are cleared rapidly.

Systemic Lupus Erythematosus

Rheumatoid Arthritis

15-3 Antigens in immunologically privileged sites do not induce immune attack but can serve as targets.

Foreign tissue grafts placed in some body sites do not elicit immune responses. For instance, grafts placed in the brain and anterior chamber of the eye do not induce rejection. Such locations are termed **immunologically privileged sites** (Fig. 15.4). It was originally believed that immunological privilege arose from the failure of antigens to leave privileged sites and induce immune responses. Subsequent studies have shown that antigens do leave these sites and interact with T cells. However, instead of eliciting an effector immune response, they induce a tolerogenic response that does not injure the tissue.

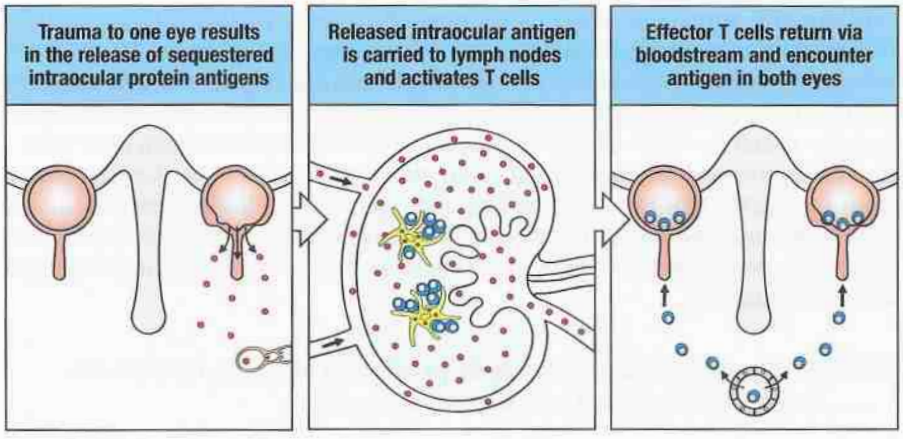
Immunologically privileged sites
Brain
Eye
Testis
Uterus (fetus)

Fig. 15.4 Some sites in the body are immunologically privileged. Tissue grafts placed in these sites often last indefinitely, and antigens placed in these sites do not elicit destructive immune responses.

Immunologically privileged sites seem to be unusual in three ways. First, communication between the privileged site and the body is atypical in that extracellular fluid does not pass through conventional lymphatics, although proteins placed in these sites do leave and can have immunological effects. Privileged sites are generally surrounded by tissue barriers that exclude naive lymphocytes. The brain, for example, is guarded by the blood–brain barrier. Second, soluble factors that affect the course of an immune response are produced in privileged sites. The anti-inflammatory transforming growth factor-β (TGF-β) seems to be particularly important in this regard. Under homeostatic conditions, antigens recognized in concert with TGF-β tend to induce T_{reg} responses, rather than pro-inflammatory T_H17 responses, which are induced by TGF-β in the presence of IL-6 (see Section 9-15). Third, the expression of Fas ligand in immunologically privileged sites may provide a further level of protection by inducing the apoptosis of Fas-bearing effector lymphocytes that enter these sites (see Section 11-16).

Paradoxically, antigens sequestered in immunologically privileged sites are often targets of autoimmune attack; for example, brain and spinal cord autoantigens such as myelin basic protein are targeted in the autoimmune disease **multiple sclerosis**, a chronic inflammatory demyelinating disease of the central nervous system (see Fig. 15.2). Thus, the tolerance normally shown to these antigens cannot be due to previous deletion of the self-reactive T cells. In **experimental autoimmune encephalomyelitis (EAE)**, a mouse model for multiple sclerosis, mice become diseased only when they are immunized with myelin antigens and adjuvants, which cause infiltration of the central nervous system with antigen-specific T_H17 and T_H1 cells that induce a local inflammatory response that damages nerve tissue. This result also emphasizes that autoimmunity can be provoked by inducing a specific adaptive immune response to self antigens. But in humans, autoimmunity usually arises spontaneously, and the events that initiate the immune response to self are largely unknown. Some strains of mice also exhibit spontaneous autoimmunity, but the genetic basis of the disease is known to be multigenic and is still an active area of research.

Thus, some antigens expressed in immunologically privileged sites induce neither tolerance nor lymphocyte activation in normal circumstances, but if autoreactive lymphocytes are activated elsewhere, these autoantigens can



Trauma to one eye results in the release of sequestered intraocular protein antigens
Released intraocular antigen is carried to lymph nodes and activates T cells
Effector T cells return via bloodstream and encounter antigen in both eyes

Fig. 15.5 Damage to an immunologically privileged site can induce an autoimmune response. In the disease sympathetic ophthalmia, trauma to one eye releases the sequestered eye antigens into the surrounding tissues, making them accessible to T cells (left panel). Antigens that localize to lymph nodes can activate effector cells and induce an immune response (middle panel). These lymphocytes can then attack the traumatized eye and also infiltrate and attack the healthy eye (right panel). Thus, although the sequestered antigens do not induce a response by themselves, if a response is induced elsewhere they can serve as targets for attack.

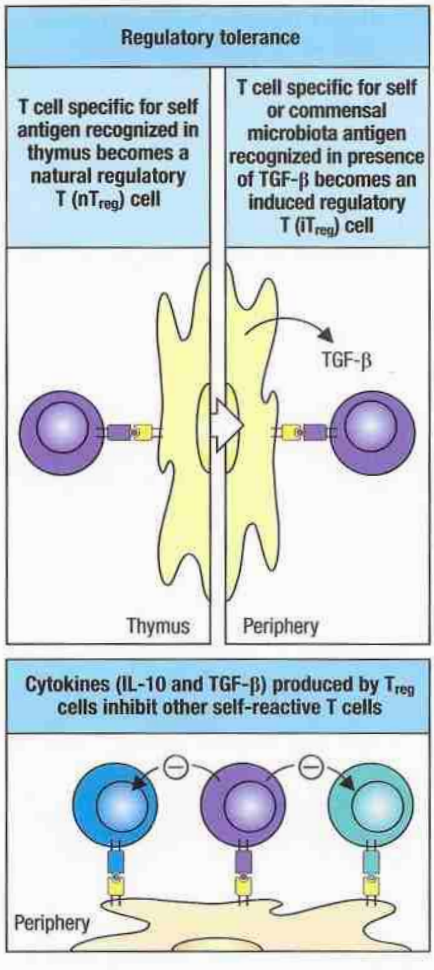
become targets for autoimmune attack. Likely, T cells specific for antigens sequestered in immunologically privileged sites are in a state of immunological ignorance. Further evidence comes from the eye disease **sympathetic ophthalmia** (Fig. 15.5). If one eye is ruptured by a blow or other trauma, an autoimmune response to eye proteins can occur, although this happens only rarely. Once the response is induced, it often attacks both eyes. Immunosuppression—and, rarely, removal of the damaged eye, the source of antigen—is required to preserve vision in the undamaged eye.

Unsurprisingly, effector T cells can enter immunologically privileged sites when such sites become infected by some pathogen. Effector T cells can enter most tissues after activation (see Chapter 11), but the accumulation of these cells is seen only when antigen is recognized in the site, triggering the production of cytokines that alter tissue barriers.

15-4 Autoimmune responses can be controlled at various stages by regulatory T cells.

Tolerance due to regulatory lymphocytes is distinguished from other forms of self-tolerance by the fact that T_{reg} cells have the potential to suppress self-reactive lymphocytes that recognize antigens different from those recognized by the T_{reg} cell (Fig. 15.6). This type of tolerance is known as **regulatory tolerance**. The key feature of regulatory tolerance is that regulatory cells can suppress autoreactive lymphocytes that recognize a variety of different self antigens, as long as the antigens are from the same tissue or are presented by the same antigen-presenting cell.

As discussed in Chapter 9, two general types of regulatory T cells have been defined experimentally. 'Natural' T_{reg} (nT_{reg}) cells are programmed in the thymus to express the transcription factor FoxP3 in response to self antigens. When activated by the same antigens in peripheral tissues, nT_{reg} cells inhibit other self-reactive T cells that recognize antigens in the same tissue to prevent their differentiation into effector T cells or prevent their effector



Regulatory tolerance
T cell specific for self antigen recognized in thymus becomes a natural regulatory T (nT_{reg}) cell
T cell specific for self or commensal microbiota antigen recognized in presence of TGF-β becomes an induced regulatory T (iT_{reg}) cell
TGF-β
Thymus
Periphery
Cytokines (IL-10 and TGF-β) produced by T_{reg} cells inhibit other self-reactive T cells
Periphery

Fig. 15.6 Tolerance mediated by regulatory T cells can inhibit multiple autoreactive T cells that all recognize antigens from the same tissue. Specialized autoreactive natural regulatory T (nT_{reg}) cells develop in the thymus in response to stimulation by self antigens that is too weak to cause deletion but is greater than required for simple positive selection (upper left panel). Regulatory T cells can also be induced (iT_{reg} cells) from naive self-reactive T cells in the periphery if the naive T cell recognizes its antigen and is activated in the presence of the cytokine TGF-β (upper right panel). nT_{reg} and iT_{reg} cells are able to inhibit other self-reactive T cells (lower panel), in part by secretion of inhibiting cytokines such as IL-10 and TGF-β that inhibit all surrounding autoreactive T cells, regardless of their precise autoantigen specificity.

function. 'Induced' T_{reg} (iT_{reg}) cells also express FoxP3 but develop in peripheral immune tissues in response to antigens recognized in the presence of TGF-β but in the absence of pro-inflammatory cytokines. Giving animals large amounts of self antigen orally, which induces so-called **oral tolerance** (see Section 12-7), can sometimes lead to unresponsiveness to these antigens when given by other routes and can prevent autoimmune disease. Oral tolerance is routinely generated to antigens such as food antigens and is accompanied by the generation of iT_{reg} cells in the gut-draining mesenteric lymph nodes. These cells are able to suppress immune responses to the given antigen in the gut.

A protective role for FoxP3-expressing T_{reg} cells has been demonstrated in several autoimmune syndromes in mice, including diabetes, EAE, SLE, and inflammation of the large intestine, or colon (colitis). Experiments in mouse models of these diseases have established that $FoxP3^+$ T_{reg} cells actively suppress disease in the normal immune system, as depletion of these cells results in multi-organ autoimmune disease. T_{reg} cells have also been shown to prevent or ameliorate other immunopathologic syndromes, such as graft-versus-host disease and graft rejection, which are described later in this chapter.

FoxP3-expressing T_{reg} cells are not the only type of regulatory lymphocyte that has been identified. For example, FoxP3-negative regulatory T cells characterized by their production of IL-10 are enriched in the intestinal tissues, where they may suppress inflammatory bowel disease (IBD) through an IL-10–dependent mechanism. The developmental origins of these cells are not currently understood. Almost every type of lymphocyte has been shown to display regulatory activity in some circumstance. Even B cells can regulate experimentally induced autoimmune syndromes, including collagen-induced arthritis (CIA) and EAE. This activity is probably mediated in a similar way to that of regulatory CD4 T cells, with the secretion of cytokines that inhibit proliferation and differentiation of effector T cells.

In addition to the extrinsic regulation of autoreactive T and B cells by regulatory cells, lymphocytes have intrinsic proliferation and survival limits that can help restrict autoimmune as well as normal responses (see Section 11-16). This is illustrated by the development of spontaneous autoimmunity that is caused by mutations in pathways that control apoptosis, such as the Bcl-2 pathway or the Fas pathway (see Section 9-21); mutations in these pathways lead to spontaneous autoimmunity. This form of autoimmunity provides evidence that autoreactive cells are normally generated but are then eliminated by apoptosis. This seems to be an important mechanism for both T- and B-cell tolerance.

Summary.

Self-reactive lymphocytes always exist in the natural immune repertoire but are not often activated due to several different mechanisms. Under various conditions, self-reactive lymphocytes become activated by autoantigens and, if activation persists, can cause autoimmune diseases. The various tolerance mechanisms normally work together to prevent autoimmunity (see Fig. 15.1), but failure of these mechanisms can lead to a variety of different diseases (see Fig. 15.2). Central tolerance relies on eliminating overtly autoreactive cells during lymphocyte development in the thymus and bone marrow. Central tolerance also involves the generation of 'natural' (or 'thymic') T_{reg} cells that suppress autoimmune responses after exiting the thymus. Mechanisms of peripheral tolerance, such as anergy and deletion, or the extrathymic production of 'induced' (or 'peripheral') T_{reg} cells, complement these central tolerance mechanisms for antigens that are not expressed in the thymus or bone marrow. Tissue barriers and immune-privileged sites also control autoimmune responses by restricting access to antigens and by providing a

tolerogenic environment through external apoptosis-inducing signals, such as those mediated by Fas. Weak self-reactivity in lymphocytes does not result in deletion, as this may too severely limit the immune repertoire and impair responses to pathogens. Instead, weakly self-reactive cells are normally suppressed in the periphery by the absence of danger signals that induce the necessary co-stimulatory molecules and by T_{reg} cells of related tissue specificity.

Autoimmune diseases and pathogenic mechanisms.

In this part of the chapter, we describe some common clinical autoimmune syndromes, along with the mechanisms by which self-reactive lymphocytes can cause tissue damage. The mechanisms of pathogenesis resemble in many ways those that target invading pathogens. Damage by autoantibodies, mediated through the complement and Fc receptor systems, has an important role in some diseases, such as SLE. Similarly, self-reactive cytotoxic T cells can destroy tissues in the same way they would eliminate virus-infected cells; this is one way by which pancreatic β cells are destroyed in diabetes. However, unlike most pathogens, self proteins are not typically eliminated, so that, with rare exceptions—such as the islet cells in the pancreas—the response persists chronically. Some pathogenic mechanisms are unique to autoimmunity, such as antibodies against cell-surface receptors that affect their function, as in myasthenia gravis.

15-5 Autoimmunity can be classified into either organ-specific or systemic disease.

From a clinical perspective, it is useful to classify autoimmunity into two major patterns: 'organ-specific' autoimmune diseases restricted to specific organs, and 'systemic' autoimmune diseases that affect many tissues of the body. Examples of both kinds are listed in Fig. 15.7. Both kinds of disease tend to become chronic because most autoantigens persist in the body. Even when the response completely destroys the target tissue, as in **type 1 diabetes mellitus**, where the insulin-producing pancreatic β cells are eliminated and the autoimmune response abates, the consequences are nonetheless chronic. Some autoimmune diseases seem to be dominated by the pathogenic effects of a particular immune effector pathway, either autoantibodies or effector T cells. However, both of these pathways often contribute to the overall pathogenesis.

In organ-specific diseases, autoantigens from one or a few organs are targeted, and disease is limited to those organs. Examples include **Hashimoto's thyroiditis** and **Graves' disease**, which both predominantly affect the thyroid gland, and type 1 diabetes mellitus, which is caused by immune attack on insulin-producing pancreatic β cells. Examples of systemic autoimmune disease are SLE and primary **Sjögren's syndrome**, in which tissues as diverse as the skin, kidneys, and brain may all be affected (see Fig. 15.7).

The autoantigens recognized in these two categories of disease are themselves organ-specific and systemic, respectively. Thus, Graves' disease is characterized by the production of antibodies against the thyroid-stimulating hormone (TSH) receptor, Hashimoto's thyroiditis by antibodies against thyroid peroxidase, and type 1 diabetes mellitus by anti-insulin antibodies. By contrast, SLE is characterized by the presence of antibodies against antigens that are ubiquitous and abundant in every cell of the body, such as chromatin and the proteins of the pre-mRNA splicing machinery—the spliceosome complex.

Organ-specific autoimmune diseases
Type 1 diabetes mellitus
Goodpasture's syndrome
Multiple sclerosis Crohn's disease Psoriasis
Graves' disease Hashimoto's thyroiditis Autoimmune hemolytic anemia Autoimmune Addison's disease Vitiligo Myasthenia gravis
Systemic autoimmune diseases
Rheumatoid arthritis
Scleroderma
Systemic lupus erythematosus Primary Sjögren's syndrome Polymyositis

Fig. 15.7 Some common autoimmune diseases classified according to their 'organ-specific' or 'systemic' nature. Diseases that tend to occur in clusters are grouped in single boxes. Clustering is defined as more than one disease affecting a single individual or different members of a family. Not all autoimmune diseases can be classified according to this scheme. For example, autoimmune hemolytic anemia can occur in isolation or in association with systemic lupus erythematosus.

A strict separation of diseases into organ-specific and systemic categories does break down to some extent, however, because not all autoimmune diseases can be usefully classified in this manner. For example, autoimmune hemolytic anemia, in which red blood cells are destroyed, sometimes occurs as a solitary entity and could be classified as an organ-specific disease. In other circumstances it can occur in conjunction with SLE as part of a systemic autoimmune disease.

A prevalent variant of chronic inflammatory disease is **inflammatory bowel disease (IBD)**, which includes two main clinical entities: **Crohn's disease** (discussed later in this chapter) and **ulcerative colitis**. We discuss IBD in this chapter because it has many features of an autoimmune disease, even though it is not primarily targeted against self-tissue antigens. Instead, the targets of the dysregulated immune response in IBD are antigens derived from the commensal microbiota resident in the intestines. Strictly speaking, therefore, IBD is an outlier among autoimmune diseases in that the immune response is not directed against 'self' antigens; rather, it is directed against microbial antigens of the resident, or 'self,' microbiota. Nevertheless, features of immune tolerance breakdown are also seen in IBD, and, as with the organ-specific autoimmune diseases, the tissue destruction wrought by the aberrant immune response is primarily localized to a single organ—the intestines.

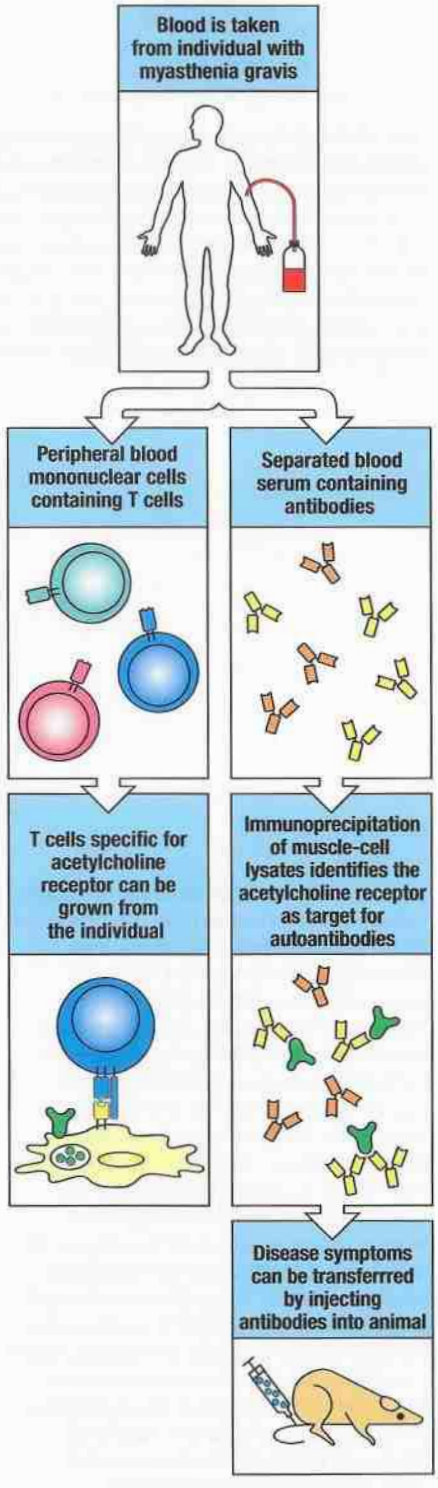
15-6 Multiple components of the immune system are typically recruited in autoimmune disease.

Understanding which parts of the immune system mediate different autoimmune syndromes can be useful in determining the disease etiology and in developing therapies. For example, in **myasthenia gravis**, it is the autoantibodies produced against the acetylcholine receptor that cause disease by blocking receptor function at the neuromuscular junction, resulting in muscle weakness. In other autoimmune conditions, antibodies in the form of immune complexes are deposited in tissues and cause tissue damage as a consequence of the inflammation that results from complement activation (see Section 2-14) and ligation of Fc receptors on inflammatory cells (see Section 10-20).

Relatively common autoimmune diseases in which effector T cells seem to be the main destructive agents include type 1 diabetes mellitus, psoriasis, IBD, and multiple sclerosis. In these diseases, T cells recognize self peptides or peptides derived from the commensal microbiota that are complexed with self MHC molecules. The damage in such diseases is caused by T cells recruiting and activating myeloid cells of the innate immune system to cause local inflammation or by direct T-cell damage to tissue cells.

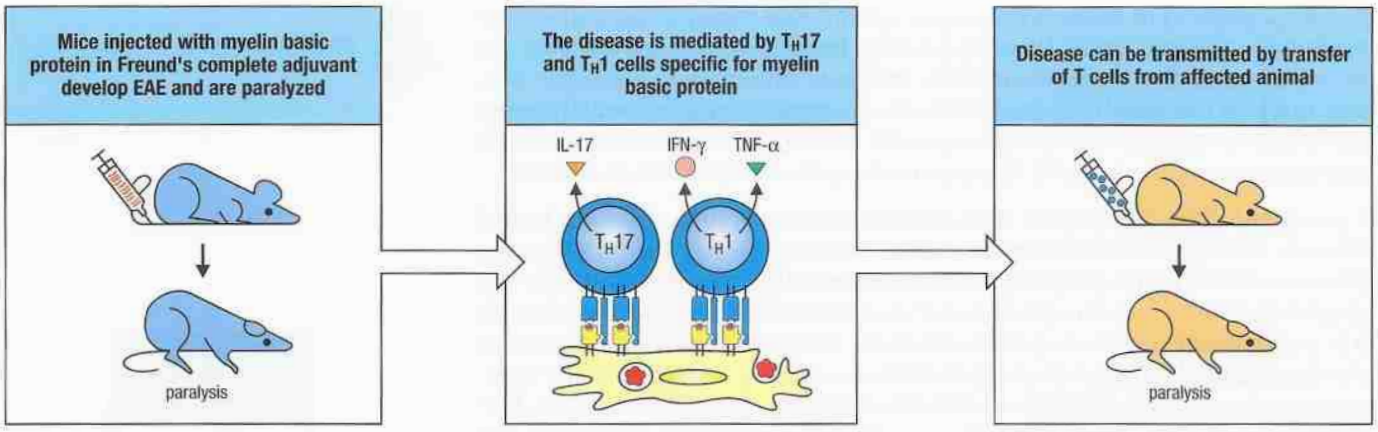
The ability to transfer disease from a diseased individual to a healthy one by transferring autoantibodies and/or self-reactive T cells both confirms that the disease is autoimmune in nature and proves the involvement of the transferred material in the pathological process. In myasthenia gravis, serum from affected individuals can transfer symptoms to animal recipients, thus proving the pathogenic role of the anti-acetylcholine autoantibodies (Fig. 15.8).

Myasthenia Gravis



Blood is taken from individual with myasthenia gravis
Peripheral blood mononuclear cells containing T cells
Separated blood serum containing antibodies
T cells specific for acetylcholine receptor can be grown from the individual
Immunoprecipitation of muscle-cell lysates identifies the acetylcholine receptor as target for autoantibodies
Disease symptoms can be transferrred by injecting antibodies into animal

Fig. 15.8 Identification of autoantibodies that can transfer disease in individuals with myasthenia gravis. Autoantibodies from the serum of individuals with myasthenia gravis immunoprecipitate the acetylcholine receptor from lysates of skeletal muscle cells (right-hand panels). Because the antibodies can bind to both the murine and the human acetylcholine receptor, they can transfer disease when injected into mice (bottom panel). This experiment demonstrates that the antibodies are pathogenic. However, to be able to produce antibodies, the same individuals should have CD4 T cells that respond to a peptide derived from the acetylcholine receptor. To detect them, T cells from individuals with myasthenia gravis are isolated and grown in the presence of the acetylcholine receptor plus antigen-presenting cells of the correct MHC type (left-hand panels). T cells specific for epitopes of the acetylcholine receptor are stimulated to proliferate and can thus be detected.



Mice injected with myelin basic protein in Freund's complete adjuvant develop EAE and are paralyzed
paralysis

T_H1
Disease can be transmitted by transfer of T cells from affected animal
paralysis

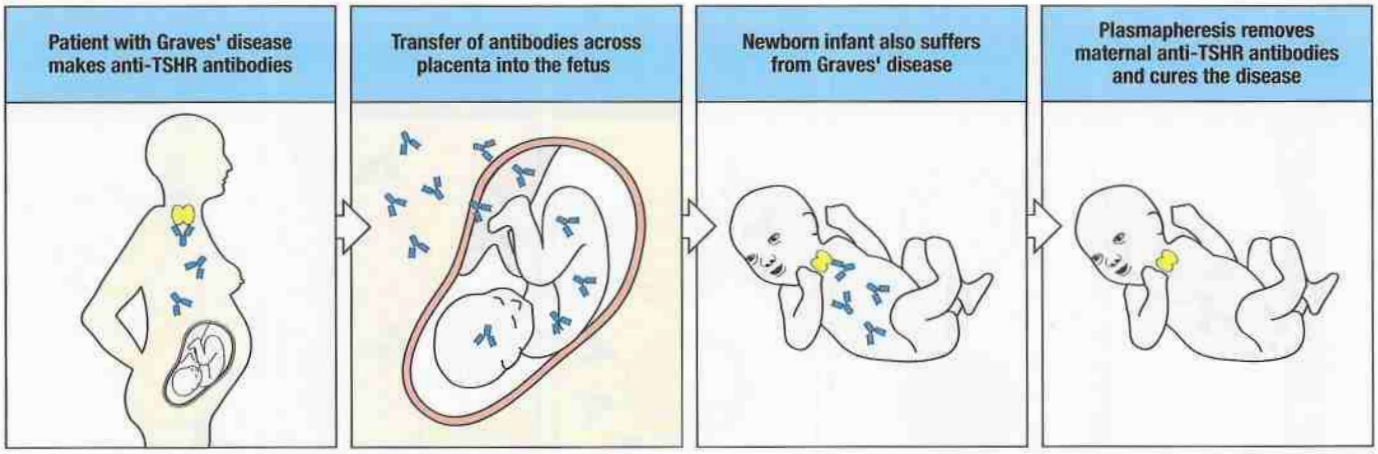
Fig. 15.9 T cells specific for myelin basic protein mediate inflammation of the brain in experimental autoimmune encephalomyelitis (EAE). Disease is induced by injecting mice with isolated spinal cord homogenized in Freund's complete adjuvant. This generates an inflammatory reaction in the brain that produces a progressive paralysis, first affecting the tail and hind limbs and progressing to forelimb paralysis and eventual death. One autoantigen identified in the spinal cord homogenate is myelin basic protein (MBP). Immunization with MBP alone in Freund's complete adjuvant can also cause these disease symptoms. Inflammation of the brain and paralysis are mediated by T_H1 and T_H17 cells specific for MBP. Production of GM-CSF and recruitment of myeloid cells contributes to disease. Cloned MBP-specific T_H1 cells can transfer symptoms of EAE to naive recipients provided that the recipients carry the correct MHC allele. Other purified components of the myelin sheath can also induce the symptoms of EAE, so there is more than one autoantigen in this disease.

Similarly, in the animal model disease EAE, T cells from affected animals can transfer disease to normal animals (Fig. 15.9).

Pregnancy can demonstrate a role for antibodies in disease, because IgG antibodies, but not T cells, can cross the placenta (see Section 10-17). The autoantibodies produced in several autoimmune diseases can cross the placenta and into the fetus and neonate (Fig. 15.10). For example, in Graves' disease, autoantibodies produced against the mother's thyroid-stimulating hormone (TSH) receptor can pass into the fetal circulation to produce disease in the neonate (Fig. 15.11). The symptoms of disease in the newborn infant typically disappear rapidly as the maternal antibody is catabolized, but in some cases the antibodies cause organ injury before they are removed. In SLE or Sjögren's syndrome, damage to the conducting tissue of the heart can occur in babies. Antibody clearance can be accelerated by exchange of the infant's blood or plasma (plasmapheresis), although this is not useful after permanent injury has occurred.

Fig. 15.10 Some autoimmune diseases can be transferred across the placenta by pathogenic IgG autoantibodies. These diseases are caused mostly by autoantibodies against cell-surface or tissue-matrix molecules. This suggests an important factor determining whether an autoantibody that crosses the placenta causes disease in the fetus or newborn baby is the accessibility of the antigen to the autoantibody. Autoimmune congenital heart block is caused by fibrosis of the developing cardiac conducting tissue, which expresses abundant Ro antigen. Ro protein is a constituent of an intracellular small cytoplasmic ribonucleoprotein, but it is unclear whether or not it is expressed at the cell surface of cardiac conducting tissue to act as a target for autoimmune tissue injury. Nevertheless, autoantibody binding leads to tissue damage and results in slowing of the heart rate (bradycardia). TSH, thyroid-stimulating hormone.

Autoimmune diseases transferred across the placenta to the fetus and newborn infant		
Disease	**Autoantibody**	**Symptom**
Myasthenia gravis	Anti-acetylcholine receptor	Muscle weakness
Graves' disease	Anti-TSH receptor	Hyperthyroidism
Thrombocytopenic purpura	Anti-platelet antibodies	Bruising and hemorrhage
Neonatal lupus rash and/or congenital heart block	Anti-Ro antibodies Anti-La antibodies	Photosensitive rash and/or bradycardia
Pemphigus vulgaris	Anti-desmoglein-3	Blistering rash



Patient with Graves' disease makes anti-TSHR antibodies
Transfer of antibodies across placenta into the fetus
Newborn infant also suffers from Graves' disease
Plasmapheresis removes maternal anti-TSHR antibodies and cures the disease

Fig. 15.11 Antibody-mediated autoimmune diseases can appear in the infants of affected mothers as a consequence of transplacental antibody transfer. In pregnant women, IgG antibodies cross the placenta and accumulate in the fetus before birth (see Fig. 10.30). Babies born to mothers with IgG-mediated autoimmune disease therefore frequently show symptoms similar to those of the mother in the first few weeks of life. Fortunately, there is little lasting damage because the symptoms disappear along with the maternal antibody. In Graves' disease, the symptoms are caused by antibodies against the thyroid-stimulating hormone receptor (TSHR). Children of mothers making thyroid-stimulating antibody are born with hyperthyroidism. These symptoms usually disappear as the maternal antibodies are eventually degraded but can be corrected by replacing the plasma with normal plasma (plasmapheresis), thus removing the maternal antibody.

Figure 15.12 lists a selection of autoimmune diseases, along with the parts of the immune response that contribute to their pathogenesis. These examples illustrate that disease may engage multiple effector pathways, but that not all may act to drive disease. Similar to immune responses to pathogens, autoimmune diseases may involve T, B, and innate immune cells. Indeed, innate immune cells—particularly phagocytic myeloid cells—mediate tissue damage in most autoimmune diseases.

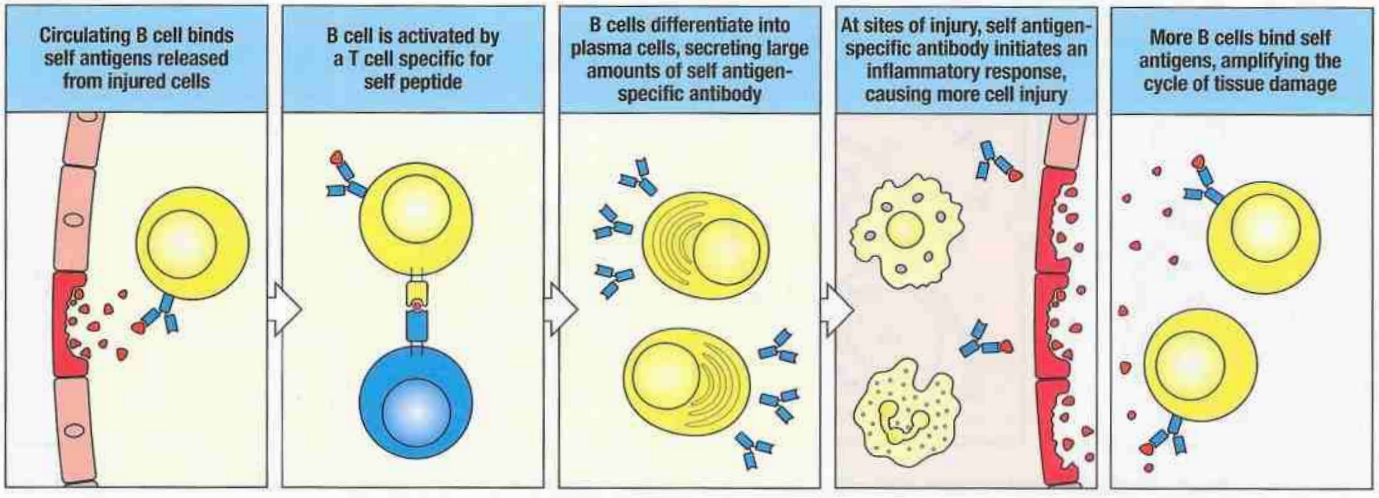
15-7 Chronic autoimmune disease develops through positive feedback from inflammation, inability to clear the self antigen, and a broadening of the autoimmune response.

In general, autoimmune diseases are characterized by an early activation phase with the involvement of only a few autoantigens, followed by a chronic stage. Also, many self antigens are present at a relative excess compared with the amount of antigens associated with pathogens. The persistence of self antigens may produce a chronic response, which may cause the release of more autoantigens as a result of tissue damage. This effect also breaks a restraint on autoimmunity known as 'sequestration,' by which many self antigens are

Autoimmune diseases involve all aspects of the immune response

Disease	T cells	B cells	Antibody
Systemic lupus erythematosus	Pathogenic Help for antibody	Present antigen to T cells	Pathogenic
Type 1 diabetes mellitus	Pathogenic	Present antigen to T cells	Present, but role unclear
Myasthenia gravis	Help for antibody	Antibody secretion	Pathogenic
Multiple sclerosis	Pathogenic	Present antigen to T cells	Present, but role unclear

Fig. 15.12 Autoimmune diseases involve all aspects of the immune response. Although some autoimmune diseases have traditionally been thought to be mediated by B cells or T cells, it is useful to consider that, typically, all aspects of the immune system have a role. For four important autoimmune diseases, the figure lists the roles of T cells, B cells, and antibody. In some diseases, such as SLE, T cells can have multiple roles such as helping B cells to make autoantibody and directly promoting tissue damage. B cells can have either of two roles—presenting autoantigens to stimulate T cells and secreting pathogenic autoantibodies.



Circulating B cell binds self antigens released from injured cells
B cell is activated by a T cell specific for self peptide
B cells differentiate into plasma cells, secreting large amounts of self antigen-specific antibody
At sites of injury, self antigen-specific antibody initiates an inflammatory response, causing more cell injury
More B cells bind self antigens, amplifying the cycle of tissue damage

Fig. 15.13 Autoantibody-mediated inflammation can lead to the release of autoantigens from damaged tissues, which in turn promotes further activation of autoreactive B cells. Autoantigens, particularly intracellular ones that are targets in SLE, stimulate B cells only when released from dying cells (first panel). The result is the activation of autoreactive T and B cells (second panel) and the eventual secretion of autoantibodies (third panel). These autoantibodies can mediate tissue damage through a variety of effector functions resulting in further cell death (fourth panel). These additional autoantigens released form a positive feedback loop that recruits and activates additional autoreactive B cells (fifth panel).

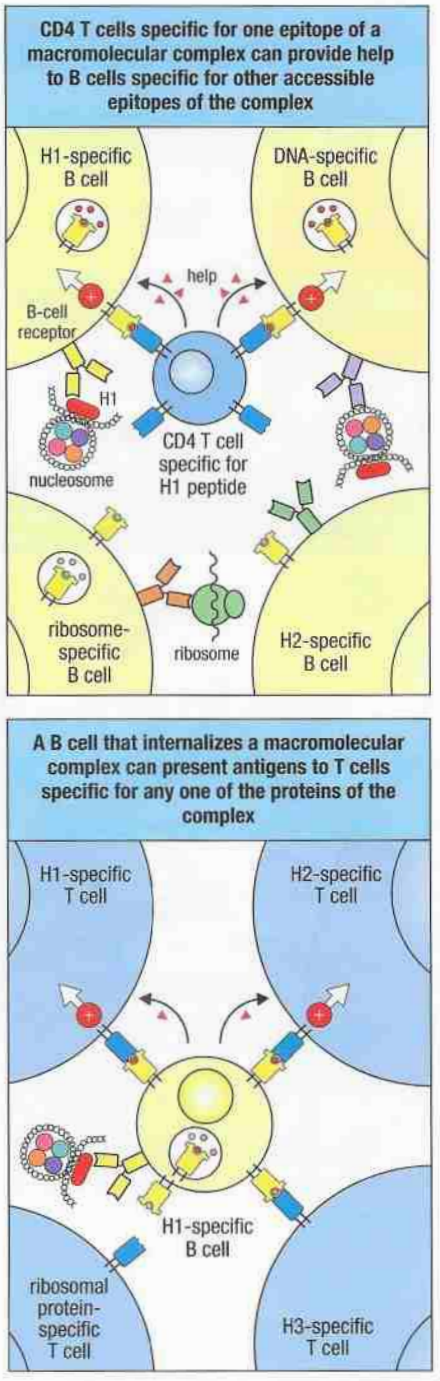
normally kept apart from the immune system. Chronic responses also attract nonspecific effector cells, such as macrophages and neutrophils, which can release cytokines and chemokines from injured tissues, thus further propagating a self-destructive process (Fig. 15.13).

As an autoimmune response progresses, additional clones of lymphocytes are recruited that are reactive to new epitopes of the original autoantigen, as well as to new autoantigens. This phenomenon, known as **epitope spreading**, can occur in several ways. Self antigens that have already induced autoantibodies can be captured and processed by B cells more efficiently for presentation to T cells. Some peptide epitopes that were previously not presented to T cells, called **cryptic epitopes**, may become processed and presented, and then induce additional autoreactive T cells, which may further provide help to any B cells presenting these peptides, enhancing a greater variety of autoantibodies. Further, by binding and internalizing specific antigen via their B-cell receptor, B cells will also internalize any other molecules closely associated with that antigen. By this route, B cells can act as antigen-presenting cells for peptides derived from antigens completely different from the original autoantigen that initiated the autoimmune reaction.

Epitope spreading is illustrated in SLE, in which autoantibodies are eventually produced against both the DNA and protein components of chromatin (Fig. 15.14). The initial autoreactive B cells that are specific for DNA can capture histone proteins, another component of chromatin, and thereby process and present peptide epitopes to T cells. This serves to recruit T cells specific for such epitopes into the autoimmune response. In turn, these T cells provide help not only to the original DNA-specific B cells but also to histone-specific B cells, resulting in the production of both anti-DNA and anti-histone antibodies.

Pemphigus Vulgaris

Epitope spreading is also linked to the progression of the autoimmune disease **pemphigus vulgaris**, characterized by severe blistering of the skin and mucosal membranes. This disease is caused by autoantibodies against desmogleins, a type of cadherin present in cell junctions (desmosomes) that holds cells of the epidermis together (Fig. 15.15). Binding of autoantibodies to the extracellular domains of these adhesion molecules causes dissociation of the junctions and dissolution of the affected tissue. Pemphigus vulgaris usually starts



CD4 T cells specific for one epitope of a macromolecular complex can provide help to B cells specific for other accessible epitopes of the complex
H1-specific B cell
DNA-specific B cell
help
B-cell receptor
H1
nucleosome
CD4 T cell specific for H1 peptide
ribosome-specific B cell
ribosome
H2-specific B cell
A B cell that internalizes a macromolecular complex can present antigens to T cells specific for any one of the proteins of the complex
H1-specific T cell
H2-specific T cell
H1-specific B cell
ribosomal protein-specific T cell
H3-specific T cell

Fig. 15.14 Epitope spreading occurs when B cells specific for various components of a complex antigen are stimulated by an autoreactive helper T cell of a single specificity. In individuals with SLE, an ever-broadening immune response is made against nucleoprotein antigens such as nucleosomes, which consist of histones and DNA and are released from dying and disintegrating cells. The upper panel shows how the emergence of a single clone of autoreactive CD4 T cells can lead to a diverse B-cell response to nucleosome components. The T cell in the center is specific for a particular peptide (red) from the linker histone H1, which is present on the surface of the nucleosome. The B cells at the top are specific for epitopes on the surface of a nucleosome, on histone H1 (left side) and DNA (right side), and thus bind and endocytose intact nucleosomes, process the constituents, and present the H1 peptide to the helper T cell. These B cells will be activated to make antibodies, which in the case of the DNA-specific B cell will be anti-DNA antibodies. The B cell at the bottom right is specific for an epitope on histone H2, which is hidden inside the intact nucleosome and is thus inaccessible to the B-cell receptor. This B cell does not bind the nucleosome and does not become activated by the H1-specific helper T cell. A B cell specific for another type of nucleoprotein particle, the ribosome (which is composed of RNA and specific ribosomal proteins), will not bind nucleosomes (bottom left) and will not be activated by the T cell. In reality, a T cell interacts with one B cell at a time, but different members of the same T-cell clone will interact with B cells of different specificity. The lower panel shows the broadening of the T-cell response to the nucleosome. The H1-specific B cell in the center has processed an intact nucleosome and is presenting a variety of nucleosome-derived peptide antigens on its MHC class II molecules. This B cell can activate a T cell specific for any of these peptide antigens, which will include those from the internal histones H2, H3, and H4 as well as those from H1. This H1-specific B cell will not activate T cells specific for peptide antigens of ribosomes because ribosomes do not contain histones.

with lesions in the oral and genital mucosa; only later does the skin become involved. In the mucosal stage, autoantibodies are directed against only certain epitopes on desmoglein Dsg-3, which seem unable to cause skin blistering. But epitope spreading leads to antibodies against additional regions of Dsg-3 that can cause deep skin blistering and against regions of another desmoglein, Dsg-1, which is more abundant in the epidermis. Dsg-1 is also the autoantigen in a less severe variant of the disease, pemphigus foliaceus. In that disease, the autoantibodies first produced against Dsg-1 cause no damage, and disease appears only after autoantibodies are made against epitopes on parts of the protein involved in the adhesion of epidermal cells.

15-8 Both antibody and effector T cells can cause tissue damage in autoimmune disease.

Historically, the mechanisms of tissue injury in autoimmunity have been classified according to the scheme of 'hypersensitivity' reactions defined by Gell and Coombs in the early 1960s, which we introduced at the beginning of Chapter 14. It is now possible to classify autoimmune diseases using a more modern understanding of immune mechanisms, as illustrated in Fig. 15.16 for several common autoimmune diseases. The dominant effector mechanisms used to clear various types of pathogens are also the ones that become dysregulated in autoimmunity. It is the mechanism by which the antigen-bearing tissues are damaged that determines the nature of the pathology and clinical expression of the disease.

Type 2 immune responses mediated by IgE (previously referred to as type I hypersensitivity) typically cause allergic or atopic inflammatory disease (see Chapter 14) and are not a major component in most forms of autoimmunity. By contrast, antibody-mediated tissue damage, caused either by direct recognition of cell surfaces or extracellular matrix (type II hypersensitivity) or by immune-complex deposition in tissues (type III hypersensitivity), appears to be linked to dysregulated type 3 (T_H17) or type 1 (T_H1) immunity or to T cell–independent generation of IgM-producing B cells. Such diseases can be either organ-specific or systemic, because antibodies can damage specific cell or tissue types (for example, autoimmune thyroiditis), or alternately can result from

Extracellular matrix
Antibodies made against Dsg-1 and Dsg-3 unzip the adhesive interactions in desmosomes

Fig. 15.15 Pemphigus vulgaris is a skin-blistering disease caused by autoantibodies specific for desmoglein. Desmogleins are adhesion molecules in the cell junctions that hold keratinocytes together. They are cell-surface proteins with five extracellular domains (EC1–EC5; upper panel). Early in the autoimmune response, antibodies are made against the EC5 domain of shed desmoglein-3 (Dsg-3) but do not cause disease. However, in time, intramolecular and intermolecular epitope spreading occurs, and IgG antibodies are made against the EC1 and EC2 domains of Dsg-3 and Dsg-1. These autoantibodies can inhibit adhesion of desmoglein in desmosomes (lower panel) and thereby interfere with the physiological adhesive interactions of desmoglein that are necessary for maintaining skin integrity. Consequently, the antibodies cause the outer layers of the skin to separate, producing blisters.

Some common autoimmune diseases classified by immunopathogenic mechanism

Syndrome	Autoantigen	Consequence
Antibody against cell-surface or matrix antigens		
Autoimmune hemolytic anemia	Rh blood group antigens, I antigen	Destruction of red blood cells by complement and FcR^+ phagocytes, anemia
Autoimmune thrombocytopenic purpura	Platelet integrin GpIIb:IIIa	Abnormal bleeding
Goodpasture's syndrome	Noncollagenous domain of basement membrane collagen type IV	Glomerulonephritis, pulmonary hemorrhage
Pemphigus vulgaris	Epidermal cadherin	Blistering of skin
Acute rheumatic fever	Streptococcal cell-wall antigens. Antibodies cross-react with cardiac muscle	Arthritis, myocarditis, late scarring of heart valves
Immune-complex disease		
Mixed essential cryoglobulinemia	Rheumatoid factor IgG complexes (with or without hepatitis C antigens)	Systemic vasculitis
Rheumatoid arthritis	Rheumatoid factor IgG complexes	Arthritis
T cell-mediated disease		
Type 1 diabetes mellitus	Pancreatic β-cell antigen	β-cell destruction
Rheumatoid arthritis	Unknown synovial joint antigen	Joint inflammation and destruction
Multiple sclerosis	Myelin basic protein, proteolipid protein, myelin oligodendrocyte glycoprotein	Brain and spinal cord invasion by CD4 T cells, muscle weakness, and other neurological symptoms
Crohn's disease	Antigens of intestinal microbiota	Regional intestinal inflammation and scarring
Psoriasis	Unknown skin antigens	Inflammation of skin with formation of plaques

Fig. 15.16 Mechanisms of tissue damage in autoimmune diseases. Autoimmune diseases can be grouped according to the predominant type of immune response and the mechanism by which it damages tissues. In many autoimmune diseases, several immunopathogenic mechanisms operate in parallel. This is illustrated here for rheumatoid arthritis, which appears in more than one category of immunopathogenic mechanism.

immune complexes that are deposited in specific vascular beds (for example, rheumatoid arthritis). In some forms of autoimmunity, such as SLE, autoantibodies cause damage by both of these mechanisms. Finally, several organ-specific autoimmune diseases are due to a type 1 immune response in which T_H1 cells and/or cytotoxic T cells directly cause tissue damage (type IV hypersensitivity; for example, type 1 diabetes mellitus); alternatively, some such diseases are due to a type 3 immune response in which T_H17 cells promote inflammation at barrier tissues (for example, psoriasis or Crohn's disease).

In most autoimmune diseases, however, several mechanisms of pathogenesis operate. Thus, helper T cells are almost always required for the production of pathogenic autoantibodies. Reciprocally, B cells often have an important role in the maximal activation of T cells that mediate tissue damage or help autoantibody production. In type 1 diabetes mellitus and rheumatoid arthritis, for example, both T cell–mediated and antibody-mediated pathways cause tissue injury. SLE is an example of autoimmunity that was previously thought to be mediated solely by antibodies and immune complexes but is now known to have a component of T cell–mediated pathogenesis. Moreover, in virtually all autoimmune diseases, innate immune cells contribute to inflammation and antibody-mediated or T cell–mediated tissue injury.

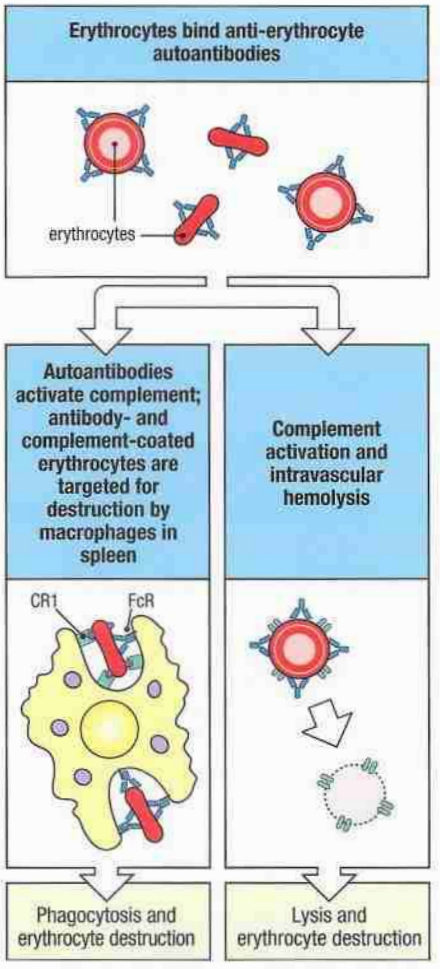
15-9 Autoantibodies against blood cells promote their destruction.

IgG or IgM responses against antigens located on the surface of blood cells lead to their rapid destruction, as occurs in **autoimmune hemolytic anemia**. Red-cell destruction can occur in two ways (Fig. 15.17). First, the IgG or IgM antibody bound to red cells can interact with Fc or complement receptors, respectively, on cells of the mononuclear-macrophage phagocytic system, particularly in the spleen, leading to red-cell clearance from the circulation. Alternatively, the autoantibody-sensitized red blood cells can be lysed by formation of the membrane-attack complex of complement. In **autoimmune thrombocytopenic purpura**, autoantibodies against the GpIIb:IIIa fibrinogen receptor or other platelet-specific surface antigens can cause thrombocytopenia (a depletion of platelets), which can in turn cause hemorrhage.

Lysis of nucleated cells by complement is less common because these cells are better defended by complement-regulatory proteins, which protect cells against immune attack by interfering with the activation of complement components (see Section 2-16). Nevertheless, circulating nucleated cells targeted by autoantibodies are still destroyed by cells of the mononuclear phagocytic system or NK cells via antibody-dependent cell-mediated cytotoxicity (ADCC). Autoantibodies against neutrophils, for example, cause neutropenia, which increases susceptibility to infection with pyogenic bacteria. In all these cases, accelerated clearance of autoantibody-sensitized cells is the cause of their depletion. One therapeutic approach to this type of autoimmunity is removal of the spleen, the organ in which the main clearance of red cells, platelets, and leukocytes occurs. Another is the administration of large quantities of nonspecific IgG (termed IVIG, for intravenous immunoglobulin), which among other mechanisms inhibits the Fc receptor–mediated uptake of antibody-coated cells and activates inhibitory Fc receptors to suppress production of inflammatory mediators by myeloid cells.

15-10 The fixation of sublytic doses of complement to cells in tissues stimulates a powerful inflammatory response.

The binding of IgG and IgM antibodies to cells in tissues causes inflammatory injury by a variety of mechanisms. One of these is the fixation of complement. Although nucleated cells are relatively resistant to lysis by complement, the assembly of sublytic amounts of the membrane-attack complex on their surface provides a powerful activating stimulus. Depending on the cell type, this interaction can cause cytokine release, a respiratory burst, or the mobilization



Erythrocytes bind anti-erythrocyte autoantibodies

Lysis and erythrocyte destruction

Fig. 15.17 Antibodies can destroy red blood cells by clearance and by lysis. In autoimmune hemolytic anemias, red blood cells (erythrocytes) coated with IgG autoantibodies against a cell-surface antigen (upper panel) are rapidly cleared from the circulation by uptake by Fc receptor–bearing macrophages located primarily in the spleen (lower left panel). Erythrocytes coated with IgM autoantibodies fix C3 and are cleared by CR1-bearing macrophages. The binding of certain rare autoantibodies that fix complement extremely efficiently causes the formation of the membrane-attack complex on the red cells, leading to intravascular hemolysis (lower right panel).

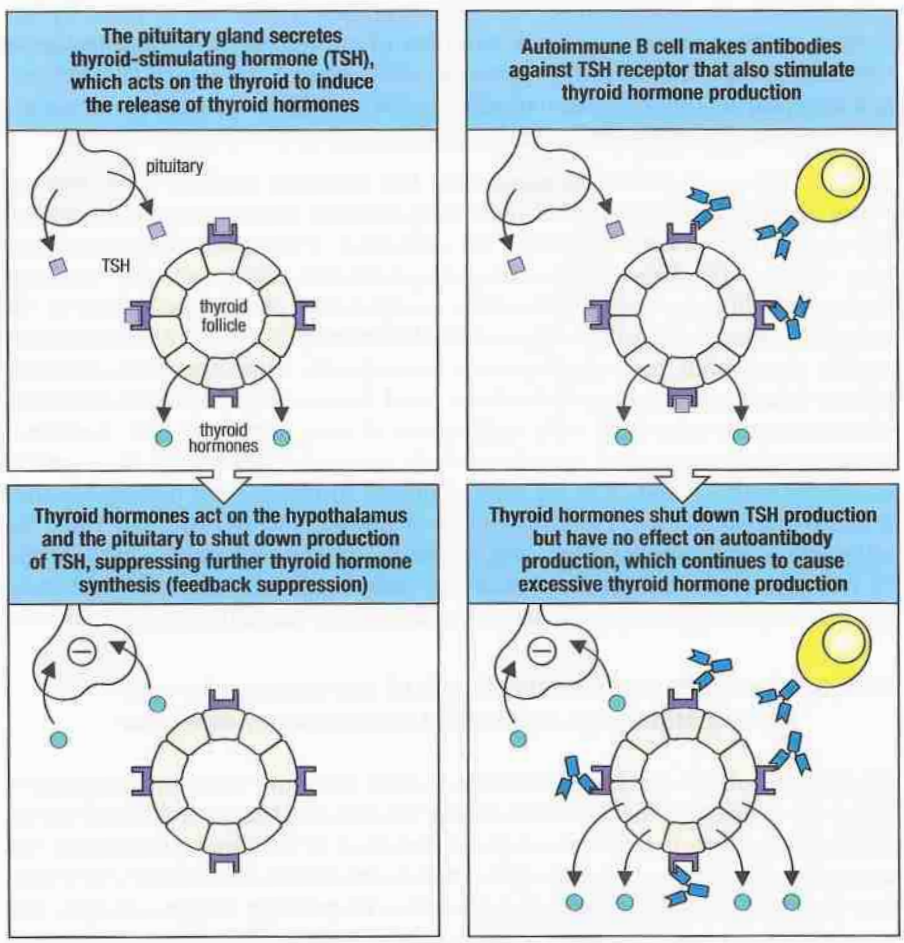
Autoimmune Hemolytic Anemia

of membrane phospholipids to generate arachidonic acid—the precursor of prostaglandins and leukotrienes, lipid mediators of inflammation.

Most cells in tissues are fixed in place, and innate and adaptive immune cells are attracted to them by chemoattractant molecules. One such molecule is the complement fragment C5a, which is released as a result of complement activation triggered by autoantibody binding. Other chemoattractants, such as leukotriene B4, can be released by the autoantibody-targeted cells. Inflammatory leukocytes are further activated by binding to autoantibody Fc regions and fixed complement C3 fragments on cells. Tissue injury can result from the products of the activated leukocytes and by ADCC mediated by NK cells (see Section 10-23). A probable example of this type of autoimmunity is Hashimoto's thyroiditis, in which autoantibodies against tissue-specific antigens are found at extremely high levels for prolonged periods. Direct T cell–mediated cytotoxicity, which we discuss later, is probably also important in this disease.

15-11 Autoantibodies against receptors cause disease by stimulating or blocking receptor function.

Autoimmune disease can occur when autoantibody binds a cell-surface receptor. Antibody binding to a receptor can either stimulate the receptor or block stimulation by the natural ligand. In Graves' disease, autoantibodies against the thyroid-stimulating hormone (TSH) receptor on thyroid cells stimulate excessive production of thyroid hormone. The production of thyroid hormone is normally controlled by feedback regulation; high levels of thyroid hormone inhibit the release of TSH by the pituitary. In Graves' disease, feedback inhibition fails because the autoantibody continues to stimulate the TSH receptor in the absence of TSH, and the individual produces chronically elevated levels of thyroid hormone ('hyperthyroidism'; Fig. 15.18).



The pituitary gland secretes thyroid-stimulating hormone (TSH), which acts on the thyroid to induce the release of thyroid hormones
pituitary
TSH
thyroid follicle
thyroid hormones
Autoimmune B cell makes antibodies against TSH receptor that also stimulate thyroid hormone production
Thyroid hormones act on the hypothalamus and the pituitary to shut down production of TSH, suppressing further thyroid hormone synthesis (feedback suppression)
Thyroid hormones shut down TSH production but have no effect on autoantibody production, which continues to cause excessive thyroid hormone production

Fig. 15.18 Feedback regulation of thyroid hormone production is disrupted in Graves' disease. Graves' disease is caused by autoantibodies specific for the receptor for thyroid-stimulating hormone (TSH). Normally, thyroid hormones are produced in response to TSH and limit their own production by inhibiting the production of TSH by the pituitary gland (left panels). In Graves' disease, the autoantibodies are agonists for the TSH receptor expressed in the thyroid gland and therefore directly stimulate the production of thyroid hormones (right panels). The thyroid hormones inhibit TSH production in the normal way but do not affect production of the autoantibody; the excessive thyroid hormone production induced in this way causes hyperthyroidism.

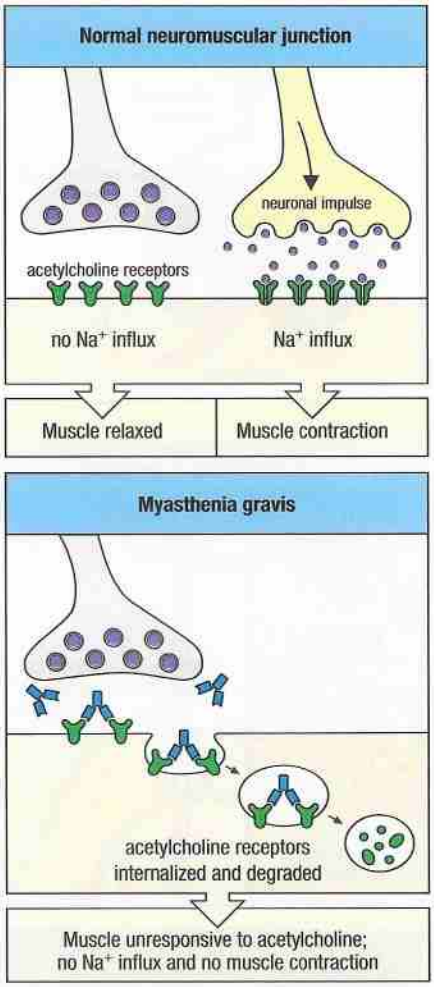


Fig. 15.19 Autoantibodies inhibit receptor function in myasthenia gravis. In normal circumstances, acetylcholine released from stimulated motor neurons at the neuromuscular junction binds to acetylcholine receptors expressed on skeletal muscle cells, triggering muscle contraction (upper panel). Myasthenia gravis is caused by autoantibodies against the α subunit of the receptor for acetylcholine. These autoantibodies bind to the receptor without activating it and also cause the receptor to be internalized and degraded (lower panel). As the number of receptors on the muscle is decreased, the muscle becomes less responsive to acetylcholine, causing weakness.

In myasthenia gravis, autoantibodies against the α chain of the nicotinic acetylcholine receptor present at neuromuscular junctions in skeletal muscle cells can block stimulation of muscle contraction. The antibodies are believed to drive internalization and degradation of the receptor (Fig. 15.19). Individuals with myasthenia gravis develop potentially fatal progressive weakness as a result of their disease. Diseases caused by autoantibodies that act as agonists or antagonists on cell-surface receptors are listed in Fig. 15.20.

15-12 Autoantibodies against extracellular antigens cause inflammatory injury.

Antibody responses to extracellular matrix molecules are infrequent but can be very damaging. In **Goodpasture's syndrome**, antibodies are formed against the α_3 chain of basement membrane collagen (type IV collagen). These antibodies bind to the basement membranes of renal glomeruli (Fig. 15.21) and, in some cases, to the basement membranes of pulmonary alveoli, causing a rapidly fatal disease if untreated. The autoantibodies bound to basement membrane ligate Fcγ receptors on innate effector cells, such as monocytes and neutrophils, leading to their activation. These cells, in turn, release chemokines that attract a further influx of monocytes and neutrophils into glomeruli, causing severe tissue injury. The autoantibodies also cause a local activation of complement, which amplifies tissue injury.

Immune complexes are produced when there is an antibody response to a soluble antigen. Normally, such complexes cause little tissue damage because they are cleared efficiently by red blood cells that bear complement receptors and by phagocytes of the mononuclear phagocytic system that have both complement and Fc receptors. This clearance system can, however, fail in circumstances where the production of immune complexes exceeds the capacity of the normal clearance mechanisms or when there are deficiencies in normal clearance mechanisms. An example of the former is serum sickness (see Section 14-14), which is caused by the injection of large amounts of serum proteins or by small-molecule drugs binding to serum proteins and acting as

Drug-Induced Serum Sickness

Diseases mediated by antibodies against cell-surface receptors

Syndrome	Antigen	Antibody	Consequence	Target cell
Graves' disease	Thyroid-stimulating hormone receptor	Agonist	Hyperthyroidism	Thyroid epithelial cell
Myasthenia gravis	Acetylcholine receptor	Antagonist	Progressive muscle weakness	Muscle
Insulin-resistant diabetes	Insulin receptor	Antagonist	Hyperglycemia, ketoacidosis	All cells
Hypoglycemia	Insulin receptor	Agonist	Hypoglycemia	All cells
Chronic urticaria	Receptor-bound IgE or IgE receptor	Agonist	Persistent itchy rash	Mast cells

Fig. 15.20 Autoimmune diseases caused by autoantibodies against cell-surface receptors. These antibodies produce different effects depending on whether they are agonists (which stimulate the receptor) or antagonists (which inhibit it). Note that different autoantibodies against the insulin receptor can either stimulate or inhibit signaling.

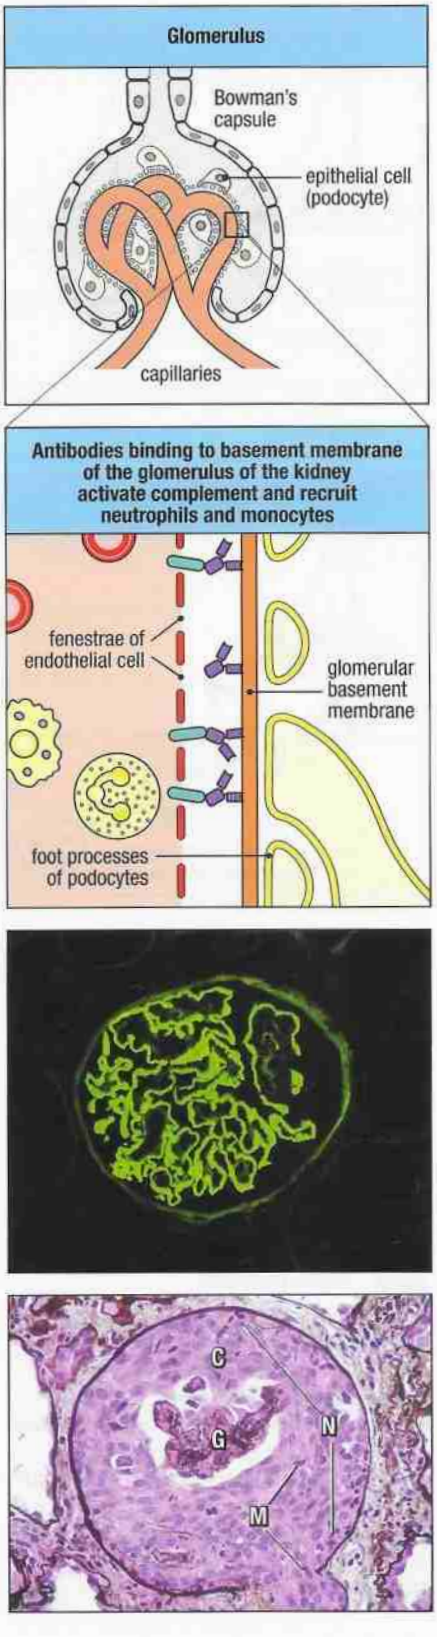

Fig. 15.21 Autoantibodies reacting with glomerular basement membrane cause the inflammatory glomerular disease known as Goodpasture's syndrome. Upper two panels: The autoantibody binds to type IV collagen within the basement membrane of the glomerular capillaries, causing complement activation and recruitment and activation of neutrophils and monocytes. Third panel: In this biopsy from a kidney of an individual with Goodpasture's syndrome, the glomerulus is stained for IgG deposition by immunofluorescence (green) showing the antibody to be deposited in a linear fashion along the glomerular basement membrane. Bottom panel: Silver staining of a section through a renal glomerulus shows that the glomerulus capillaries (G) are compressed by the formation of a crescent (C), composed of proliferating epithelial cells and an influx of neutrophils (N) and monocytes (M), that have filled the urinary (Bowman's) space surrounding the glomerular capillaries.

haptens. Serum sickness is a transient disease, lasting until the immune complexes have been cleared. Similarly, normal clearance mechanisms can be overwhelmed in chronic infections, such as bacterial endocarditis, in which the immune response to bacteria lodged on a cardiac valve is incapable of clearing the infection. The persistent release of bacterial antigens from the valve infection in the presence of a strong antibacterial antibody response causes widespread immune-complex injury to small blood vessels in organs such as the kidney and the skin. Other chronic infections, such as hepatitis C infection, can lead to the production of cryoglobulins and the condition **mixed essential cryoglobulinemia**, in which immune complexes are deposited in joints and tissues. Alternatively, there can be inherited impairment of mechanisms that contribute to normal clearance of immune complexes; such impairment may be caused by reduced expression of or functional defects in specific components of either complement or its receptors or by reduced expression of or functional defects in Fc receptors, each of which occurs in subsets of people with SLE.

Indeed, SLE can result from either the overproduction or the defective clearance of immune complexes, or both, at multiple levels (Fig. 15.22). In this disease, there is chronic IgG antibody production directed at ubiquitous self antigens present in nucleated cells, leading to a wide range of autoantibodies against common cellular constituents. The main antigens are three types of intracellular nucleoprotein particles—the nucleosome subunits of chromatin, the spliceosome, and a small cytoplasmic ribonucleoprotein complex containing two proteins known as Ro and La (named after the first two letters of the surnames of the two individuals in whom autoantibodies against these proteins were discovered). For these autoantigens to participate in immune-complex formation, they must become extracellular. The autoantigens of SLE are exposed on dead and dying cells released from injured tissues.

In SLE, large quantities of antigen are available, so large amounts of small immune complexes are produced continually and are deposited in the walls of small blood vessels in the renal glomerular basement membrane, joints, and other organs (Fig. 15.23). This leads to the activation of phagocytic cells through their Fc receptors. A hereditary deficiency of some complement proteins, specifically those for C1q, C2, and C4, is strongly associated with the development of SLE in humans. C1q, C2, and C4 are early components in the classical complement pathway, which is important in antibody-mediated clearance of apoptotic cells and immune complexes (see Chapter 2). If apoptotic cells and immune complexes are not cleared, the chance that their antigens will activate low-affinity self-reactive lymphocytes in the periphery is increased. The consequent tissue damage releases more nucleoprotein complexes, which in turn form more immune complexes. During this process, autoreactive T cells also become activated, although much less is known about their specificity. Animal models for SLE cannot be initiated without the help of T cells, and T cells can also be directly pathogenic, forming part of the cellular infiltrates in the skin and kidney. As discussed in the next section, T cells contribute to autoimmune disease in two ways: by helping B cells make antibodies, analogous to a normal

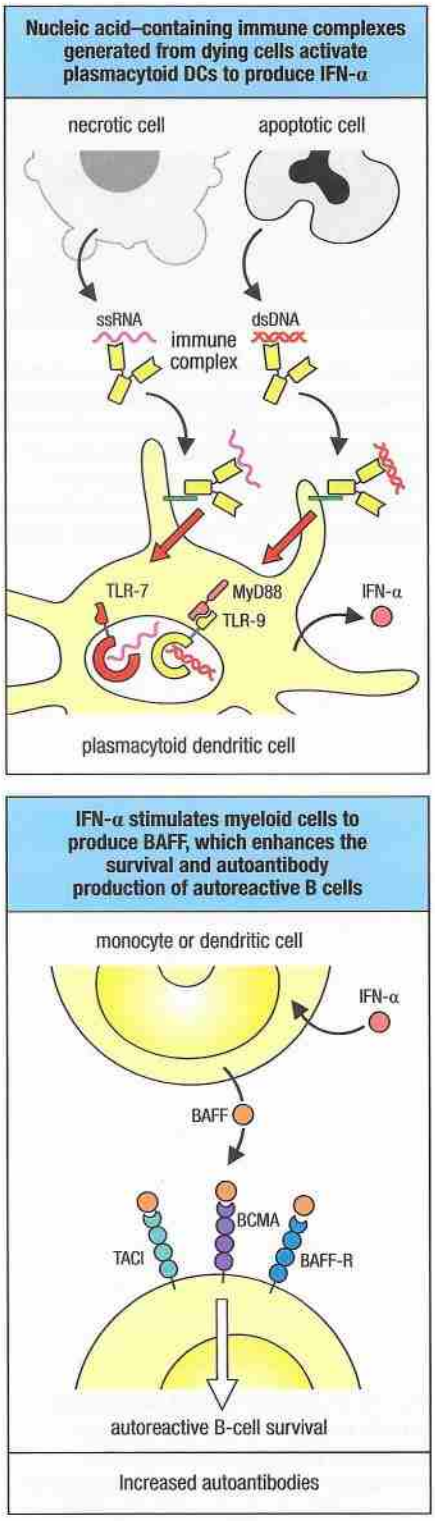

Fig. 15.22 Defective clearance of nucleic acid–containing immune complexes activates overproduction of BAFF and type I interferons that can cause SLE. In SLE, antibody:nucleic acid immune complexes, containing ssRNA or dsDNA from dead cells, are bound by FcγRIIA (green rods) on plasmacytoid dendritic cells. The Fc receptor–bound ssRNA and dsRNA are delivered to endosomes, where they activate TLR-7 and TLR-9, respectively, to induce IFN-α production (upper panel). IFN-α increases BAFF production by monocytes and dendritic cells, and BAFF interacts with receptors on B cells. Excess BAFF can increase autoreactive B-cell survival, leading to increased autoantibody production (lower panel).

T-dependent immune response, and by direct effector functions as they infiltrate and destroy target tissues.

15-13 T cells specific for self antigens can cause direct tissue injury and sustain autoantibody responses.

Traditionally, it has been more difficult to demonstrate the existence of autoreactive T cells than to show the presence of autoantibodies for a number of reasons. First, autoreactive human T cells cannot transfer disease to experimental animals because T-cell recognition is MHC-restricted. Second, autoantibodies can be used to stain self tissues to reveal distribution of the autoantigen, whereas T cells cannot be used in the same way. However, the use of fluorophore-labeled peptide:MHC tetramers (see Appendix I, Section A-24) to stain antigen-specific T cells for flow cytometry provides a means to both identify and track autoreactive T cells *in vivo* in autoimmune diseases. Furthermore, there is already strong evidence for the involvement of autoreactive T cells in many autoimmune diseases. In type 1 diabetes mellitus, for example, the insulin-producing β cells of the pancreatic islets are selectively destroyed by cytotoxic T cells. This is borne out by the finding that in the rare cases in which persons with diabetes were transplanted with half a pancreas from an identical twin donor, the β cells in the grafted tissue were rapidly and selectively destroyed by the recipient's T cells. Recurrence of disease can be prevented by the immunosuppressive drug cyclosporin A (see Chapter 16), which inhibits T-cell activation.

Autoantigens recognized by CD4 T cells can be identified by adding cells or tissues containing autoantigens to cultures of blood mononuclear cells and testing for recognition by CD4 cells derived from an autoimmune individual. If the autoantigen is present, it should be effectively recognized by autoreactive CD4 T cells. The identification of autoantigenic peptides is particularly difficult in autoimmune diseases in which CD8 T cells have a role, because autoantigens recognized by CD8 T cells are not effectively presented in such cultures. Peptides presented by MHC class I molecules must usually be made by the target cells themselves (see Chapter 6); intact cells of target tissue from the individual must therefore be used to study autoreactive CD8 T cells that cause tissue damage. Conversely, the pathogenesis of the disease can itself give clues to the identity of the antigen in some CD8 T cell–mediated diseases. For example, in type 1 diabetes mellitus, the insulin-producing β cells seem to be specifically targeted and destroyed by CD8 T cells (Fig. 15.24). This suggests a protein unique to β cells is the source of the peptide recognized by the pathogenic CD8 T cells. Studies in the NOD (non-obese diabetic) mouse model of type 1 diabetes mellitus have shown that peptides from insulin itself are recognized by pathogenic CD8 T cells, confirming insulin as one of the principal autoantigens in this model of diabetes.

Multiple sclerosis (MS) is a T cell–mediated neurological disease caused by a destructive immune response against central nervous system myelin antigens, including myelin basic protein (MBP; not to be confused with *major basic protein*), proteolipid protein (PLP), and myelin oligodendrocyte

Multiple Sclerosis

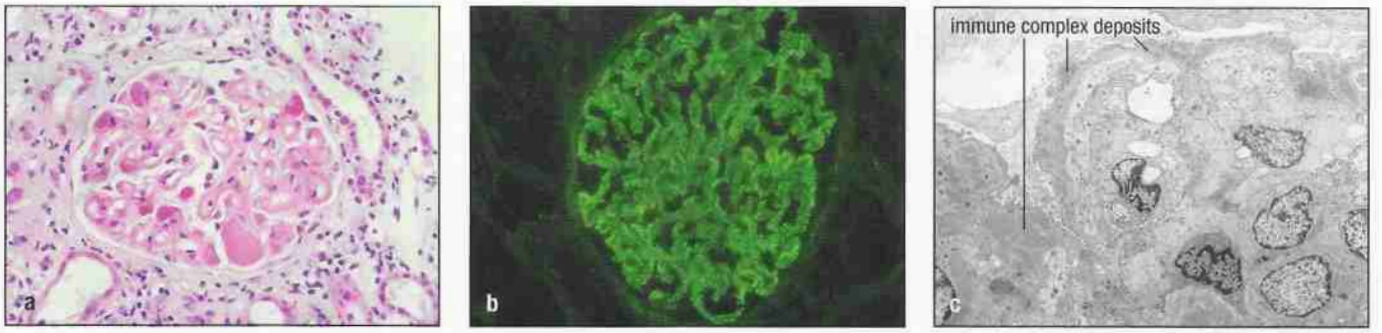

Fig. 15.23 Deposition of immune complexes in the renal glomeruli causes renal failure in systemic lupus erythematosus (SLE). Panel a: A microscopic section stained with hematoxylin and eosin shows a renal glomerulus from an individual with SLE. The deposition of immune complexes has caused thickening of the glomerular basement membrane that appears as the clear 'canals' running through the glomerulus. Panel b: A similar section stained with fluorescently labeled anti-immunoglobulin, revealing immunoglobulin deposits in the basement membrane. Panel c: The immune complexes are seen under the electron microscope as dense protein deposits between the glomerular basement membrane and the renal epithelial cells. Polymorphonuclear neutrophilic leukocytes are also present, attracted by the deposited immune complexes.

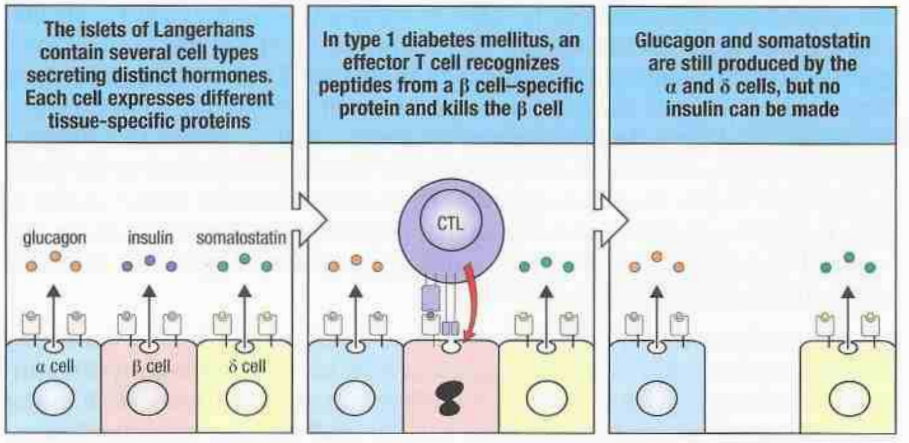
glycoprotein (MOG) (Fig. 15.25). MS takes its name from the hard (sclerotic) lesions, or plaques, that develop in the white matter of the central nervous system. These lesions show dissolution of the myelin sheath that normally surrounds nerve-cell axons, along with inflammatory infiltrates of lymphocytes and macrophages, particularly surrounding blood vessels. People with MS may develop a variety of neurological symptoms, including muscle weakness, ataxia, blindness, and paralysis. Normally, few lymphocytes cross the blood–brain barrier, but if this barrier breaks down, activated CD4 T cells specific for myelin antigens and expressing $\alpha_4\beta_1$ integrin can bind vascular cell adhesion molecules (VCAMs) on activated endothelium (see Section 11-4), enabling the T cells to migrate out of the blood vessel. There they reencounter their specific autoantigen presented by MHC class II molecules on infiltrating macrophages or microglial cells (phagocytic macrophage-like cells resident in the central nervous system). Inflammation causes increased vascular permeability, and the site becomes heavily infiltrated by T_H17 and T_H1 effector CD4 T cells, which produce IL-17, IFN-γ, and GMCSF. Cytokines and chemokines produced by these effector T cells in turn recruit and activate myeloid cells that exacerbate inflammation, resulting in further recruitment of T cells, B cells, and innate immune cells to the lesion. Autoreactive B cells produce autoantibodies against myelin antigens with help from T cells. These combined activities lead to demyelination and interference with neuronal function.



The islets of Langerhans contain several cell types secreting distinct hormones. Each cell expresses different tissue-specific proteins
In type 1 diabetes mellitus, an effector T cell recognizes peptides from a β cell–specific protein and kills the β cell
Glucagon and somatostatin are still produced by the α and δ cells, but no insulin can be made

Fig. 15.25 The pathogenesis of multiple sclerosis (MS). The initiating trigger of MS remains unknown, but its pathophysiology is more clear. At sites of inflammation, activated T cells autoreactive for brain antigens can cross the blood–brain barrier and enter the brain, where they reencounter their antigens on microglial cells and secrete cytokines such as GM-CSF and IFN-γ. The production of cytokines by T cells and macrophages further increases inflammation and recruits additional cells and blood proteins (such as complement) into the affected site. The individual roles of these components in demyelination and loss of neuronal function are still not well understood. CNS, central nervous system.

The clinical course of MS both mirrors what is seen in other autoimmune diseases and also displays how the tissue specificity of such conditions affects their progression. Most people with MS experience a disease course characterized by acute attacks (relapse) followed by a reduction in disease activity (remission) that may last for months or years. This relapsing–remitting course is characteristic of many autoimmune diseases in terms of both the symptoms individuals experience and the degree of immune-cell infiltration into the affected organ. Not only are the triggers of relapses not always clear, but also the events leading to spontaneous disease remission—even when the autoantigen is still present in the organ—remain to be discovered. Furthermore, the relapsing–remitting nature of diseases such as MS makes conducting clinical trials around these disorders especially difficult, as they must be performed over relatively long periods of time to ensure a therapy is effective in preventing relapses and disability.

Ultimately, often after decades, most people with MS change from a relapsing–remitting disease course to 'secondary progressive' MS. In this phase they begin to undergo a steady neurological decline without overt periods of remission, and for many people their disease becomes less responsive to the therapies that effectively target the adaptive immune system in relapsing–remitting MS, although the reasons for this are unclear.

Rheumatoid arthritis (RA) is a chronic disease characterized by inflammation of the synovium (the thin lining of a joint). As disease progresses, the inflamed synovium invades and damages the cartilage; this is followed by bone erosion (Fig. 15.26), leading to chronic pain, loss of function, and disability. RA was first considered an autoimmune disease driven by B cells producing anti-IgG autoantibodies called rheumatoid factor (see Section 15-2). However, the identification of rheumatoid factor in some healthy individuals, and its absence in some individuals with rheumatoid arthritis, suggested that more complex mechanisms orchestrate this pathology. The discovery that RA has an association with particular class II HLA-DR genes of the MHC suggested that T cells are also involved in the pathogenesis of this disease. In RA, as in MS, most data from humans and mouse models indicate that, at least early in disease development, autoreactive T_H17 cells become activated. Autoreactive

Fig. 15.26 The pathogenesis of rheumatoid arthritis. Inflammation of the synovial membrane, initiated by some unknown trigger, attracts autoreactive lymphocytes and macrophages to the inflamed tissue. Autoreactive effector CD4 T cells activate macrophages, and pro-inflammatory cytokines such as IL-1, IL-6, IL-17, and TNF-α are produced. Fibroblasts activated by cytokines produce matrix metalloproteinases (MMPs), which contribute to tissue destruction. The TNF family cytokine RANK ligand (RANKL), expressed by T cells and fibroblasts in the inflamed joint, is the primary activator of bone-destroying osteoclasts. Antibodies against several joint proteins are also produced (not shown), but their role in pathogenesis is uncertain.

T cells provide help to B cells to produce arthritogenic antibodies. The activated T_H17 cells also produce cytokines that recruit neutrophils and monocytes/macrophages, which, along with endothelial cells and synovial fibroblasts, are stimulated to produce more pro-inflammatory cytokines such as TNF-α, IL-1, or chemokines (CXCL8, CCL2), and finally matrix metalloproteinases, which are responsible for tissue destruction. IL-17A, which has been found in high concentrations in the synovium and synovial fluid of people with RA, can induce expression of the ligand for receptor activator of NFκB (RANKL), which stimulates the differentiation of osteoclast precursors into mature osteoclasts that resorb bone in affected joints. Although we do not yet know how RA starts, mouse models have shown that both T cells and B cells are needed to initiate disease. Notably, interrupting this complex cascade at multiple levels—including therapeutic antibodies against cytokines (TNF-α), B cells, and T-cell activation—have all been successful in treating the symptoms of the disease.

Studies of the targets of autoantibodies in RA have yielded insights into how this disease develops and have also identified a more global mechanism by which self proteins may be seen as foreign in other autoimmune conditions. During inflammation, the amino acid arginine can be converted into citrulline, and this change may result in structural alterations of the self protein that cause the immune system to now view it as nonself (Fig. 15.27). Experimental models have shown that antibodies against these altered proteins can be pathogenic, and diagnostic tests for anti-citrullinated protein antibodies (ACPAs) are highly specific for RA. Notably, smoking—long known as the most important environmental risk factor for RA development—has been associated with APCAs in individuals with HLA risk alleles, suggesting that

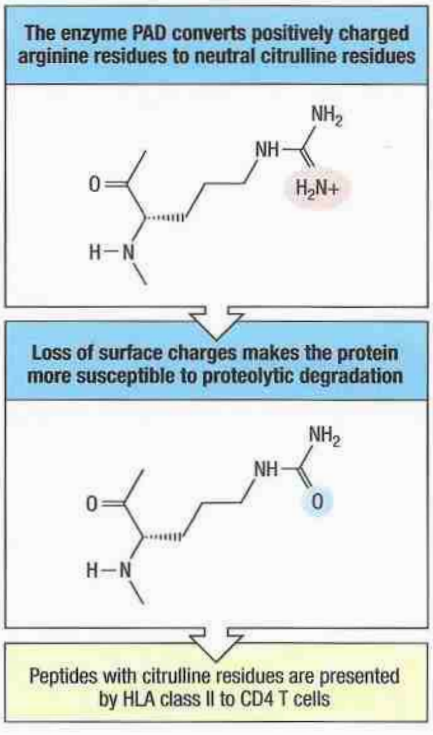

Fig. 15.27 The enzyme peptidyl arginine deiminase converts the arginine residues of tissue proteins to citrulline. In tissues stressed by wounds or infection, peptidyl arginine deiminase (PAD) activity is induced. By converting arginine residues to citrulline, PAD destabilizes proteins and makes them more susceptible to degradation. This also introduces novel B-cell and T-cell epitopes into tissue proteins that can stimulate an autoimmune response.

this tolerance-breaking mechanism may be an important node in the gene–environment interactions that lead to autoimmunity. Finally, other post-translational modifications (oxidation, glycosylation) of self proteins in the periphery have now been shown to stimulate T- and B-cell responses in other autoimmune diseases.

Summary.

Autoimmune diseases can be broadly classified into those that affect a specific organ and those that affect tissues throughout the body. Organ-specific autoimmune diseases include type 1 diabetes mellitus, multiple sclerosis, Graves' disease, and Crohn's disease. In each case the effector functions target autoantigens that are restricted to particular organs—insulin-producing β cells of the pancreas (type 1 diabetes mellitus), the myelin sheathing on axons in the central nervous system (multiple sclerosis), and the thyroid-stimulating hormone receptor (Graves' disease)—or, in the case of Crohn's disease, components of the intestinal microbiota. In contrast, systemic diseases such as systemic lupus erythematosus (SLE) cause inflammation in multiple tissues because their autoantigens, which include chromatin and ribonucleoproteins, are found in most cells of the body. In some organ-specific diseases, immune destruction of the target tissue and the unique self antigens it expresses leads to cessation of autoimmune activity, but systemic diseases tend to be chronically active if untreated, because their autoantigens cannot be cleared.

Another way of classifying autoimmune diseases is according to the effector functions that are most important in pathogenesis. Autoimmune diseases are mediated by autoreactive lymphocytes and their soluble products, pro-inflammatory cytokines, and autoantibodies responsible for inflammation and tissue injury. A few autoimmune diseases are caused by antibodies that bind to cell-surface receptors, causing either excess activity or inhibition of receptor function. In some diseases, transplacental passage of IgG autoantibodies can cause disease in the fetus and neonate. T cells can be involved directly in inflammation or cellular destruction, and they are typically required to initiate and sustain an autoantibody response. Similarly, B cells are important antigen-presenting cells for sustaining autoantigen-specific T-cell responses and causing epitope spreading. It is becoming clear, however, that many diseases once thought to be mediated solely by one effector function actually involve several. In this way, autoimmune diseases resemble pathogen-directed immune responses, which typically elicit the activities of multiple effectors—adaptive and innate. In spite of our knowledge of the mechanisms of tissue damage and the therapeutic approaches that this information has engendered, it remains to be determined how autoimmune responses are induced.

The genetic and environmental basis of autoimmunity.

Given the complex mechanisms that exist to prevent autoimmunity, it is not surprising that autoimmune diseases are the result of multiple factors, both genetic and environmental. We first discuss the genetic basis of autoimmunity, attempting to understand how genetic defects can perturb various tolerance mechanisms. Genetic defects alone are not, however, always sufficient to cause autoimmune disease. Environmental factors also play a part, although these factors are poorly understood. As we shall see, genetic and environmental factors together can overcome tolerance mechanisms and result in disease.

15-14 Autoimmune diseases have a strong genetic component.

It is increasingly clear that susceptibility to acquiring autoimmune diseases has a strong genetic component. Some autoimmune diseases, including type 1 diabetes mellitus, run in families, and most convincingly, if one identical (monozygotic) twin is affected, the other twin is quite likely to be affected as well, whereas concordance of disease is much less in nonidentical (dizygotic) twins. Not surprisingly, a number of autoimmune-like symptoms can be generated in mice by targeted mutations in genes that encode proteins that clear antigen or antigen:antibody complexes or that encode cytokines, co-receptors, co-stimulatory molecules, or proteins involved in apoptosis (Fig. 15.28). It is easy to speculate how alteration in such genes could contribute to autoimmunity, but in most cases a precise explanation is missing. Notably, results from experimental systems do not ensure that similar autoimmune diseases are caused by mutations in the same genes in humans.

In humans, genetic susceptibility to autoimmune disorders has been assessed recently by large-scale **genome-wide association studies (GWASs)**, which we introduced in Section 14-3. These studies look for a correlation between disease frequency and genetic variants, usually **single-nucleotide polymorphisms,** or **SNPs**. Such studies typically involve thousands of people with a given autoimmune disease diagnosis and healthy controls in order to identify highly significant associations. Figure 15.29 shows a 'Manhattan' plot for a GWAS analyzing SNPs associated with Crohn's disease. Resembling a skyscraper skyline, these graphs show strength of association of all genetic loci with a particular disease, specifically plotting the *p* value of the association as a function of the genomic coordinate. Each dot represents one SNP. Hundreds of significant variants have been identified for multiple autoimmune diseases, suggesting that genetic susceptibility to autoimmune disease in humans may be due to a combination of susceptibility alleles at multiple loci.

GWASs have suggested that allelic variation in certain immune pathways may be common to different forms of autoimmunity. For example, type 1 diabetes mellitus, Graves' disease, Hashimoto's thyroiditis, rheumatoid arthritis, and multiple sclerosis all show genetic association with the *CTLA4* locus on chromosome 2. CTLA-4 is expressed on the surface of activated T cells and is an inhibitory receptor for B7 co-stimulatory molecules (see Section 9-17). But it remains unclear how the allelic variations identified by these SNPs contribute directly to autoimmunity. The majority of risk-associated SNPs (>80%) are not contained within exons that encode proteins, but are typically found kilobases away from immunologically relevant genes in intragenic regions that presumably influence the timing or level of gene expression. Figure 15.30 illustrates how various candidate genes collected from different GWASs may influence the effector mechanisms of eight different autoimmune diseases that exhibit characteristics of T_H1 or T_H17 response. This figure illustrates that candidate genes may impact different steps in each of these pathways, may act in either dendritic cells or T cells, and may contribute to more than one disease, in some cases as many as seven different diseases.

15-15 Monogenic defects of immune tolerance.

While many autoimmune diseases are associated with multiple SNPs, there are several monogenic autoimmune diseases in which one mutant allele confers a very high risk of disease to the individual (Fig. 15.31). Such variants are typically rare and have a low overall impact on the population but are of great interest because they identify important pathways normally required to prevent development of autoimmune responses. Monogenic autoimmune disease was first observed in mutant mice in which the inheritance of

Proposed mechanism	Murine models	Disease phenotype	Human gene affected	Disease phenotype
Antigen clearance and presentation	C1q knockout	Lupus-like	*C1QA*	Lupus-like
	C4 knockout		*C2, C4*	
			Mannose-binding lectin	
	AIRE knockout	Multi-organ autoimmunity resembling APECED	*AIRE*	APECED
	Mer knockout	Lupus-like		
Signaling	SHP-1 knockout	Lupus-like		
	Lyn knockout			
	CD22 knockout			
	CD45 E613R point mutation			
	B cells deficient in all Src family kinases (triple knockout)			
	FcγRIIB knockout (inhibitory signaling molecule)		*FCGR2A*	Lupus
Co-stimulatory molecules	CTLA-4 knockout (blocks inhibitory signal)	Lymphocyte infiltration into organs		
	PD-1 knockout (blocks inhibitory signal)	Lupus-like		
	BAFF overexpression (transgenic mouse)			
Apoptosis	Fas knockout (*lpr*)	Lupus-like with lymphocyte infiltrates	*FAS* and *FASL* mutations (ALPS)	Lupus-like with lymphocyte infiltrates
	FasL knockout (*gld*)			
	Bcl-2 overexpression (transgenic mouse)	Lupus-like		
	Pten heterozygous deficiency			
T_{reg} development/ function	*scurfy* mouse	Multi-organ autoimmunity	*FOXP3*	IPEX
	Foxp3 knockout			

Fig. 15.28 Categories of genetic defects that lead to autoimmune syndromes. Many genes have been identified in which mutations predispose to autoimmunity in humans and in animal models. These are best understood by the type of process affected by the genetic defect. Such genes or the related protein are listed in the table according to the immune process they perform. Some of these genes have been identified in both mice and humans. In other cases, different genes affecting the same mechanism are implicated in mice and humans. ALPS, autoimmune lymphoproliferative syndrome; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked.

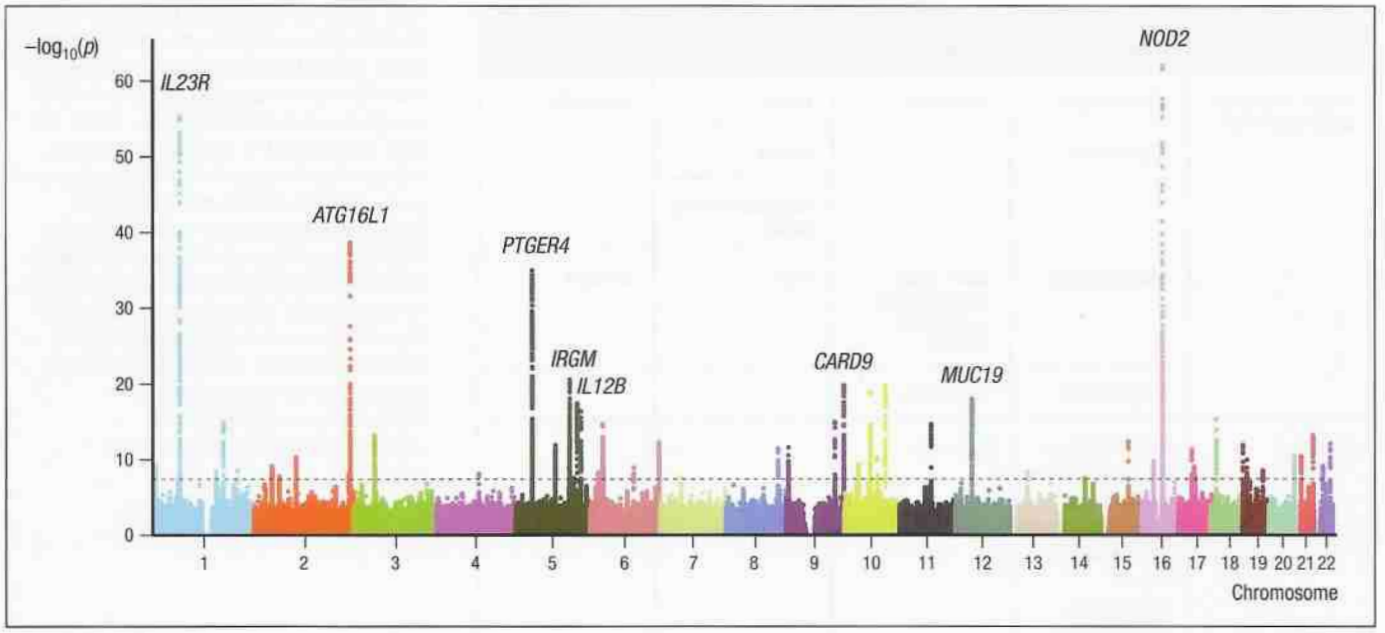

Fig. 15.29 Manhattan plot depicting risk alleles from genome-wide association studies (GWASs) of Crohn's disease. The plot highlights several gene loci identified by analyses of single-nucleotide polymorphisms (SNPs) as being associated with Crohn's disease. Each dot represents an individual SNP. The height of a dot reflects the statistical significance of the association. The horizontal position of a dot represents its genomic location. The dotted line indicates the threshold for significant associations (5×10^{-8}).

an autoimmune syndrome followed a pattern consistent with a single-gene defect. Such alleles are often recessive or X-linked. For example, the disease APECED described in Section 15-1 is a recessive autoimmune disease caused by a defect in the gene *AIRE*.

Immune Dysregulation, Polyendocrinopathy, Enteropathy, X-linked Syndrome

Two monogenic autoimmune syndromes have been linked to defects in regulatory T cells. The X-linked recessive autoimmune syndrome **IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked)** is typically caused by missense mutations in the gene encoding the transcription factor FoxP3, which is key in the differentiation and function of some types of T_{reg} cells (see Section 9-15). This disease is characterized by severe allergic inflammation, autoimmune polyendocrinopathy, secretory diarrhea, hemolytic anemia, and thrombocytopenia and usually leads to early death. Despite mutation of the gene *FOXP3*, the number of FoxP3$^+$ T_{reg} cells in the blood of individuals with IPEX is comparable to the number in healthy individuals; however, the suppressive function normally displayed by these cells is impaired. A spontaneous frameshift mutation in the mouse gene *Foxp3* (the *scurfy* mutation) that results in loss of the DNA-binding domain of FoxP3 or complete knockout of *Foxp3* leads to an analogous systemic autoimmune disease, in this case associated with the absence of FoxP3$^+$ T_{reg} cells.

Autoimmunity caused by defective development and survival of T_{reg} cells also results from mutation of the gene *IL2RA*, which encodes CD25, the high-affinity chain of the IL-2 receptor complex that is constitutively expressed by T_{reg} cells (see Section 9-10). Because deficiency of CD25 affects the development and function of effector T cells as well, in addition to autoimmunity, persons affected by this mutation suffer multiple immunological deficiencies and susceptibility to infections. These findings further confirm the importance of T_{reg} cells in the regulation of the immune system.

Autoimmune Lymphoproliferative Syndrome (ALPS)

An interesting case of a monogenic autoimmune disease is **autoimmune lymphoproliferative syndrome (ALPS)**, a systemic autoimmune syndrome caused by mutations in the gene encoding Fas. Fas is normally present on the surface of

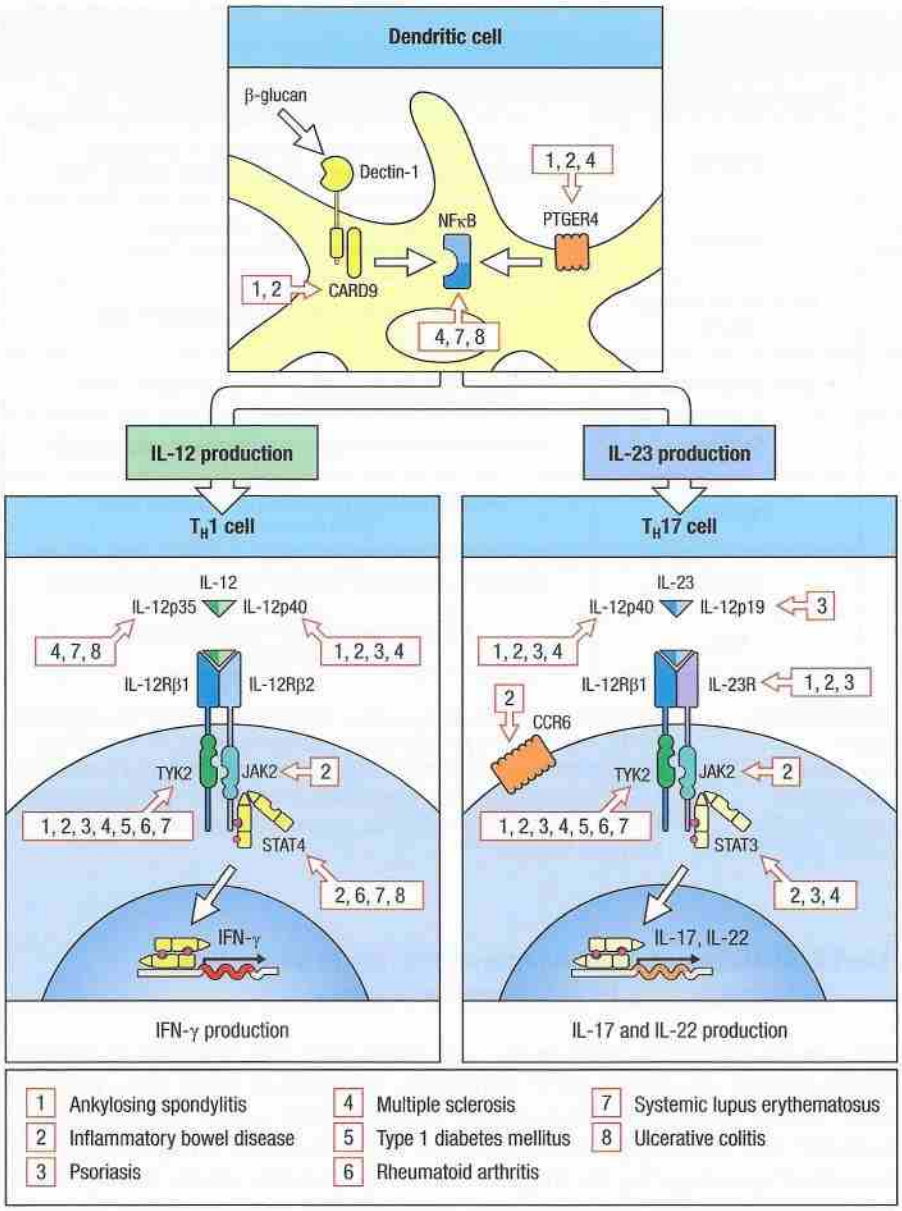

Fig. 15.30 Associations of components of the IL-12R and IL-23R response pathways with autoimmune diseases. Multiple components of the interleukin-12 receptor (IL-12R) and IL-23 receptor (IL-23R) response pathways show significant genome-wide associations with a broad range of immune-mediated diseases; that is, these components map within genomic intervals that are associated with the respective disease in genome-wide association studies. Although this figure shows these components in the conventional context of T helper 1 (T_H1) and T_H17 lymphocytes, it is now recognized that they are widely expressed in innate lymphoid cells, and the specific cell type may vary from phenotype to phenotype.

activated T and B cells, and when ligated by Fas ligand, it signals the Fas-bearing cell to undergo apoptosis (see Section 11-16). In this way it functions to limit the extent of immune responses. Mutations that eliminate or inactivate Fas lead in humans to a massive accumulation of lymphocytes, especially T cells, and in mice to the production of large quantities of pathogenic autoantibodies and a disease that resembles SLE. A mutation leading to this autoimmune syndrome was first observed in the MRL mouse strain and named *lpr*, for lymphoproliferation; it was subsequently identified as a mutation in *Fas*. The study of human individuals with the rare autoimmune lymphoproliferative syndrome, which is similar to the syndrome in the MRL/*lpr* mice, led to the identification of *FAS* as the mutant gene responsible for most of these cases (see Fig. 15.31).

Single-gene traits associated with autoimmunity			
Gene	**Human disease**	**Mouse mutant or knockout**	**Mechanism of autoimmunity**
AIRE	APECED (APS-I)	Knockout	Decreased expression of self antigens in the thymus, resulting in defective negative selection of self-reactive T cells
CTLA4	Association with Graves' disease, type 1 diabetes mellitus, and others	Knockout	Failure of T-cell anergy and reduced activation threshold of self-reactive T cells
FOXP3	IPEX	Knockout and mutation (*scurfy*)	Decreased function of CD4 CD25 regulatory T cells
FAS	ALPS	*lpr/lpr; gld/gld* mutants	Failure of apoptotic death of self-reactive B and T cells
C1q	SLE	Knockout	Defective clearance of immune complexes and apoptotic cells
ATG16L1	IBD	Hypomorph	Defective autophagy/clearance of bacteria by innate cells in intestines
IL10RA, IL10RB	IBD	Knockout	Defective IL-10 signaling; impaired anti-inflammatory response
INS	Type 1 diabetes mellitus	None	Decreased expression of insulin in thymus; impaired negative selection

Fig. 15.31 Single-gene traits associated with autoimmunity. Listed are examples of monogenic disorders that cause autoimmunity in humans. Mice with targeted deletions (knockout) or spontaneous mutations (for example, *lpr/lpr*) in homologous genes have similar disease characteristics and are useful models for the study of the pathogenic basis for these disorders. APECED, autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy; APS-I, autoimmune polyglandular syndrome type I; IPEX, immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome; ALPS, autoimmune lymphoproliferative syndrome. The *lpr* mutation in mice affects the gene for Fas, whereas the *gld* mutation affects the gene for FasL.

15-16 MHC genes have an important role in controlling susceptibility to autoimmune disease.

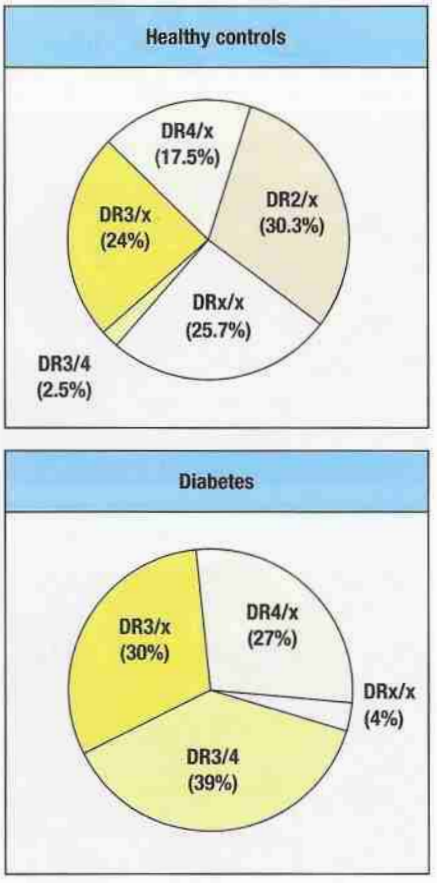
The genetic loci most consistently associated with susceptibility to autoimmune disease are certain MHC genotypes, particularly MHC class II alleles (Fig. 15.32). Recall from Section 6-11 that the MHC genes are highly polymorphic and have hundreds of different allelic variants. This association is identified by comparing the frequencies of various MHC alleles in individuals having a disease with the frequencies in the normal population. For example, HLA-DR3 and HLA-DR4 alleles are much more prevalent in individuals with type 1 diabetes mellitus than in the general population (Fig. 15.33). Similar analysis shows that the MHC class II allele HLA-DR2 has a dominant protective effect: individuals carrying HLA-DR2, even in association with one of the susceptibility alleles, rarely develop diabetes. It has also been shown that two siblings affected with the same autoimmune disease are far more likely than expected to share the same MHC haplotypes (Fig. 15.34). As HLA genotyping has become more exact through DNA sequencing, disease associations originally discovered by serotyping have been defined more precisely. For example, the association between type 1 diabetes mellitus and the DR3 and DR4 alleles is now known to be due to their tight genetic linkage to DQβ alleles that confer susceptibility to the disease. Indeed, susceptibility is most closely associated with polymorphisms at a particular position in the DQβ amino acid sequence that affect the peptide-binding cleft of MHC class II (Fig. 15.35). The diabetes-prone NOD strain of mice also has a serine residue polymorphism at that same position in the homologous mouse MHC class II molecule, known as I-A^{g7}.

The association of MHC genotype with autoimmune disease may result from allelic variants having different abilities to bind antigenic self peptides,

HLA- and gender-associated risk for autoimmune disease			
Disease	**HLA allele**	**Relative risk**	**Sex ratio ♀:♂**
Ankylosing spondylitis	B27	87.4	0.3
Type 1 diabetes mellitus	DQ2 and DQ8	~25	~1
Goodpasture's syndrome	DR2	15.9	~1
Pemphigus vulgaris	DR4	14.4	~1
Autoimmune uveitis	B27	10	<0.5
Psoriasis vulgaris	CW6	7	~1
Systemic lupus erythematosus	DR3	5.8	10–20
Addison's disease	DR3	5	~13
Multiple sclerosis	DR2	4.8	10
Rheumatoid arthritis	DR4	4.2	3
Graves' disease	DR3	3.7	4–5
Hashimoto's thyroiditis	DR5	3.2	4–5
Myasthenia gravis	DR3	2.5	~1
Type 1 diabetes mellitus	DQ6	0.02	~1

Fig. 15.32 Associations of HLA and sex with susceptibility to autoimmune disease. The 'relative risk' for an HLA allele in an autoimmune disease is calculated by comparing the observed number of individuals carrying the HLA allele with the number that would be expected, given the prevalence of the HLA allele in the general population. For type 1 diabetes mellitus (insulin-dependent diabetes mellitus), the association is in fact with the HLA-DQ gene, which is tightly linked to the DR genes but is not detectable by serotyping. Some diseases show a significant bias in the sex ratio; this is taken to imply that sex hormones are involved in pathogenesis. Consistent with this association, the difference in the sex ratio in these diseases is greatest between menarche and menopause, when levels of such hormones are highest.

consistent with the involvement of T cells in particular diseases. In diabetes, for example, there are associations with both MHC class I and MHC class II alleles, consistent with the finding that both CD8 and CD4 T cells mediate the autoimmune response. Evidence suggests that this explanation applies to the activation of insulin peptide-reactive T cells in the NOD strain of mice. An alternative hypothesis proposes that self peptides associated with certain MHC molecules may drive the positive selection of developing thymocytes that are specific for particular autoantigens. Such autoantigenic peptides might be expressed at too low a level or bind too poorly to MHC molecules to drive thymic negative selection but might be present at a sufficient level or bind strongly enough to drive positive selection.



15-17 Genetic variants that impair innate immune responses can predispose to T cell–mediated chronic inflammatory disease.

Section 15-5 introduced Crohn's disease (CD) as one of two major types of inflammatory bowel disease. CD is thought to result from abnormal hyper-responsiveness of CD4 T cells to antigens of the commensal gut microbiota

Fig. 15.33 Population studies show association of susceptibility to type 1 diabetes mellitus with HLA genotype. The HLA genotypes (determined by serotyping) of individuals with diabetes (lower panel) are not representative of those found in the general population (upper panel). Almost all individuals with diabetes express HLA-DR3 and/or HLA-DR4, and HLA-DR3/DR4 heterozygosity is greatly overrepresented in diabetics compared with controls. These alleles are linked tightly to HLA-DQ alleles that confer susceptibility to type 1 diabetes mellitus. By contrast, HLA-DR2 protects against the development of diabetes and is found only extremely rarely in individuals with diabetes. The small letter 'x' represents any allele other than DR2, DR3, or DR4.

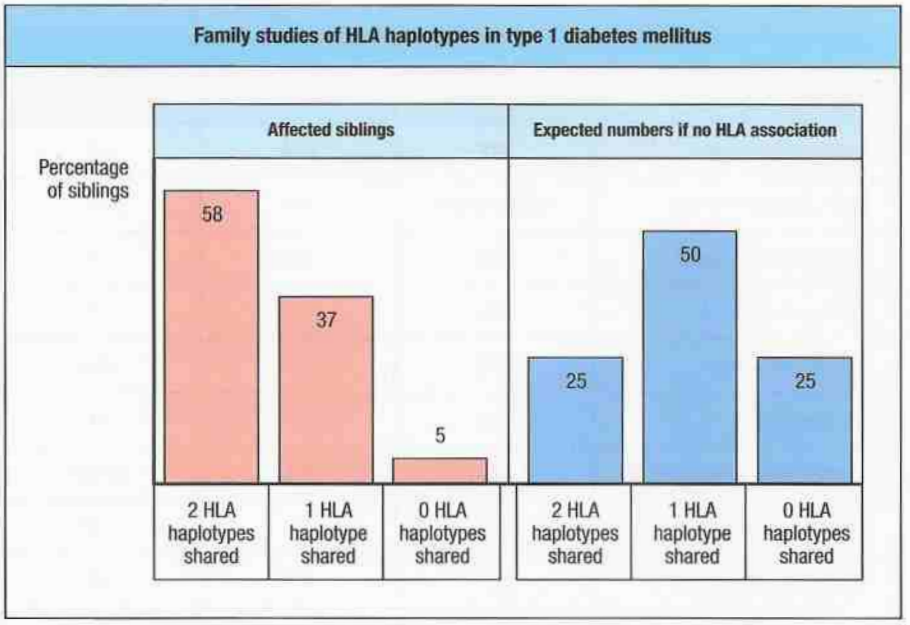


Fig. 15.34 Family studies show strong linkage of susceptibility to type 1 diabetes mellitus with HLA genotype. In families in which two or more siblings have type 1 diabetes mellitus, it is possible to compare the HLA genotypes of affected siblings. Affected siblings share two HLA haplotypes much more frequently than would be expected if the HLA genotype did not influence disease susceptibility.

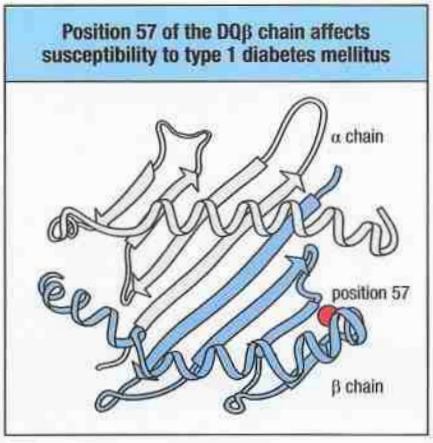

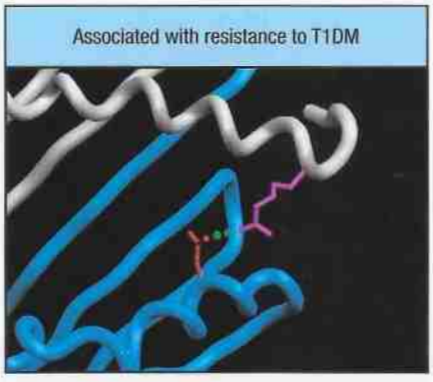

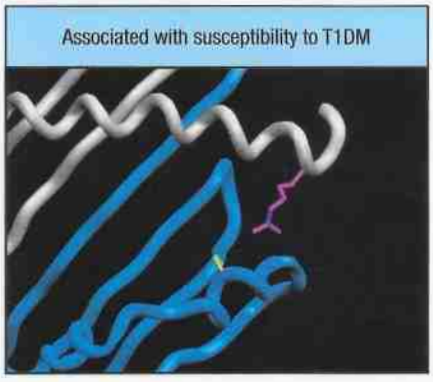

rather than to true self antigens. Dysregulation of T_H17 and T_H1 cells is thought to be pathogenic. Individuals with CD have episodes of severe inflammation that commonly affect the terminal ileum, with or without involvement of the colon—hence the alternative name 'regional ileitis' for this disease—but any part of the gastrointestinal tract can be involved. The disease is characterized by chronic inflammation and granulomatous lesions in the mucosa and submucosa of the intestine. Disease may result from a failure of mucosal innate immune mechanisms to sequester luminal bacteria from the adaptive immune system, from T cell–intrinsic defects that cause heightened effector responses, or from failure of T_{reg} cells to suppress microbiota-reactive T_H17 and T_H1 cells (Fig. 15.36).

Genetic analysis of people with CD and their families has identified a growing list of disease-susceptibility genes (see Fig. 15.29). One of the earliest to be identified was *NOD2* (also known as *CARD15*), which is expressed predominantly in monocytes, dendritic cells, and the Paneth cells of the small intestine and is involved in recognition of microbial antigens as part of the innate immune response (see Section 3-8). Mutations and rare polymorphic variants in NOD2 are strongly associated with CD. Mutations in the same gene are also the cause of a dominantly inherited granulomatous disease named **Blau syndrome**, in which granulomas typically develop in the skin, eyes, and joints. Whereas CD results from a loss of function of NOD2, it is thought that Blau syndrome results from a gain of function.

Fig. 15.35 Amino acid changes in the sequence of an MHC class II protein correlate with susceptibility to and protection from diabetes. The HLA-$DQ\beta_1$ chain contains an aspartic acid (Asp) residue at position 57 in most people. In Caucasoid populations, individuals with type 1 diabetes mellitus (T1DM) more often have valine, serine, or alanine at this position instead, as well as other differences. Asp57, shown in red on the backbone structure of the DQβ chain in the top panel, forms a salt bridge (shown in green in the center panel) to an arginine residue (shown in pink) in the adjacent α chain (gray). The change to an uncharged residue (for example, alanine, shown in yellow in the bottom panel) disrupts this salt bridge, altering the stability of the DQ molecule. The non-obese diabetic (NOD) strain of mice, which develops spontaneous diabetes, has a similar substitution of serine for the aspartic acid at position 57 of the homologous I-Aβ chain, and NOD mice transgenic for β chains with Asp57 have a marked reduction in diabetes incidence.

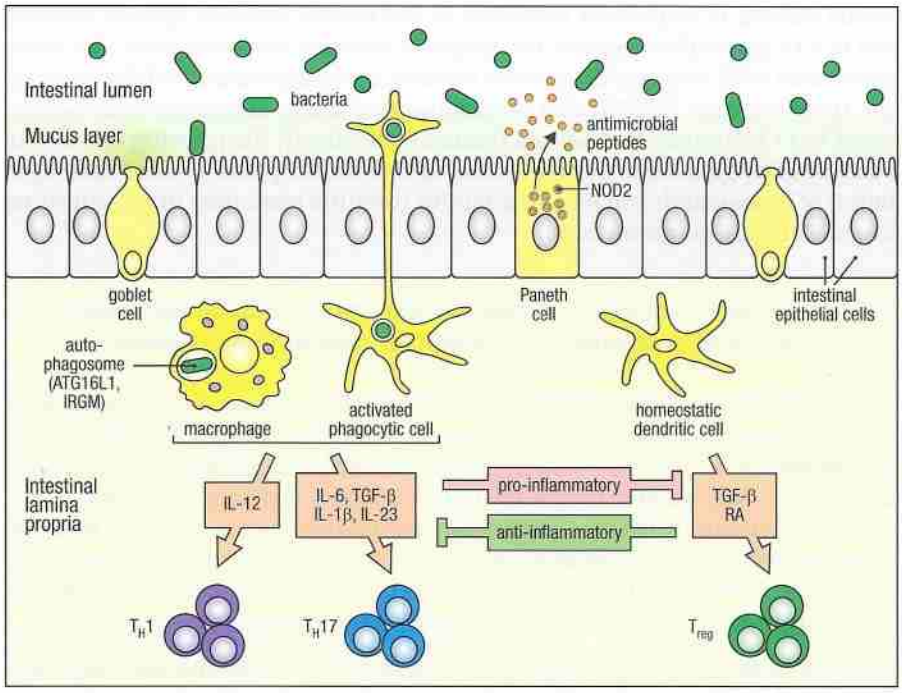

Fig. 15.36 Crohn's disease results from a breakdown of the homeostatic mechanisms that normally limit inflammatory responses to gut microbiota. The innate and adaptive immune systems normally cooperate to limit inflammatory responses to intestinal bacteria through a combination of mechanisms: a mucus layer produced by goblet cells; tight junctions between the intestinal epithelial cells; antimicrobial peptides released from epithelial cells and Paneth cells; and induction of T_{reg} cells that inhibit effector CD4 T-cell development and promote the production of IgA antibodies that are transported into the intestinal lumen, where they inhibit translocation of intestinal bacteria (not shown). In individuals with impaired homeostatic mechanisms, dysregulated T_H1- and T_H17-cell responses to the intestinal microbiota can result, generating disease-causing chronic inflammation. Crohn's disease susceptibility genes of innate immunity include *NOD2* and the autophagy genes *ATG16L1* and *IRGM*. A major susceptibility gene that affects adaptive immune cells is *IL23R*, which is expressed by T_H17 cells (see also Fig. 15.30). RA, retinoic acid.

NOD2 is an intracellular receptor for the muramyl dipeptide derived from bacterial peptidoglycan, and its stimulation activates the transcription factor NFκB and the expression of genes encoding pro-inflammatory cytokines and chemokines (see Section 3-10 and Fig. 12.38). In Paneth cells—specialized intestinal epithelial cells in the base of the small intestinal crypts—activation of NOD2 stimulates the release of granules containing antimicrobial peptides that help sequester commensal bacteria to the intestinal lumen, away from the adaptive immune system. Mutant forms of NOD2 that have lost this function limit this innate antibacterial response, thereby predisposing the individual to heightened effector CD4 T-cell responses to the commensal microbiota and consequent chronic intestinal inflammation (see Sections 3-10 and 12-17).

ANIMATION 15.1

Crohn's Disease

In addition to NOD2, other deficiencies in innate immunity have been identified in people with CD, including defective CXCL8 production and neutrophil accumulation, which can synergize with NOD2 defects to promote intestinal inflammation. Thus, compound defects in innate immunity and the regulation of inflammation may act synergistically to promote immunopathology in CD. Other candidate genes for CD may be linked to impaired innate immune functions (see Fig. 15.29). Defects in two genes (*ATG16L1* and *IRGM*) that contribute to autophagy have been linked to CD, suggesting that clearance of phagocytosed bacteria might be impaired, and thus predispose to chronic intestinal inflammation (see Section 6-6).

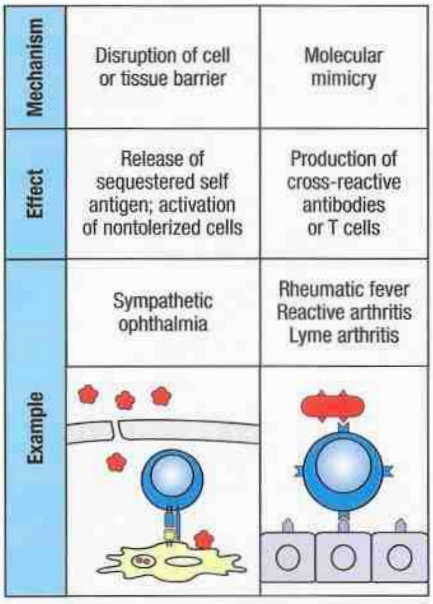

Fig. 15.37 Infectious agents could break self-tolerance in several different ways. Left panels: Some antigens are sequestered from the circulation, either behind a tissue barrier or retained within a cell. An infection can disrupt tissue barriers and damage cells, exposing hidden antigens to the immune system. Right panels: Molecular mimicry might result in infectious agents inducing either T- or B-cell responses that can cross-react with self antigens.

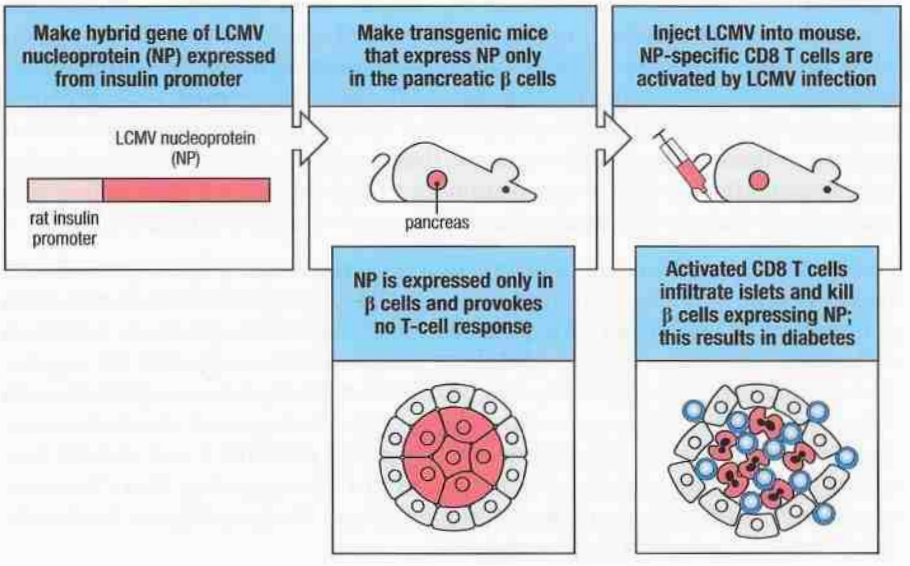
While defects in important pathways of the innate immune system contribute to CD, genes that regulate the adaptive immune response have also been associated with susceptibility. Most notably, there are variants of the gene for the IL-23 receptor (*IL23R*) that predispose to disease, consistent with heightened T_H17 responses in diseased tissues. Collectively, the growing number of susceptibility genes that confer increased risk for CD point to abnormal regulation of homeostatic innate and adaptive immune responses to the intestinal microbiota as a common factor.

15-18 Cross-reactivity between foreign molecules on pathogens and self molecules can promote autoimmune disease.

During infections, inflammatory mediators are released from antigen-presenting cells and lymphocytes. These can activate so-called bystander cells, which are lymphocytes that are not themselves specific for the antigens of the infectious agent. Self-reactive lymphocytes can become activated in these circumstances, particularly if tissue destruction by the infection leads to an increase in the availability of the self antigen (Fig. 15.37, left panels). Pro-inflammatory cytokines, such as IL-1 and IL-6, can also reduce the suppressive activity of regulatory T cells, further allowing an autoimmune response.

Infection with certain pathogens is associated with autoimmune sequelae. Some pathogens express antigens that resemble host molecules, a phenomenon called **molecular mimicry**. In such cases, antibodies produced against a pathogen epitope may cross-react with a self molecule (see Fig. 15.37, right panels). Such structures do not necessarily have to be identical: it is sufficient that they be similar enough to be recognized by the same antibody. Molecular mimicry may also activate autoreactive T cells and result in an attack on self tissues if a processed peptide from a pathogen antigen is similar to a host peptide. A model system to demonstrate molecular mimicry has been generated by using transgenic mice expressing a viral antigen in the pancreas. Normally, there is no response to this virus-derived 'self' antigen, but upon infection with the virus that was the source of the transgenic antigen, mice develop diabetes, because the virus activates T cells that are cross-reactive with the 'self' viral antigen (Fig. 15.38).

Some examples of autoimmune syndromes thought to involve molecular mimicry are the **rheumatic fever** that sometimes follows streptococcal infection and the reactive arthritis that can occur after enteric infection. Once self-reactive lymphocytes have been activated by such a mechanism, their effector



Make hybrid gene of LCMV nucleoprotein (NP) expressed from insulin promoter
LCMV nucleoprotein (NP)
rat insulin promoter

pancreas
Inject LCMV into mouse. NP-specific CD8 T cells are activated by LCMV infection
NP is expressed only in β cells and provokes no T-cell response
Activated CD8 T cells infiltrate islets and kill β cells expressing NP; this results in diabetes

Fig. 15.38 Virus infection can break tolerance to a transgenic viral protein expressed in pancreatic β cells. Mice made transgenic for the lymphocytic choriomeningitis virus (LCMV) nucleoprotein under the control of the rat insulin promoter express the nucleoprotein in their pancreatic β cells but do not respond to this protein and therefore do not develop an autoimmune diabetes. However, if the transgenic mice are infected with LCMV, a potent antiviral cytotoxic T-cell response is elicited, and this kills the β cells, leading to diabetes. It is thought that infectious agents can sometimes elicit T-cell responses that cross-react with self peptides (a process known as molecular mimicry) and that this could cause autoimmune disease in a similar way.

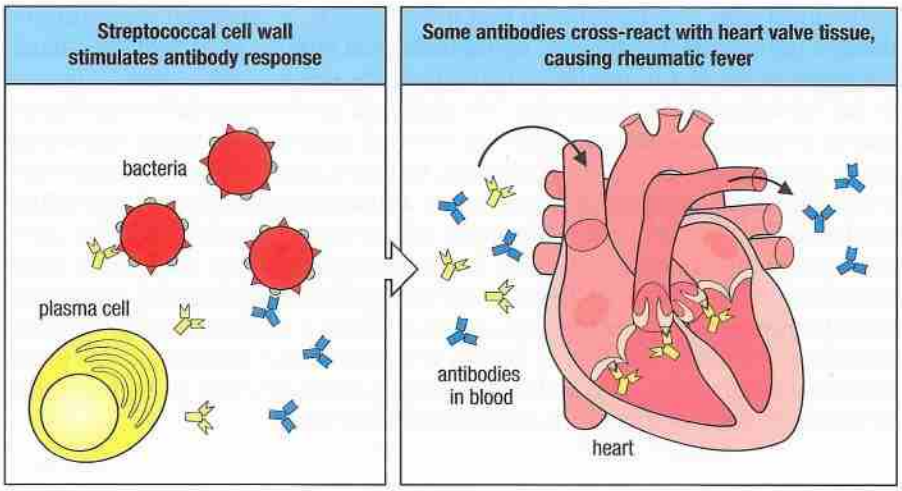

Fig. 15.39 Antibodies against streptococcal cell-wall antigens cross-react with antigens on heart tissue. The immune response to the bacteria produces antibodies against various epitopes of the bacterial cell surface. Some of these antibodies (yellow) cross-react with the heart valves, whereas others (blue) do not. An epitope in the heart (orange) is structurally similar but not identical to a bacterial epitope (red).

functions can destroy tissues. Autoimmunity of this type is sometimes transient and remits when the inciting pathogen is eliminated. This is the case in the autoimmune hemolytic anemia that follows *Mycoplasma* infection. The anemia ensues when antibodies against the pathogen cross-react with an antigen on red blood cells, leading to hemolysis (see Section 15-9). The autoantibodies disappear when the individual recovers from the infection. Sometimes, however, the autoimmunity persists well beyond the initial infection. This is true in some cases of rheumatic fever (Fig. 15.39), which occasionally follows a sore throat, scarlet fever, or local skin infections (impetigo) caused by *Streptococcus pyogenes*. The similarity of epitopes on streptococcal antigens to self epitopes leads to antibody-mediated, and possibly T cell–mediated, damage to a variety of tissues, including heart valves and the kidney. Although the tissue injury is typically transient, especially with antibiotic treatment, it can become chronic. Similarly, Lyme disease, an infection with the spirochete *Borrelia burgdorferi*, can be followed by late-developing autoimmunity (Lyme arthritis). In this case, the mechanism is not entirely clear, but it is likely to involve cross-reactivity of pathogen and host components, leading to autoimmunity.

Finally, certain external causative agents can result in human autoimmunity, specifically certain drugs that can elicit autoimmune reactions in a small proportion of individuals. Procainamide, a drug used to treat heart arrhythmias, is notable for inducing autoantibodies similar to those in SLE, although these are rarely pathogenic. Several drugs are associated with the development of autoimmune hemolytic anemia, in which autoantibodies against surface components of red blood cells attack and destroy these cells (see Section 15-9). Toxins in the environment can also cause autoimmunity. When heavy metals, such as gold or mercury, are administered to susceptible strains of mice, a predictable autoimmune syndrome, including the production of autoantibodies, ensues. The extent to which heavy metals promote autoimmunity in humans is unclear, but the animal models show that environmental factors such as toxins could have roles in certain syndromes. The mechanisms by which drugs and toxins cause autoimmunity are uncertain. Some drugs are thought to react chemically with self proteins and form derivatives that the immune system recognizes as foreign. The immune response to these haptenated self proteins can lead to inflammation, complement deposition, destruction of tissue, and finally immune responses to the original self proteins.

Autoimmune Hemolytic Anemia

Summary.

The specific causes of most autoimmune diseases are not known. Genetic risk factors, including particular alleles of MHC class II molecules and polymorphisms or mutations of other genes, have been identified, but many

individuals with genetic variants that predispose to a particular autoimmune disease do not get the disease. Epidemiological studies of genetically identical populations of animals have highlighted the role of environmental factors in the initiation of autoimmunity, but although environmental factors have a strong influence on disease, they are not well understood. Some toxins and drugs are known to cause autoimmunity, but their role in the common autoimmune diseases is unclear. Similarly, some autoimmune syndromes can follow viral or bacterial infections. Pathogens can promote autoimmunity by causing nonspecific inflammation and tissue damage and can sometimes elicit responses to self proteins if they express molecules resembling self, a phenomenon known as molecular mimicry. More research is needed to define specific contributions of environmental factors to autoimmune diseases. It may prove that most diseases are triggered not by a single environmental factor but rather by a combination of triggers or even random events.

Responses to alloantigens and transplant rejection.

Although organ transplantation is now a common and important medical therapy, immune rejection of transplants remains a major impediment. Rejection is primarily caused by immune responses to proteins expressed by the graft. These proteins, which vary between individuals and are perceived as foreign by the recipient, are called alloantigens. Section 6-13 introduced the basis of the alloreactive T-cell response to the polymorphic MHC molecules, which almost always trigger a response against the grafted organ. Matching the MHC type of the donor and the recipient increases the success rate of grafts, but perfect matching of all MHC loci is possible only when donor and recipient are closely related, and even in these cases, genetic differences at other loci can still trigger rejection, although less severely. Nevertheless, advances in immunosuppression and transplantation medicine now mean that the precise matching of tissues for transplantation is no longer the major factor in graft survival. In blood transfusion, the earliest and most common tissue transplant, MHC matching is not necessary for routine transfusions, because red blood cells and platelets express small amounts of MHC class I molecules and do not express MHC class II molecules; thus, they are not usually T-cell targets. However, antibodies made against platelet MHC class I molecules can be a problem when repeated transfusions of platelets are required. Blood must be matched for ABO and Rh blood group antigens to avoid the rapid destruction of mismatched red blood cells by antibodies in the recipient (see Appendix I, Sections A-6 and A-7), but because there are only four major ABO types and two Rh types, this is a relatively easy form of tissue matching.

In this part of the chapter, we examine the immune response to tissue grafts and also ask why such responses do not reject the one foreign tissue graft that is tolerated routinely—the mammalian fetus.

15-19 Transplant rejection is mediated primarily by T-cell responses to MHC molecules.

The basic rules of tissue grafting were first elucidated by skin transplantation between inbred strains of mice. Skin can be grafted with 100% success between different sites on the same animal or person (an **autograft**) or between genetically identical animals or people (a **syngeneic graft**). However, when skin is grafted between unrelated or **allogeneic** individuals (an **allograft**), the graft initially survives but is then rejected about 10–13 days after grafting (Fig. 15.40). This response is called an **acute rejection**, and it depends on a T-cell response,

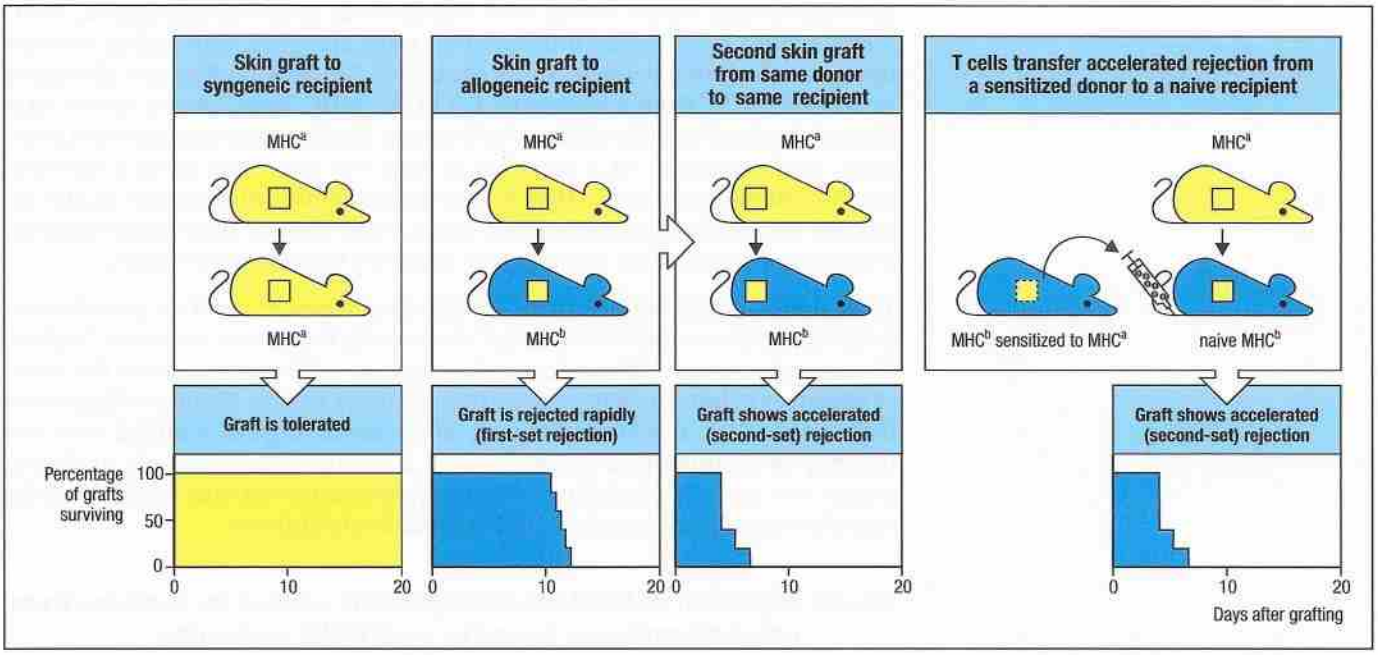

Fig. 15.40 Skin graft rejection is the result of a T cell–mediated anti-graft response. Grafts that are syngeneic are permanently accepted (first panels), but grafts differing at the MHC are rejected about 10–13 days after grafting (first-set rejection, second panels). When a mouse is grafted for a second time with skin from the same donor, it rejects the second graft faster (third panels). This is called a second-set rejection, and the accelerated response is MHC-specific; skin from a second donor of the same MHC type is rejected equally fast, whereas skin from an MHC-different donor is rejected in a first-set pattern (not shown). Naive mice that are given T cells from a sensitized donor behave as if they had already been grafted (final panels).

because skin grafted onto *nude* mice, which lack T cells, is not rejected. The ability to reject skin can be restored to *nude* mice by the adoptive transfer of normal T cells.

When a recipient that has previously rejected a graft (called first-set rejection) is regrafted with skin from the same donor, the second graft is rejected more rapidly (6–8 days) in an **accelerated rejection** (see Fig. 15.40). Skin from a third-party donor grafted onto the same recipient at the same time does not show this faster response but follows a first-set rejection course. The rapid course of second-set rejection can also be transferred to new recipients by T cells from the initial recipient, showing that second-set rejection is caused by a memory-type response (see Chapter 11) from clonally expanded and primed T cells specific for the donor skin.

Adaptive immune responses to a graft's foreign proteins are the major barrier to effective tissue transplantation. These responses can be mediated by CD8 or CD4 T cells, or both. Antigens that differ between members of the same species are known as **alloantigens**, and an immune response against such antigens is known as an **alloreactive** response. When donor and recipient express different MHC alleles, the host will mount an alloreactive immune response against the graft's nonself allogeneic MHC molecules. In most tissues these are predominantly MHC class I antigens. Once a recipient has rejected a graft of a particular MHC type, any further graft bearing the same nonself MHC will be rapidly rejected in a second response. As described in Section 6-13, the frequency of T cells specific for any nonself MHC molecule is relatively high, making allogeneic MHC molecules a potent trigger for graft rejection. Indeed, the MHC was originally so named because of its central role in graft rejection.

Once it became clear that nonself MHC molecules were a major trigger of graft rejection, a considerable amount of effort was put into MHC matching

of recipient and donor. Today, with advances in immunosuppression, MHC matching has become less important for most allografts, although it remains important for bone marrow transplantation, for reasons that are discussed in Section 15-25. Even a perfect match at the MHC locus, known as the HLA (human leukocyte antigen) locus in humans, does not prevent rejection reactions. Grafts between HLA-identical siblings will invariably incite a rejection reaction, albeit more slowly than an unmatched graft, unless donor and recipient are identical twins. This reaction is the result of allelic differences between antigens from non-MHC proteins that also vary between individuals.

Thus, unless donor and recipient are identical twins, all graft recipients must be given immunosuppressive drugs chronically to prevent rejection. Indeed, the current success of clinical transplantation of solid organs is more the result of advances in immunosuppressive therapy (see Chapter 16) than of improved tissue matching. The limited supply of cadaveric organs, coupled with the urgency of identifying a recipient once a donor organ becomes available, means that accurate matching of tissue types is achieved only rarely, with the notable exception of matched-sibling donation of kidneys.

15-20 Rejection of MHC-identical grafts is caused by peptides from other alloantigens bound to graft MHC molecules.

When donor and recipient are identical at the MHC locus but differ at other genetic loci, graft rejection is not as rapid, but left unchecked it will still destroy the graft (Fig. 15.41). This is the reason that grafts between HLA-identical siblings (but not identical twins) would be rejected without immunosuppressive treatment. MHC class I and class II molecules bind and present a large selection of peptides derived from self proteins made in the cell, and if these proteins are polymorphic, then different peptides will be produced from them in different members of a species. Such proteins can also be recognized as **minor histocompatibility antigens** (Fig. 15.42). One set of proteins that induce minor histocompatibility responses is encoded on the male Y chromosome. Responses induced by these proteins are known collectively as H-Y. Because Y chromosome–specific genes are not expressed in females, females generate H-Y responses against male cells. However, male anti-female responses do not occur, because both sexes express X-chromosome genes. One H-Y antigen has

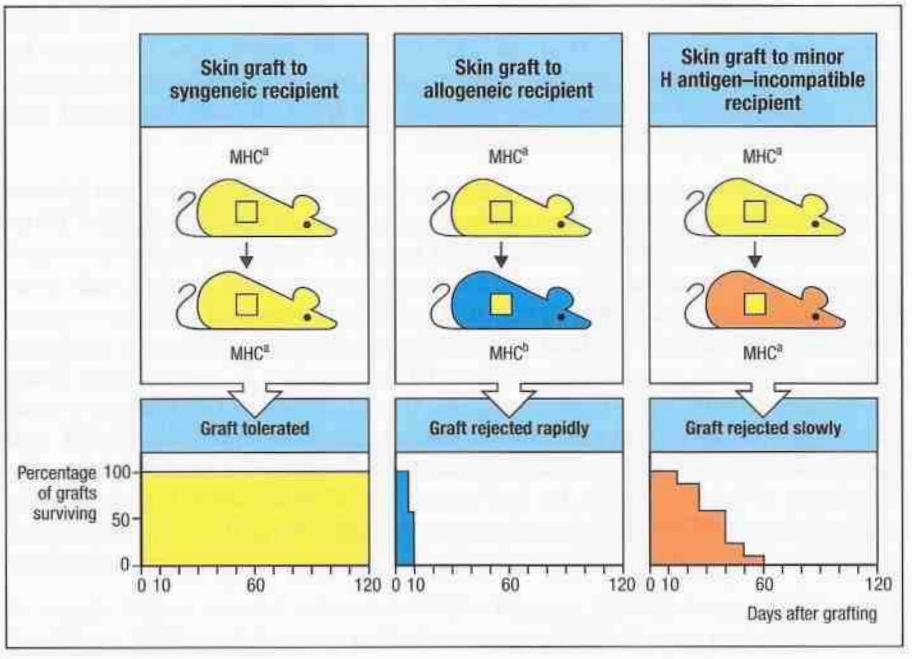

Fig. 15.41 Even complete matching at the MHC locus does not ensure graft survival. Although syngeneic grafts are not rejected (left panels), MHC-identical grafts from donors can differ at other loci (minor H antigen loci) that can generate peptides presented by the syngeneic MHC that are recognized as foreign by the recipient. This can lead to the graft being rejected (right panels), albeit more slowly than MHC-disparate grafts (center panels).

TAP
Endoplasmic reticulum
Polymorphic self proteins that differ in amino acid sequence between individuals give rise to minor H antigen differences between donor and recipient

Fig. 15.42 Minor H antigens are peptides derived from polymorphic cellular proteins bound to MHC class I molecules. Self proteins are routinely digested by proteasomes within the cell's cytosol, and peptides derived from them are delivered to the endoplasmic reticulum, where they are loaded onto MHC class I molecules and delivered to the cell surface. If a polymorphic protein differs between the graft donor (shown in red on the left) and the recipient (shown in blue on the right), it can give rise to an antigenic peptide (red on the donor cell) that can be recognized by the recipient's T cells as nonself and elicit an immune response, even when the donor and host have identical MHC alleles (shown as yellow). Such antigens are called minor histocompatibility (H) antigens.

been identified in mice and humans as peptides from a protein encoded by the gene *Smcy*. An X-chromosome homolog of *Smcy* (or *Kdm5d*), called *Smcx* (or *Kdm5c*), does not contain these peptide sequences, which are therefore expressed uniquely in males. Most minor histocompatibility antigens are encoded by autosomal genes, and their identity is largely unknown, although an increasing number have now been identified at the genetic level.

The response to minor histocompatibility antigens is in many ways analogous to the response to viral infection. However, whereas an antiviral response eliminates only infected cells, a large fraction of cells in the graft expresses minor histocompatibility antigens, and thus the graft is destroyed in the response against these antigens. Given the virtual certainty of mismatches in minor histocompatibility antigens between two individuals, and the potency of the reactions they incite, it is understandable that successful transplantation requires the use of powerful immunosuppressive drugs.

15-21 Alloreactive T cells reject transplanted organs by direct and indirect allorecognition.

For naive alloreactive T cells to become activated and acquire effector activities that cause organ rejection requires that they contact antigen-presenting cells expressing the allogeneic MHC and co-stimulatory molecules. Transplanted organs carry immune cells of donor origin, including tissue-resident dendritic cells and other antigen-presenting cells. These cells have been called passenger leukocytes. Until recently, it was presumed that passenger leukocytes were responsible for the direct activation of host alloreactive T cells, mediated by migration of the passenger leukocytes from the graft into secondary lymphoid tissues of the recipient. Because the lymphatic drainage of solid organ allografts is interrupted by transplantation, migration of donor antigen-presenting cells was initially thought to occur via the blood, and not the lymphatics. The alloreactive effector T cells activated in the lymph nodes or spleen would then circulate to the graft and mediate an immune attack (Fig. 15.43). In support of this **direct allorecognition** pathway (Fig. 15.44, upper panel) is the observation that the depletion of antigen-presenting cells from grafted tissue, carried out by treatment with antibodies or by prolonged incubation, can prolong graft survival. However, in experimental systems, it has been observed that only a small number of donor antigen-presenting cells reach secondary lymphoid

Fig. 15.43 Acute rejection of a kidney graft through the direct pathway of allorecognition. Donor dendritic cells in the graft (or exosomes that they secrete) carry complexes of donor HLA molecules and donor peptides on their surfaces via the blood to secondary lymphoid organs (in this case, a lymph node). In the case of exosomes, their membrane can be inserted directly into the membrane of host dendritic cells and presented to T cells (not shown). The recipient's alloreactive T cells (both CD8 and CD4) are activated by direct allorecognition (that is, with donor peptides bound to donor MHC). The effector T cells then travel in the blood to the grafted organ and attack cells that display the donor peptide:HLA molecule complexes for which the T cells are specific.

organs. Recently, a second route to activating host T cells via direct allorecognition has been observed and is based on the secretion of exosomes from donor antigen-presenting cells present in the graft. Exosomes are membrane-bound extracellular vesicles produced by the endocytic compartment of cells and are secreted by a budding process from the cell membrane. Exosomes secreted by donor antigen-presenting cells contain the allogeneic MHC of the donor and can circulate in the blood. By a reverse process, exosomes can be taken up by host dendritic cells in secondary lymphoid organs and incorporated directly into their plasma membrane, allowing direct presentation of allogeneic MHC to host alloreactive T cells. While this route has been demonstrated in experimental systems, it is still an area of active research, and the individual contributions of these two pathways to transplant rejection are still somewhat unclear.

A second mechanism of allograft recognition leading to graft rejection is the uptake of allogeneic proteins by the recipient's own antigen-presenting cells and their presentation to T cells by self MHC molecules. This is known as **indirect allorecognition** (see Fig. 15.44, lower panel). Peptides derived from both the foreign MHC molecules themselves and minor histocompatibility antigens can be presented by indirect allorecognition.

Direct allorecognition is thought to be largely responsible for acute rejection, especially when MHC mismatches mean that the frequency of directly alloreactive recipient T cells is high. Furthermore, a direct cytotoxic T-cell attack on graft cells can be made only by T cells that recognize the graft MHC molecules directly. Nonetheless, T cells with specificity for alloantigens presented on self MHC can contribute to graft rejection by activating macrophages, which cause tissue injury and fibrosis. T cells with indirect allospecificity are

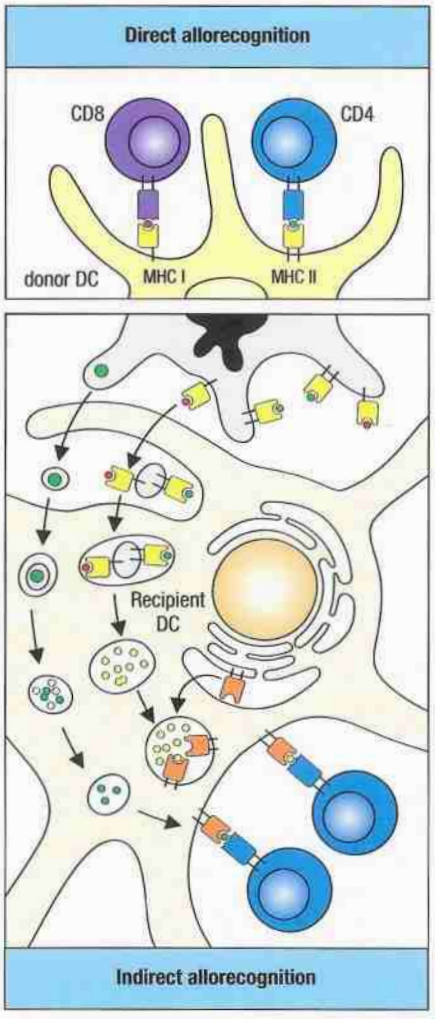

Fig. 15.44 Direct and indirect pathways of allorecognition contribute to graft rejection. In direct allorecognition (upper panel), T-cell receptors of alloreactive CD4 and CD8 T cells in the recipient immediately recognize the allogeneic HLA class I and class II allotypes on a donor dendritic cell (donor DC). In indirect allorecognition (lower panel), antigens from donor cells are processed and presented to peptide-specific T cells by the recipient's dendritic cells (recipient DC), which can be delivered by membrane vesicles such as exosomes. These antigens include peptides derived from the minor H antigens (green) and from allogeneic HLA class I and class II allotypes (yellow), both of which are presented by the recipient's HLA molecules (orange). Presentation by HLA class II molecules to CD4 T cells (blue) is shown here, but peptides can also be presented by recipient HLA class I molecules to CD8 T cells (not shown).

also likely to be important in the development of an antibody response to a graft. Antibodies produced against nonself antigens from the same species are known as **alloantibodies**.

15-22 Antibodies that react with endothelium cause hyperacute graft rejection.

Antibody responses are an important potential cause of graft rejection. Preexisting alloantibodies against blood group antigens and polymorphic MHC antigens can cause rapid rejection of transplanted organs in a complement-dependent reaction that can occur within minutes of transplantation. This type of reaction is known as **hyperacute graft rejection**. Most grafts that are transplanted routinely in clinical medicine are vascularized organ grafts linked directly to the recipient's circulation. In some cases the recipient may have preexisting antibodies against donor graft antigens. Antibodies of the ABO type can bind to all tissues, not just red blood cells. In addition, antibodies against other antigens can be produced in response to a previous transplant or a blood transfusion. All such preexisting antibodies can cause rapid rejection of vascularized grafts because they react with antigens on the vascular endothelial cells of the graft and initiate the complement and blood-clotting cascades. The vessels of the graft become blocked, or thrombosed, causing its rapid destruction. Such grafts become engorged and purple-colored from hemorrhaged blood, which becomes deoxygenated (Fig. 15.45). This problem can be avoided by ABO matching and **cross-matching** donor and recipient. Cross-matching involves determining whether the recipient has antibodies that react with the white blood cells of the donor. Antibodies of this type, when found, have hitherto been considered a serious contraindication to transplantation of most solid organs, because in the absence of any treatment they lead to near-certain hyperacute rejection.

For reasons that are incompletely understood, some transplanted organs, particularly the liver, are less susceptible to this type of injury and can be transplanted despite ABO incompatibilities. In addition, the presence of donor-specific MHC alloantibodies and a positive cross-match are no longer considered an absolute contraindication for transplantation, as treatment with intravenous immunoglobulin has been successful in a proportion of people in whom antibodies against the donor tissue were already present.

A similar problem prevents routine use of animal organs—**xenografts**—in transplantation. If xenografts could be used, it would circumvent a limitation in organ replacement therapy: the shortage of donor organs. Pigs have been suggested as a source of organs for xenografting, but most humans have antibodies that react with a ubiquitous cell-surface carbohydrate antigen (galactose-α-1,3-galactose; α-Gal) of other mammalian species, including pigs. When pig xenografts are placed in humans, these antibodies trigger hyperacute rejection by binding graft endothelial cells and initiating complement and clotting cascades. The problem of hyperacute rejection is exacerbated in xenografts because complement-regulatory proteins such as CD59, DAF (CD55), and MCP (CD46) (see Sections 2-10 and 2-17) work less efficiently across a species barrier. A recent step toward xenotransplantation has been the development of transgenic pigs expressing human DAF as well as pigs that lack α-Gal. These approaches might one day reduce or eliminate hyperacute rejection in xenotransplantation.

15-23 Late failure of transplanted organs is caused by chronic injury to the graft.

The success of immunosuppression means that about 90% of cadaveric kidney grafts are still functioning a year after transplantation. There has, however, been little improvement in rates of long-term graft survival: the half-life for

Fig. 15.45 Preexisting antibody against donor graft antigens can cause hyperacute graft rejection. Prior to transplantation, some recipients have made antibodies that react with donor ABO or HLA class I antigens. When the donor organ is grafted into such a recipient, these antibodies bind to the vascular endothelium in the graft, initiating the complement and clotting cascades. Blood vessels in the graft become obstructed by clots and leak, causing hemorrhage of blood into the graft. The graft becomes engorged, turns purple from the presence of deoxygenated blood, and dies.

Fig. 15.46 Chronic rejection in the blood vessels of a transplanted kidney. Left panel: Chronic rejection is initiated by the interaction of anti-HLA class I alloantibodies with blood vessels of the transplanted organ. Antibodies bound to endothelial cells recruit Fc receptor–bearing monocytes and neutrophils. Right panel: Accumulating damage leads to thickening of the internal elastic lamina and to infiltration of the underlying intima with smooth muscle cells, macrophages, granulocytes, alloreactive T cells, and antibodies. The net effect is to narrow the lumen of the blood vessel and create a chronic inflammation that intensifies tissue remodeling. Eventually the vessel becomes obstructed, ischemic, and fibrotic.

functional survival of renal allografts remains about 8 years. Although traditionally the late failure of a transplanted organ has been termed **chronic rejection**, it is typically difficult to determine whether the cause of chronic allograft injury involves specific immune alloreactivity, nonimmune injury, or both.

The pattern of chronic injury to transplanted organs is variable, depending on the tissue. A major component of late failure of vascularized transplanted organs is a chronic reaction called **chronic allograft vasculopathy**, which is a prominent cause of injury in heart and kidney allografts. This is characterized by concentric arteriosclerosis of graft blood vessels, which leads to hypoperfusion of the graft and its eventual fibrosis and atrophy (Fig. 15.46). Multiple mechanisms may contribute to this form of vascular injury, although the major cause is thought to be recurring, subclinical acute rejection events, whether due to the development of allospecific antibodies reactive to the vascular endothelium of the graft (so-called donor-specific antibodies) or to allograft-reactive effector T cells, or both. Some forms of immunosuppressive therapy (for example, calcineurin inhibitors such as cyclosporin A) also cause vascular injury, although this is typically more limited to very small arteries and causes a different pattern of injury, referred to as arteriolar hyalinosis, which is marked by proteinaceous deposits that narrow the vascular lumen. In transplanted livers, chronic rejection is associated with loss of bile ducts, the so-called vanishing bile duct syndrome, whereas in transplanted lungs, the major cause of late organ failure is accumulation of scar tissue in the bronchioles, termed bronchiolitis obliterans. Alloreactive responses can occur months to years after transplantation and may be associated with gradual loss of graft function that is hard to detect clinically.

Other important causes of chronic graft dysfunction include ischemia–reperfusion injury, which can promote sterile inflammatory signals at the time of grafting because of the restoration of blood flow after a period of poor perfusion of the organ to be transplanted; viral infections that emerge as a result of immunosuppression; and recurrence of the same disease in the allograft that destroyed the original organ. Irrespective of etiology, chronic allograft injury is typically irreversible and progressive, ultimately leading to complete failure of allograft function.

15-24 A variety of organs are transplanted routinely in clinical medicine.

Three major advances have made it possible to use organ transplantation routinely in the clinic. First, surgical techniques for performing organ replacement have advanced to the point where such surgeries are now relatively

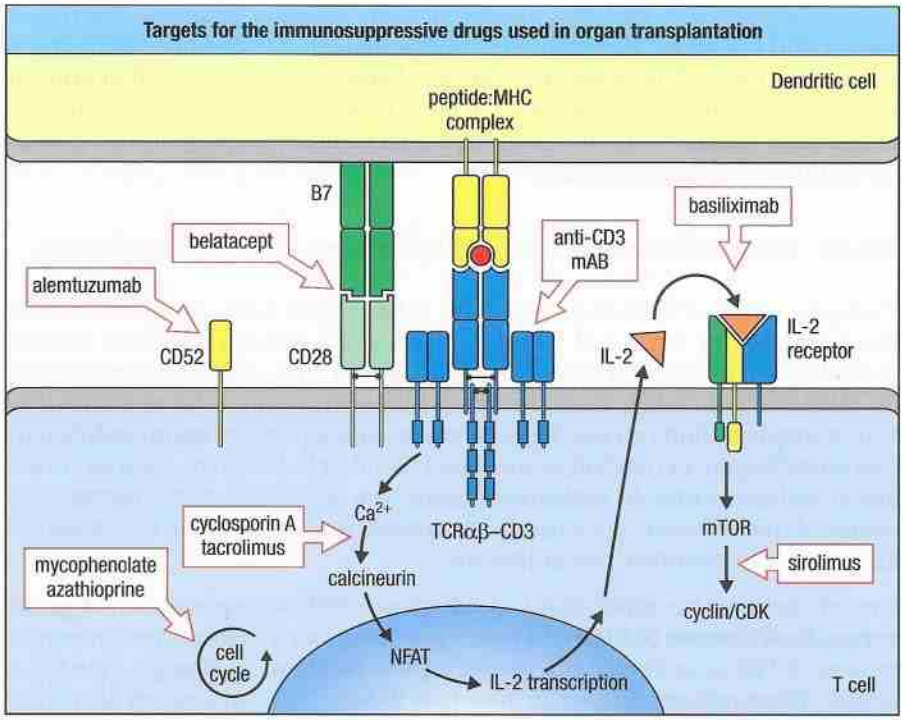

Fig. 15.47 Immunosuppressive drugs act at different stages in the activation of alloreactive T cells. The diagram illustrates the site of action of various immunosuppressive drugs. Rabbit anti-thymocyte globulin (Thymoglobulin) and anti-CD52 monoclonal antibody (alemtuzumab) are used to deplete T cells and other leukocytes before transplantation. Anti-CD3 monoclonal antibody (mAb) blocks signaling by the T-cell receptor complex. Cyclosporin A and tacrolimus inhibit calcineurin and prevent the translocation of nuclear factor of activated T cells (NFAT) to the nucleus. The CTLA-4–Fc fusion protein belatacept binds B7 and blocks co-stimulation of T cells by CD28. Basiliximab is an anti-CD25 antibody that binds to the high-affinity IL-2 receptor and prevents IL-2 signaling. Sirolimus interferes with activation of the mTOR cascade, which is required for differentiation of effector T cells. Azathioprine and mycophenolate inhibit the replication and proliferation of activated T cells.

routine in most major medical centers. Second, networks of transplantation centers have been organized to procure healthy organs that become available from cadaveric donors. Third, the use of powerful immunosuppressive drugs that inhibit T-cell activation, thereby limiting the development of anti-allograft effector T cells and antibodies, has markedly increased graft survival rates (Fig. 15.47). Five year survival rates for frequently transplanted organs or tissues and allografts between 2002 and 2007 are listed in Fig. 15.48, and these rates continue to improve. The most frequently transplanted solid organ is the kidney, the organ first successfully transplanted between identical twins in the 1950s; the half-life of survival of transplanted kidneys is now close to 8 years. These improvements stem from increased use of living donors and paired donors; better diagnosis of antibody-mediated rejection; improved treatment, such as anti-CD20 antibody (rituximab), which suppresses B cells; and plasma exchange therapy. Transplantation of the cornea is even more common than kidney transplantation; this tissue is a special case because it is not vascularized, and corneal grafts between unrelated people are usually successful without immunosuppression.

Many problems other than graft rejection are associated with organ transplantation. First, donor organs are difficult to obtain. Second, the disease that destroyed the transplant recipient's organ might also destroy the graft, as in the destruction of pancreatic β cells in autoimmune diabetes. Third, the

Tissue transplanted	No. of grafts in USA (2014)*	5-year graft survival
Kidney	17,815	81.4%†

Cornea	~45,000	~70%
HSC transplants	~20,000§	>80%‖

Fig. 15.48 Organs and tissues commonly transplanted in clinical medicine. The numbers of organ and tissue grafts performed in the United States in 2014 are shown. HSC, hematopoietic stem cells (includes bone marrow, peripheral blood HSCs, and cord blood transplants).*Number of grafts includes multiple organ grafts (for example, kidney and pancreas, or heart and lung). For solid organs, 5-year survival of the transplanted graft is based on transplants performed between 2002 and 2007. Data from the United Network for Organ Sharing.†Kidney survival listed (81.4%) is for kidneys from living donors; 5-year survival for cadaveric donor transplants is 69.1%.‡Pancreas survival listed (53.4%) is when transplanted alone; 5-year survival when transplanted with a kidney is 73.5%.§Includes autologous and allogeneic transplants.‖Successful HSC engraftment is assessed within weeks of transplant, not years. Nearly all solid organ grafts (for example, kidney, heart) require long-term immunosuppression.

immunosuppression required to prevent graft rejection increases the risk of cancer and infection. The problems most amenable to scientific solution are the development of more effective means of immunosuppression that prevent rejection with minimal impairment of more generalized immunity, the induction of graft-specific tolerance, and the development of xenografts as a practical solution to organ availability.

15-25 The converse of graft rejection is graft-versus-host disease.

Transplantation of hematopoietic stem cells (HSCs) from peripheral blood, bone marrow, or fetal cord blood is a successful therapy for some tumors derived from hematopoietic cells, such as certain leukemias and lymphomas. By replacing genetically defective stem cells with normal donor stem cells, HSC transplantation can also be used to cure some primary immunodeficiencies (see Chapter 13) and other inherited blood-cell disorders, such as severe forms of thalassemia. In leukemia therapy, the recipient's bone marrow, the source of the leukemia, must first be destroyed by a combination of irradiation and aggressive cytotoxic chemotherapy.

Graft-Versus-Host Disease

One of the major complications of allogeneic HSC transplantation is **graft-versus-host disease (GVHD)**, in which mature donor T cells present in preparations of HSCs recognize the tissues of the recipient as foreign, causing a severe inflammatory disease in multiple tissues, but particularly involving the skin, intestines, and liver and characterized by rashes, diarrhea, and liver dysfunction (Fig. 15.49). Because the consequences of GVHD are particularly aggressive when there is a mismatch of MHC class I or class II antigens, HLA matching between donor and recipient is more critical than in solid organ transplantation. Most transplants are therefore undertaken only when the donor and recipient are HLA-matched siblings or, less frequently, when there is an HLA-matched unrelated donor. Therefore, GVHD mostly occurs in the context of disparities between minor histocompatibility antigens, so immunosuppression must be used in every HSC transplant.

The presence of alloreactive donor T cells can be demonstrated experimentally by the **mixed lymphocyte reaction (MLR)**, in which lymphocytes from a potential donor are mixed with irradiated lymphocytes from the recipient. Naive donor T cells that recognize alloantigens on the recipient lymphocytes will proliferate or kill the recipient target cells, although the test does not accurately quantify alloreactive T cells. A more accurate test is a version of the limiting-dilution assay (see Appendix I, Section A-21), which precisely counts the frequency of alloreactive T cells.

Although GVHD is harmful to the recipient of an HSC transplant, it can have beneficial effects that are crucial to the success of the therapy. Much

Lymph node
skin
blood vessel

Fig. 15.49 Graft-versus-host disease occurs when donor T cells in the graft attack the recipient's tissues. After bone marrow transplantation (left panel), any mature donor CD4 and CD8 T cells present in the graft that are alloreactive to the recipient's HLA allotypes become activated by encountering dendritic cells in secondary lymphoid tissues (middle panel). These donor-derived effector T cells move into the circulation and preferentially enter and attack tissues of the graft recipient (right panel), particularly epithelial cells of the skin, intestines, and liver that have been damaged by the conditioning regimen of chemotherapy and irradiation prior to transplantation.

of the therapeutic effect of HSC transplantation for leukemia can be due to a **graft-versus-leukemia effect**, in which the donor T cells in the allogeneic preparations of HSCs recognize minor histocompatibility antigens expressed by the leukemic cells and kill the leukemic cells. One of the treatment options for suppressing the development of GVHD is the elimination of mature T cells from the preparations of donor HSCs *in vitro* before transplantation, thereby removing alloreactive T cells. Those T cells that subsequently mature from the donor marrow *in vivo* in the recipient are tolerant to the recipient's antigens. Although the elimination of GVHD has benefits for the patient, there is an increased risk of leukemic relapse, which provides strong evidence in support of the graft-versus-leukemia effect.

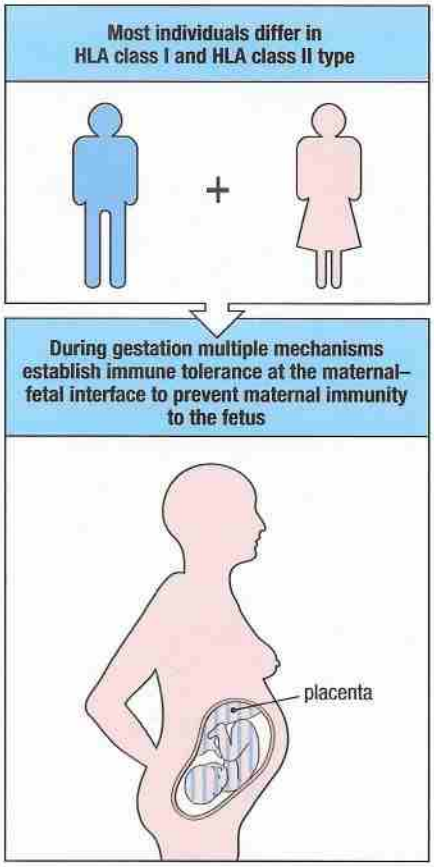
T_{reg} cells also participate in transplantation of allogeneic HSCs. In mice, depletion of $CD25^+$ T_{reg} cells in either the recipient or the HSC graft before transplantation accelerated the onset of GVHD and subsequent death, while supplementing the graft with T_{reg} cells delayed or even prevented death from GVHD. Also, treatment with a low dose of IL-2, which is thought to preferentially expand T_{reg} cells, has shown positive effects in preventing GVHD. Similar observations have been made in experimental mouse models of solid organ transplantation, where the transfer of either naturally occurring or induced T_{reg} cells significantly delayed allograft rejection. These experiments suggest that enriching or generating T_{reg} cells in preparations of donor HSCs might provide a possible therapy for GVHD in the future.

Immunodeficiency is another complication of donor T-cell depletion. Because most of the recipient's T cells are destroyed by the combination of chemotherapy and irradiation used to treat the recipient before transplant, donor T cells are the major source for reconstituting a mature T-cell repertoire early after transplant. This is particularly true in adults, who have poor residual thymic function and therefore a limited ability to repopulate their T-cell repertoire from T-cell precursors. Thus, if too many T cells are depleted from the graft, transplant recipients experience, and can die from, opportunistic infections. The need to balance the beneficial effects of the graft-versus-leukemia effect and immunocompetence with the adverse effects of GVHD caused by donor T cells has spawned much research. One particularly promising approach is to prevent donor T cells from reacting with recipient antigens that they could meet shortly after the transplant. This is accomplished by depleting the recipient's antigen-presenting cells. Here, the donor T cells are not activated during the initial inflammation that accompanies the transplant, and thereafter they do not promote GVHD. However, it is unclear whether there would be a graft-versus-leukemia effect in this context.

15-26 The fetus is an allograft that is tolerated repeatedly.

All of the transplants discussed so far are the result of advances in modern medicine. However, one 'foreign' tissue that is repeatedly grafted and tolerated is the mammalian fetus. The fetus carries paternal MHC and minor histocompatibility antigens that differ from those of the mother (Fig. 15.50), and yet a mother can successfully bear many children expressing the same nonself proteins derived from the father. The mysterious lack of fetal rejection has consistently puzzled immunologists, and no comprehensive explanation has yet emerged. One problem is that acceptance of the fetal allograft is so much the norm that it is difficult to study the mechanism that prevents rejection; if the mechanism for rejecting the fetus is rarely activated, how can one analyze the mechanisms that control it?

The mechanisms contributing to 'fetomaternal tolerance' are likely multifactorial and redundant. Although it has been proposed that the fetus is simply not recognized as foreign, women who have borne children often make antibodies



Most individuals differ in HLA class I and HLA class II type
+
During gestation multiple mechanisms establish immune tolerance at the maternal–fetal interface to prevent maternal immunity to the fetus
placenta

Fig. 15.50 The fetus is an allograft that is not rejected. With very few exceptions, the mother and father in human families have different HLA types (top panel). When the woman becomes pregnant, she carries for 9 months a fetus that expresses one HLA haplotype of maternal origin (pink) and one HLA haplotype of paternal origin (blue) (bottom panel). Although the paternal HLA class I and class II molecules expressed by the fetus are alloantigens against which the mother's immune system has the potential to respond, the fetus does not provoke such a response during pregnancy and is protected from preexisting alloreactive antibodies or T cells. Even when the mother bears several children to the same father, no sign of immunological rejection is seen.

directed against the father's MHC and red blood cell antigens. However, the placenta, which is a fetus-derived tissue, seems to sequester the fetus from the mother's T cells. The outer layer of the placenta—the interface between fetal and maternal tissues—is the trophoblast. This does not express MHC class II molecules and expresses only low levels and a restricted subset of MHC class I molecules, making it resistant to direct alloantigen recognition by maternal T cells. Tissues lacking MHC class I expression are, however, vulnerable to attack by NK cells (see Section 3-25). The trophoblast might be protected from attack by NK cells by the expression of a nonclassical and minimally polymorphic HLA class I molecule, HLA-G, which has been shown to inhibit killing by NK cells.

The placenta may also inhibit the mother's T cells by an active mechanism of nutrient depletion. The enzyme indoleamine 2,3-dioxygenase (IDO) is expressed at a high level by cells at the maternal–fetal interface. This enzyme depletes the essential amino acid tryptophan at this site, and T cells starved of tryptophan show reduced responsiveness. Inhibition of IDO in pregnant mice, using the inhibitor 1-methyltryptophan, causes rapid rejection of allogeneic, but not syngeneic, fetuses.

The cytokine milieu at the maternal–fetal interface also contributes to fetal tolerance. Both the uterine epithelium and the trophoblast secrete TGF-β and IL-10. This combination of cytokines suppresses the development of effector T cells in favor of induced T_{reg} (iT_{reg}) cells (see Section 9-14). Regulatory T cells are increased during pregnancy, including iT_{reg} cells in the placenta. These cells are important for suppressing responses to the fetus in mice, as iT_{reg} deficiency promotes fetal resorption—the equivalent of spontaneous abortion in humans—as does induction of T_H1-inducing cytokines (for example, IFN-γ and IL-12). Provocatively, a regulatory element that controls FoxP3 expression in iT_{reg} cells, but is not required for FoxP3 expression by natural T_{reg} (nT_{reg}) cells, has been found only in placental mammals. This suggests iT_{reg} cells might have evolved to play an important role in maternal–fetal tolerance. Finally, stromal cells of the specialized maternal uterine tissue that directly interfaces with the placenta—the decidua—appear to repress the local expression of key T cell–attracting chemokines. Collectively, then, both maternal and fetal factors contribute to the formation of an immunologically privileged site akin to other sites of local immune suppression that allow prolonged acceptance of tissue grafts, such as the eye (see Section 15-3).

Summary.

Clinical transplantation is now a common medical therapy that has been made possible by MHC matching, immunosuppressive drugs, and advances in surgical techniques. However, even accurate MHC matching does not prevent graft rejection, because other genetic differences between host and donor, such as minor histocompatibility antigens, can result in allogeneic responses that are based on indirect allorecognition. Because of the current inability to specifically suppress the response to the graft without compromising host defense, most transplants require generalized immunosuppression of the recipient that can increase the risk of cancer and infection. The fetus is a natural allograft that must be accepted for the species to survive. A number of mechanisms contribute to regulation of the maternal immune tolerance to the fetus, including contributions by innate cells, particularly NK cells. A better understanding of tolerance to the fetus could ultimately provide insights for inducing specific allograft tolerance in transplantation.

Summary to Chapter 15.

Ideally, the effector functions of the immune system would be targeted only to foreign pathogens and never to self tissues. There are several layers of mechanisms that act to control the production and activation of self-reactive lymphocytes, but these sometimes break down. For a chronic disease to occur, it seems that multiple layers of tolerance must fail together. These layers begin with central tolerance in the bone marrow and thymus to generate a repertoire that has been screened to remove lymphocytes with strong self-reactivity. Other mechanisms act in the periphery to control those lymphocytes that escape this screening process, including anergy or induction of apoptosis, immunological ignorance and immune-privileged sites, cytokine deviation, and regulatory T cells.

Autoimmune diseases can be classified in several ways, such as by being tissue-specific or systemic or by the predominant effector mechanisms in play. Genetic predisposition has an important role in determining which individuals will develop an autoimmune disease. Monogenic autoimmune diseases often have a clear mechanism that is based on the importance of a single gene product in maintaining tolerance. For other diseases, multiple allelic variants have been identified, but in most cases, the precise mechanism of collective action remains unclear. Environmental factors play a significant role, as even identical twins are not always both affected by the same autoimmune disease. Influences from the environment include infections, toxins, and perhaps unknown events. The effector mechanisms operating in autoimmune diseases are the same as those employed in responses to pathogens. Although the details vary from disease to disease, both antibody and T cells can be involved, and often in the same disease.

The study of the rules of skin transplantation in mice was a major factor in understanding the rules of the normal immune responses, leading to the identification of the major histocompatibility antigens that control the response to nonself transplanted organs and tissues. Transplantation has brought on syndromes of rejection that are in many ways similar to autoimmune disease, but the targets are either major or minor histocompatibility antigens. T cells are the main effectors in graft rejection and graft-versus-host disease, although antibodies can also contribute.

For each of the undesirable responses discussed here, the question is how to control the response without adversely affecting protective immunity to infection. The answer may lie in a more complete understanding of the regulation of the immune response, especially the suppressive mechanisms important in tolerance. The deliberate control of the immune response is examined further in Chapter 16.

Discussion Questions

15.1 What kind of evidence supports the idea that a genetic predisposition contributes to the development of autoimmune diseases? For the association of certain MHC alleles with autoimmune diseases, what kind of mechanisms might explain this tendency?

15.2 Discuss the evidence that environmental conditions or infectious history may play a role in the development of autoimmunity. Give an experimental example of one infectious trigger. What examples are known in humans?

15.3 A number of different candidate genes have allelic variants that are associated with various autoimmune diseases. Describe the different ways in which these genes can contribute to perturbing the normal immune response to promote autoimmunity.

15.4 In some diseases, the immune system not only damages the target tissue but also produces systemic symptoms related to the physiology of that tissue. Give some examples of these effects.

15.5 Explain the differences in mechanisms among acute rejection, chronic rejection, and hyperacute rejection.

15.6 In some transplant situations, the recipient may have preexisting antibodies that react with the donor tissues. Give an explanation for the presence of these antibodies, and describe their possible specificity.

15.7 In a transplant situation, the allogeneic MHC molecules expressed by donor dendritic cells may be responsible for the activation of alloreactive T cells that recognize the transplanted organ by direct allorecognition. As this priming step is thought to take place in the lymph nodes or spleen, describe two routes that allow donor MHC molecules to become located in those sites.

15.8 Minor histocompatibility antigens can also be targets of T cells in a transplant situation. Describe the similarities and differences between direct allorecognition of MHC molecules and indirect allorecognition of minor histocompatibility antigens.

15.9 (a) Describe how a fetus is protected from an immune response from the mother. (b) Newborns of mothers that have certain autoimmune diseases may exhibit symptoms of the same diseases. Describe how this can occur and the possible treatments to prevent it. (c) Not all types of autoimmune diseases in the mother can affect the neonate. Explain why.

Manipulation of the Immune Response

16

IN THIS CHAPTER

Fighting infectious diseases with vaccination.

Using the immune response to attack tumors.

Treatment of unwanted immune responses.

At the time of this writing, the global COVID-19 (coronavirus disease-2019) pandemic provides a daily reminder of the practical importance of the field of immunology. The efforts to generate a vaccine against severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) illustrate the advances in modern vaccine design but also reveal the great challenges to vaccine development and deployment. In this chapter, we consider ways to manipulate the immune system to induce protection against pathogens and against tumors as well. We will also discuss ways to suppress unwanted immune responses, as seen with autoimmunity, allergy, and graft rejection, using conventional drugs and new 'biologic' agents.

The intentional manipulation of the immune response dates back more than 500 years to the use of variolation in China as a measure to protect against smallpox. Following Edward Jenner's experiments with cowpox vaccination in 1796, numerous vaccines and antisera against other infectious agents had been developed by the late 1800s. Many vaccines are now routinely deployed and have brought many diseases under control. It is worth commenting that many important vaccines still in use were developed before the 'modern' era of molecular immunology. More recently, techniques of molecular biology have allowed the development of biological therapeutics, or 'biologics,' which are engineered forms of natural products, such as hormones, cytokines, and monoclonal antibodies, or derivatives of these, such as engineered fusion proteins. Such products can exert extraordinary specificity; many have been used for decades, such as the hormone insulin for type 1 diabetes mellitus, but recent advances have introduced a broad array of new biologics with very precise actions on the immune system. Long-standing efforts to use the power and specificity of adaptive immunity against tumors have resulted in major advances; biologics that target regulatory pathways have made a significant impact in clinical medicine. Along with these advances has come the identification of conventional pharmaceutical agents—typically inhibitors—that allow some control over unwanted immune reactions, and they remain an important component of clinical medicine. The categories of agents used to manipulate immune responses are listed in **Fig. 16.1**. This chapter will discuss these approaches, beginning with a discussion of vaccines against infectious diseases. We will then present more recent advances in the treatment of tumors, including the use of biologics and cell-based therapies. Finally, we discuss the use of biologics and pharmaceutical agents in clinical practice to relieve unwanted immune responses.

Fighting infectious diseases with vaccination.

Improvements in sanitation and widespread vaccination introduced over the past 100 years have markedly decreased deaths caused by infectious diseases, and yet these remain major causes of death worldwide. Modern immunology itself grew from the success of Edward Jenner's and Louis Pasteur's vaccines against smallpox and chicken cholera, respectively, and its greatest triumph has been the global eradication of smallpox, announced by the World Health Organization (WHO) in 1980. The global campaign by the WHO to eradicate

Agents used to manipulate immune responses	
Type	**Example**
Radiation	
Small molecules	
Drugs	Sirolimus (rapamycin)
Adjuvants	Alum
Macromolecules	
Hormones	Cortisol
Cytokines	Interferon-α
Antibodies	Rituximab (anti-CD20 antibody)
Fusion proteins	Abatacept (CTLA-4–Ig)
DNA vaccines	(Experimental)
Subunit vaccines	Hepatitis B vaccine
Conjugate vaccines	Hib (*Haemophilus influenzae* type b) vaccine
Cells and organisms	
Inactivated vaccines	IPV (inactivated poliovirus vaccine)
Live attenuated vaccines	MMR (measles, mumps, rubella) vaccine
Adoptive cell transfer	CAR (chimeric antigen receptor) T cells
Heterologous bone marrow transplant	

Fig. 16.1 Categories of immunomodulating agents.

polio began in 1988 and has led to elimination of the endemic wild virus in all but two countries, and the spread of the mutated oral vaccine viral strains is limited to only about 20 others. With the recent progress in basic immunology, particularly in the area of innate immunity, there is hope that vaccines for other major infectious diseases, including malaria, tuberculosis, and HIV, are within reach.

The goal of vaccination is the generation of long-lasting and protective immunity. Indeed, a single infection by a pathogen is often (but not always) sufficient to generate long-lasting protective immunity. Recognition of this effect was recorded more than 2000 years ago in accounts of the Peloponnesian War, during which two successive outbreaks of plague struck Athens. The Greek historian Thucydides noted that people who had survived infection during the first outbreak were not susceptible to infection during the second. Perhaps this recognition was what prompted the practice of **variolation** against smallpox, in which a small amount of dried material from a smallpox pustule of an infected individual was used to produce a mild infection in an uninfected individual that was then followed by long-lasting protection against reinfection. Smallpox itself has been recognized in medical literature for more than 1000 years; variolation seems to have been practiced in India and China many centuries before its introduction into the West (sometime in the 1400s to 1500s), and its practice was familiar to Jenner. However, infection after variolation was not always mild: fatal smallpox occurred in about 3% of cases, and this rate of complication would clearly not meet modern criteria of drug safety. It appears there was some recognition that milkmaids exposed to a bovine virus similar to smallpox—cowpox—seemed to be protected from smallpox infection, and there is even one historical account suggesting that cowpox inoculation had been tried before Jenner. However, Jenner's achievement was not simply the realization that infection with cowpox would provide protective immunity against smallpox in humans without the risk of significant disease, but also its experimental proof by the intentional subsequent variolation of people whom he had previously vaccinated. He named the process **vaccination** (from *vacca*, Latin for 'cow'), and Pasteur, in his honor, extended the term to the stimulation of protection against other infectious agents. Humans are not a natural host of cowpox, which establishes only a brief and limited subcutaneous infection. But the cowpox virus contains antigens that stimulate an immune response that cross-reacts with smallpox antigens and thereby confers protection against the human disease. Since the early 20th century, the virus used to vaccinate against smallpox has been vaccinia virus, which is related to both cowpox and smallpox, but whose origin is obscure.

As we will see, many current vaccines offer protection by inducing the formation of neutralizing antibodies. However, that statement contains a hidden tautology; pathogens for which current vaccines are effective may also be pathogens for which antibodies are sufficient for protection. For several major pathogens—malaria, tuberculosis, and HIV—even a robust antibody response is not sufficient to be fully protective. The elimination of these pathogens requires additional effector activities, such as the generation of strong and durable cell-mediated immunity, which are not efficiently generated by current vaccine technologies. These are the issues that face modern vaccine scientists.

16-1 Vaccines can be based on attenuated pathogens or material from killed organisms.

Vaccine development in the early part of the 20th century followed two empirical approaches. The first was the search for **attenuated** organisms (that is, those with reduced pathogenicity), which would stimulate protective immunity but

not cause disease. This approach continues into the present with the design of genetically attenuated pathogens in which desirable mutations are introduced into the organism by recombinant DNA technologies. This idea is being applied to important pathogens, such as malaria, for which vaccines are currently unavailable, and may be important in the future for designing vaccines for influenza and HIV.

The second approach was the development of vaccines that were based on killed organisms and, subsequently, on purified components of organisms that would be as effective as live whole organisms. Killed vaccines were desirable because live vaccines, including vaccinia, have the risk of causing lethal systemic infection in immunosuppressed people or mutating and gaining the ability to spread or cause more virulent disease. Use of killed organisms as vaccines led to the development of conjugate vaccines composed of a mixture of purified antigens, as described below for *Haemophilus influenzae* (see Section 16-7). This evolution continues with the use of 'reverse immunogenetics' (see Section 16-12) to identify candidate peptide antigens for T cells and with strategies to use ligands that activate Toll-like receptors (TLRs) or other innate sensors as adjuvants to enhance responses to simple antigens.

Immunization based on these approaches is now considered so safe and so important that most states in the United States require all children to be immunized against several potentially deadly diseases (Fig. 16.2). These include the viral diseases measles, mumps, and polio, for which live-attenuated vaccines are used, and the bacterial diseases tetanus (caused by *Clostridium tetani*), diphtheria (caused by *Corynebacterium diphtheriae*), and whooping cough (caused by *Bordetella pertussis*), for which vaccines composed of inactivated toxins, or **toxoids**, prepared from the respective bacteria are used. More recently, a vaccine has become available against *Haemophilus influenzae* type b (Hib), one of the causative agents of meningitis, as well as two vaccines for childhood diarrhea caused by rotaviruses, and, as described in Section 16-20, a vaccine for preventing HPV infection for protection against cervical cancer. Most vaccines are given to children within the first year of life. The vaccines against measles, mumps, and rubella (MMR), against chickenpox (varicella), and against influenza, when recommended, are usually given between the ages of 1 and 2 years.

There still are many important infectious diseases for which we lack effective vaccines (Fig. 16.3). In some cases, natural infection with the pathogen does not seem to generate protective immunity, allowing for recurrent or chronic infections. In infections of this type, which include malaria, tuberculosis, and HIV, the antibodies that are produced are insufficient to prevent reinfection and to eliminate the pathogen or provide full immunity. Instead, these infections rely more on cell-mediated immunity to limit the pathogen. So it is not the absence of an antibody response to the pathogen that is the problem, but rather that this response does not clear the pathogen, eliminate pathogenesis, or prevent reinfection.

For vaccines that are used effectively in developed countries, such as that against measles, technical and economic problems can prevent widespread use in developing countries, where mortality from the diseases may still be significant. For example, the costs of storage and deployment can be significant barriers to the use of existing vaccines in poorer countries. Therefore, vaccine development remains an important goal of immunology. The latter half of the 20th century saw a shift to approaches that are based on molecular understanding of microbial pathogenicity, of the nature of protective host responses, and of the regulation of effective T- and B-lymphocyte responses.

List of common vaccines by category
Live attenuated
Polio (Sabin), measles, mumps, rubella, varicella, smallpox (special use: influenza, vaccinia, yellow fever)
Killed pathogen
Polio (IPV, Salk), hepatitis A, rabies
Inactivated toxoid
Diphtheria and tetanus (of DTaP)
Subunit/conjugate
Hepatitis B, influenza (seasonal), *Haemophilus influenzae* type b, pertussis (of DTaP), pneumococcal, meningococcal, HPV

Fig. 16.2 List of common vaccines by category.

Some infections for which effective vaccines are not yet available	
Disease	**Estimated annual mortality**
Malaria	618,248
Schistosomiasis	21,797
Intestinal worm infestation	3,304
Tuberculosis	934,879
Diarrheal disease	1,497,724
Respiratory infections	3,060,837
HIV/AIDS	1,533,760

Fig. 16.3 Diseases for which effective vaccines are still needed. Mortality data are the most recent estimated figures available (2014).

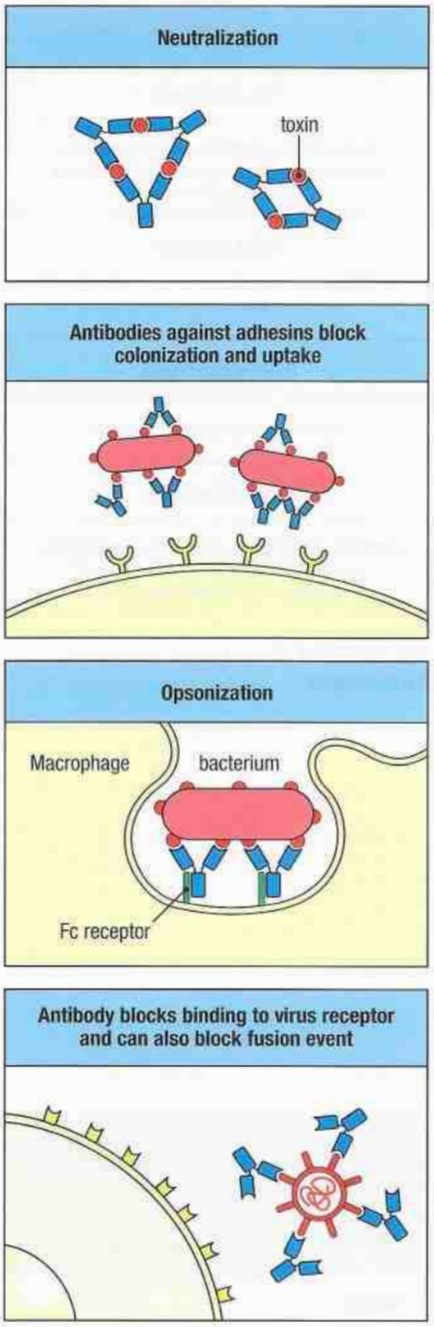

Fig. 16.4 Mechanisms of protection by antibodies. Antibodies induced by vaccines provide protection in several ways. Antibodies may neutralize toxins produced by pathogens and prevent the damage that they cause (top panel). Antibodies against bacteria can prevent infection of cells by blocking their colonization and uptake into cells (second panel) and also can enhance the destruction of bacteria through opsonization by macrophages and neutrophils (third panel). Antibodies can neutralize viruses by binding to viral proteins that mediate cellular binding and uptake through fusion of the viral and cell membranes (bottom panel) and by mediating their destruction by complement lysis, opsonization, and phagocytosis (not shown).

16-2 Most effective vaccines generate antibodies that prevent damage caused by toxins or that neutralize pathogens and stop infection.

Although the requirements for generating protective immunity vary with the nature of the infecting organism, many effective vaccines currently work by inducing antibodies against the pathogen or its products (Fig. 16.4) For many pathogens, including extracellular organisms and viruses, antibodies can provide protective immunity. This is not the case for all pathogens, unfortunately. Protection against some pathogens may require additional cell-mediated immune responses such as those mediated by CD8 T cells.

In some cases, effective protective immunity against microorganisms requires preexisting antibody at the time of infection. Preexisting antibody can be required to prevent the damage caused by certain pathogens or toxins they produce, as illustrated by vaccines against tetanus and diphtheria. In these infections, the clinical manifestations are primarily caused by extremely powerful exotoxins (see Fig. 10.31). Preexisting antibody against the exotoxin is necessary to prevent the actions of these toxins. Indeed, the tetanus exotoxin is so powerful that the tiny amount that can cause disease may be insufficient to lead to a protective immune response; consequently, even survivors of tetanus require vaccination to be protected against the risk of subsequent attack.

In other cases, preexisting antibodies can protect by preventing infection for a second time by the same pathogen, as in the case of certain viral infections. While CD8 T cells are able to kill cells that are already infected by virus, preexisting antibodies are able to prevent the infection of cells. This action is called **neutralization**. The ability of an antibody to neutralize a pathogen may depend on its affinity, its isotype subclass, complement, and the activity of phagocytic cells. For example, preexisting antibodies are required to protect against the poliovirus, which infects critical host cells very soon after entering the body. This infection is not easily controlled by T lymphocytes once intracellular infection has been established. Vaccines against seasonal influenza virus provide protection in this same manner, by inducing antibodies that reduce the chance of a second infection by the same strain of influenza. For many viruses, antibodies produced by an infection or by vaccination can neutralize the virus and prevent further spread of infection, but this is not always the case. In HIV infection, despite the generation of antibodies that can bind to surface viral epitopes, most of these antibodies fail to neutralize the virus. In addition, HIV has many different strains, or clades, and most vaccines based on HIV proteins do not induce antibodies that neutralize all clades, presenting a challenge for effective vaccine design. Recent work has identified broadly neutralizing antibodies that can recognize multiple HIV clades and bind to conserved regions of the HIV envelope protein that are unlikely to mutate away under negative selection *in vivo*. One interesting vaccine strategy aims to design antigens that induce antibodies specifically against such conserved epitopes, thus inducing a natural broadly neutralizing antibody response (see Section 13-35 and Fig. 13.36).

Antibodies produced against infectious agents usually are directed at multiple epitopes, and only some of these antibodies, if any, confer protection. The antigen epitopes recognized by T cells can affect the nature of the antibody response. In Section 10-2, we described **linked recognition**, in which antigen-specific B cells and T cells provide mutually activating signals, leading to affinity maturation and isotype switching that may be required for neutralization. Linked recognition requires that B cells present an appropriate peptide epitope to T cells, and typically this epitope is contained within the region of the protein epitope recognized by the B cell. This requirement must be considered in modern vaccine design. Indeed, the predominant antigen epitope recognized by T cells after vaccination with respiratory syncytial virus induces a vigorous inflammatory response but fails to elicit neutralizing antibodies and thus causes pathology without protection.

16-3 Effective vaccines must induce long-lasting protection while being safe and inexpensive.

A successful vaccine must possess several features in addition to its ability to provoke a protective immune response (Fig. 16.5). First, it must be safe. Vaccines must be given to huge numbers of people, relatively few of whom are likely to die of, or sometimes even catch, the disease that the vaccine is designed to prevent. This means even a low level of toxicity is unacceptable. Second, the vaccine must be able to produce protective immunity in a very high proportion of the people to whom it is given. Third, particularly in poorer countries where it is impracticable to give regular 'booster' vaccinations to dispersed rural populations, a successful vaccine must generate long-lived immunological memory. This means the vaccine must prime both B and T lymphocytes. Fourth, vaccines must be very cheap if they are to be administered to large populations. Vaccines are one of the most cost-effective measures in health care, but this benefit is eroded as the cost per dose rises.

Another benefit of an effective vaccination program is the '**herd immunity**' that it confers on the general population. By lowering the number of susceptible members in the population, vaccination decreases the natural reservoir of infected individuals in that population and so reduces the probability of transmission of infection. Thus, even unvaccinated individuals will be provided with some degree of protection because their chance of encountering the pathogen is decreased. However, the effect of such herd immunity is seen only at relatively high levels of vaccination within a population; for mumps, the necessary level is estimated to be around 80%, and below this level sporadic epidemics can occur. This is illustrated by a marked increase in mumps in the United Kingdom in 2004 to 2005 in young adults as a result of the variable use in the mid-1990s of a measles/rubella vaccine rather than the combined MMR, as the combined vaccine was in short supply at that time.

Finally, as we discuss in detail later, a vaccine must be perceived by the general population as being safe, so that it will be adopted by sufficient numbers of people to protect susceptible individuals and achieve herd immunity.

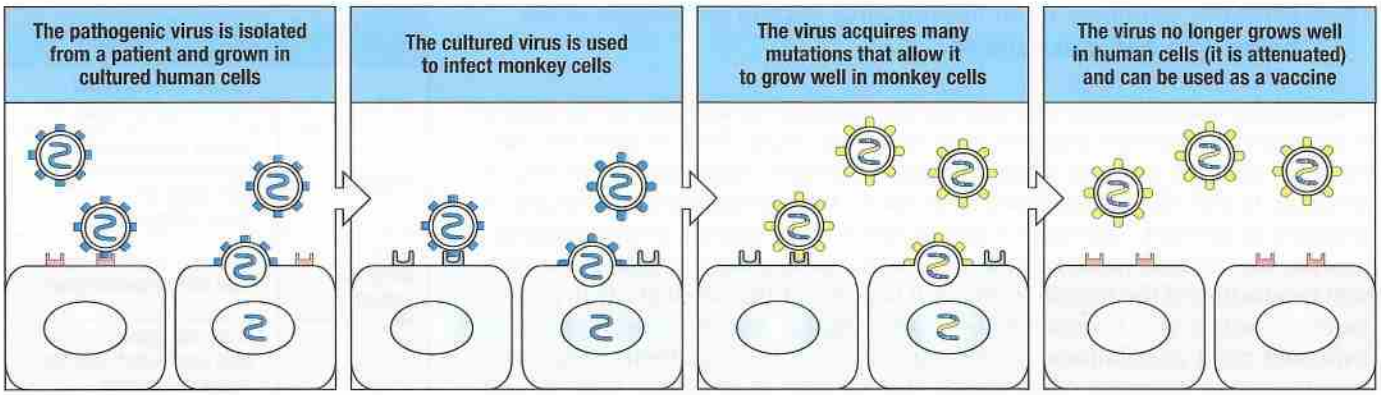
Features of effective vaccines	
Safe	Vaccine must not itself cause illness or death
Protective	Vaccine must protect against illness resulting from exposure to live pathogen
Gives sustained protection	Protection against illness must last for several years
Induces neutralizing antibody	Some pathogens (such as polio virus) infect cells that cannot be replaced (e.g., neurons). Neutralizing antibody is essential to prevent infection of such cells
Induces protective T cells	Some pathogens, particularly intracellular, are more effectively dealt with by cell-mediated responses
Practical considerations	Low cost per dose Biological stability Ease of administration Few side-effects
Perceived as safe	The perception of whether a vaccine is safe will influence the adoption by the public

Fig. 16.5 There are several criteria for an effective vaccine.

16-4 Live-attenuated viral vaccines are usually more potent than 'killed' vaccines.

Most antiviral vaccines currently in use consist of either live-attenuated viruses or inactivated viruses (see Fig. 16.2). Inactivated, or 'killed,' viral vaccines consist of viruses treated so that they are unable to infect and replicate within host cells. Because peptides from the viral antigens are not produced within host cells, CD8 T-cell responses rely solely on cross-presentation of the antigenic protein material given with the killed vaccine. As a consequence, CD8 T-cell responses are less strongly induced with killed-virus vaccines than with live-attenuated vaccines, but with killed-virus vaccines, CD8 T cells are not required to eliminate a vaccine-derived viral infection. Live-attenuated viral vaccines are generally far more potent, because they activate cytotoxic CD8 T cells as well as CD4 T cells that help to shape the antibody response for the vaccine's subsequent protective effect. Cytotoxic CD8 T cells provide protection while infection by the virus itself is under way and, if maintained, may contribute to protective memory. Attenuated live viral vaccines include the routine childhood vaccines in use for polio, measles, mumps, rubella, and varicella (see Fig. 16.2). Other attenuated live viral vaccines that are licensed for special circumstances or for use in high-risk populations include influenza, poxvirus (vaccinia), and yellow fever virus.

Traditionally, attenuation is achieved by growing the virus in cultured cells. In this process, a series of mutations accumulate in the viral genome. Viruses are



The pathogenic virus is isolated from a patient and grown in cultured human cells
The cultured virus is used to infect monkey cells
The virus acquires many mutations that allow it to grow well in monkey cells
The virus no longer grows well in human cells (it is attenuated) and can be used as a vaccine

Fig. 16.6 Viruses are traditionally attenuated by selecting for growth in nonhuman cells. To produce an attenuated virus, the virus must first be isolated by growing it in cultured human cells. The adaptation to growth in cultured human cells can cause some attenuation in itself; the rubella vaccine, for example, was made in this way. In general, however, the virus is then adapted to growth in cells of a different species, until it grows only poorly in human cells. The adaptation is a result of mutation, usually a combination of several point mutations. It is usually difficult to tell which of the mutations in the genome of an attenuated viral stock are critical to attenuation. An attenuated virus will grow poorly in the human host and will therefore produce immunity but not disease.

usually selected for preferential growth in nonhuman cells and, in the course of selection, become less able to grow in human cells (Fig. 16.6). Because these attenuated strains replicate poorly in human hosts, they induce immunity but not disease. Although attenuated virus strains contain multiple mutations in genes encoding several of their proteins, it might be possible for a pathogenic virus strain to reemerge by a further series of mutations. For example, the type 3 Sabin polio vaccine strain differs from a wild-type progenitor strain at only 10 of 7429 nucleotides. On extremely rare occasions, reversion of the vaccine to a neurovirulent strain can occur, causing paralytic disease in the unfortunate recipient.

Live-attenuated viral vaccines can also pose particular risks to immunodeficient recipients, in whom they often behave as virulent opportunistic infections. Immunodeficient infants who are vaccinated with live-attenuated poliovirus before their inherited immunoglobulin deficiencies have been diagnosed are at risk because they cannot clear the virus from their gut, and there is therefore an increased chance that mutations associated with the continuing uncontrolled replication of the virus in the gut will revert the virus to a virulent form and lead to fatal paralytic disease.

16-5 Live-attenuated viral vaccines can be made safer by the use of recombinant DNA technology.

While an empirical approach to attenuation is still in use, recombinant DNA technology provides additional ways to attenuate viruses for use as vaccines. In one approach, *de novo* attenuation of a virus could be achieved by mutating or deleting specific genes required for viral virulence (Fig. 16.7). This approach might be useful in developing live influenza vaccines. As described in Chapter 13, the influenza virus can reinfect the same host several times,

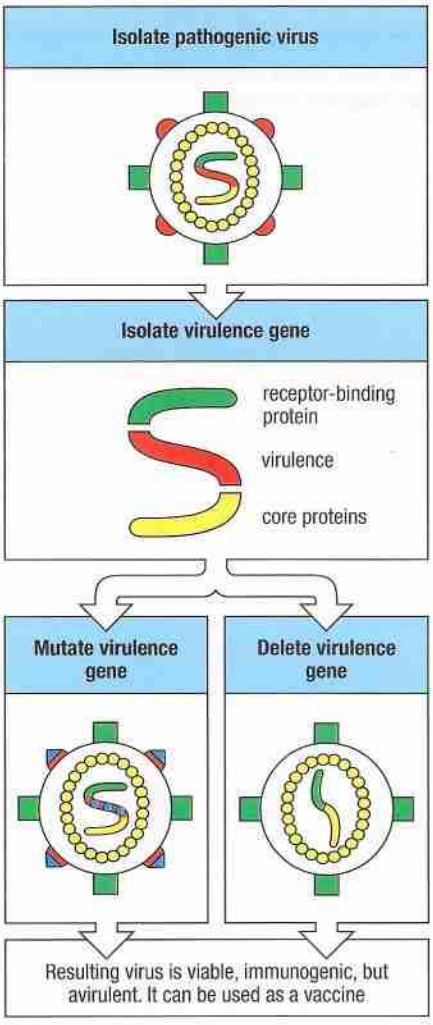


Fig. 16.7 Attenuation can be achieved more rapidly and reliably with recombinant DNA techniques. If a gene that is required for virulence but not for growth or immunogenicity can be identified in the virus, this gene can multiply either mutated (left lower panel) or deleted from the genome (right lower panel) by using recombinant DNA techniques. This procedure creates an avirulent (nonpathogenic) virus that can be used as a vaccine. The mutations in the virulence gene are usually large, so that it is very difficult for the virus to revert to the wild type.

because it undergoes antigenic shift and thus predominantly escapes the original immune response. The weak protection conferred by previous infections with a different influenza subtype is called **heterosubtypic immunity** and is observed in adults but not in children. The current approach to vaccination against influenza is to use a killed-virus vaccine that is reformulated annually on the basis of the prevalent strains of virus. The vaccine is moderately effective, reducing mortality in elderly people and illness in healthy adults. The ideal influenza vaccine would be an attenuated live organism that matched the prevalent virus strain. This could be created by first introducing a series of attenuating mutations into the gene encoding a viral polymerase protein, PB2. The mutated gene segment from the attenuated virus could then be substituted for the wild-type gene in a virus carrying the relevant **hemagglutinin** and **neuraminidase** antigen variants of the current epidemic or pandemic strain. Alternatively, broadly neutralizing antibodies that block the receptor-binding domain of the hemagglutinin can be generated in humans and could be used as a universal vaccine. Public attention has recently been directed toward the possibility of a flu pandemic caused by the **H5N1 avian flu** strain. This strain can be passed between birds and humans and is associated with a high mortality rate; however, a pandemic would occur only if human-to-human transmission could occur. A live-attenuated vaccine would be used only if a pandemic occurred, because to give it beforehand would introduce new influenza virus genes that might recombine with existing influenza viruses.

In some countries, polio infections are increasing because of the spread of certain vaccine strains of poliovirus, particularly type 2 oral vaccine. This so-called **circulating vaccine-derived poliovirus (cVDPV)** is caused by reversion mutations in the vaccine strain that enhance its replication. Once such a reversion mutation occurs in a vaccinated individual, it can spread by the usual fecal–oral route as with wild-type poliovirus, thus allowing it to spread within unvaccinated populations. Recombinant DNA technology is being applied in this setting to create new vaccine strains that cannot undergo such reversion mutations. For example, the type 2 Sabin vaccine strain had desirable mutations that reduced the stability of an RNA stem–loop structure in the 5′ untranslated region (5′ UTR), called domain V (*domV*), which reduced viral replication compared to that of wild polio strains. However, it was possible for the stem–loop's stability to be restored, and thus for viral replication to be increased, with only a single base-pair mutation. Such changes are called 'gatekeeper' mutations, because they increase the chance that the vaccine strain may acquire other mutations that increase viral virulence. A candidate vaccine has been made with a *domV* sequence such that no single nucleotide mutation can enhance stem–loop stability, thus reducing the chance for gatekeeper mutations to occur (Fig. 16.8). This vaccine is being tested by the World Health Organization in countries where cVDPV is present.

16-6 Vaccines against bacteria or parasites can be developed using nonpathogenic or disabled bacteria or genetically attenuated parasites (GAPs).

The most important example of an attenuated bacterial vaccine is the bacillus Calmette–Guérin (BCG) vaccine, which is quite effective at protecting against serious disseminated tuberculosis in children but is not protective against adult pulmonary tuberculosis. The current BCG vaccine, which remains the most widely used vaccine in the world, was obtained from a pathogenic isolate of *Mycobacterium bovis* and passaged in a laboratory at the beginning of the 20th century. Since then, several genetically diverse strains of BCG have evolved. The level of protection afforded by the BCG vaccine is extremely variable, ranging from none in some countries, such as Malawi, to 50–80% in the United Kingdom.

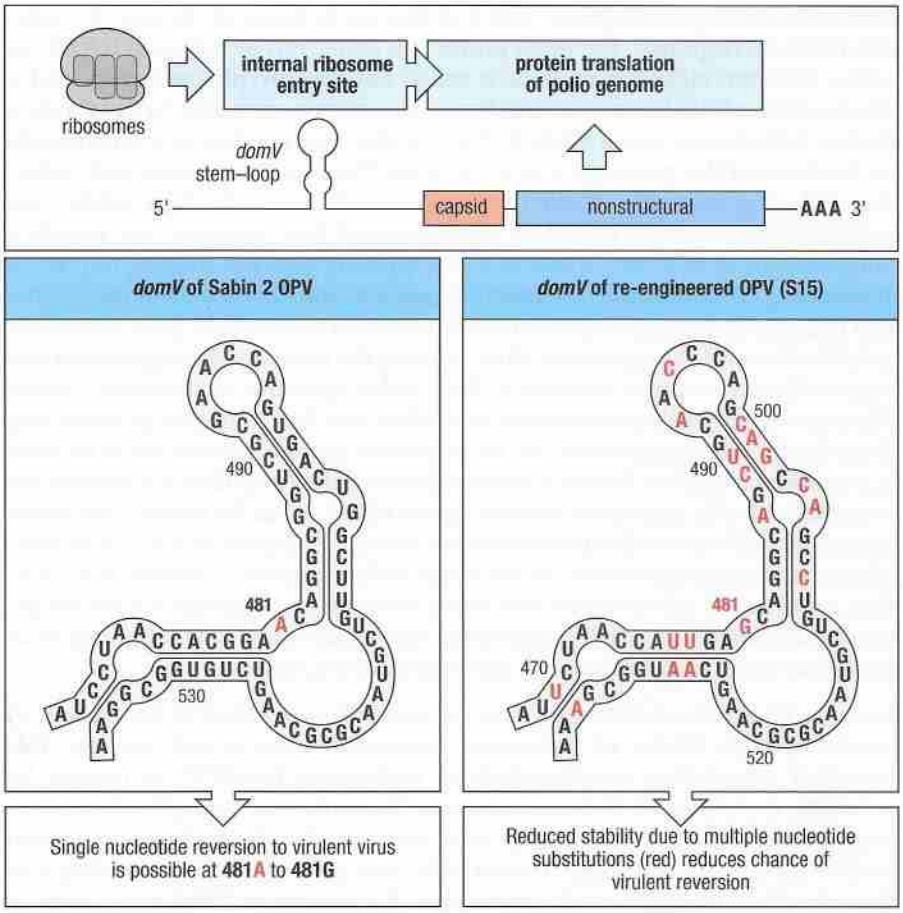

Fig. 16.8 Engineering a stable poliovirus vaccine strain that is resistant to reversion to neurovirulence. Top panel: The poliovirus genome encodes several capsid proteins (capsid) and several nonstructural proteins involved in protein processing and replication. Protein translation of the poliovirus positive-strand RNA genome is carried out by ribosomes that initiate at an internal ribosomal entry site, or IRES, formed in part by an RNA stem–loop called domain V (*domV*). Left panel: A major determinant of attenuation of the type 2 oral Sabin live viral vaccines is a mutation, 481G of wild polio to 481A (red), in *domV* of the vaccine strain. This mutation reduces stem–loop stability, impairing IRES function and reducing the virulence of the vaccine virus. However, in the original type 2 oral Sabin vaccines, stem–loop stability can be regained by a single nucleotide mutation back to 481G in *domV*, increasing the neurovirulence of revertant viruses. Right panel: In an engineered vaccine, S15, the *domV* stem–loop is redesigned to reduce its stability by the introduction of many alternative changes (shown in red), while keeping the original 481G nucleotide (red) of the wild polio sequence. By spreading the instability of the stem–loop over many nucleotide changes, no single nucleotide mutation can cause a full stabilization of the stem–loop, thus reducing the chance of reversion of the vaccine to a virulent form. OPV, oral polio vaccine.

Considering that tuberculosis remains one of the biggest killers worldwide, there is an urgent need for a new vaccine. Two recombinant BCG (rBCG) vaccines intended to prevent infection in unexposed individuals recently passed Phase I clinical trials. One was engineered to overexpress an immunodominant antigen of *M. tuberculosis*, to engender greater specificity toward the human pathogen. A second expresses the pore-forming protein listeriolysin from *Listeria monocytogenes* to induce the passage of BCG antigens from phagosomes into the cytoplasm and allow cross-presentation (see Section 6-5) on MHC class I molecules, thereby stimulating BCG-specific cytotoxic T cells.

A similar approach is being used to generate new vaccines for malaria. Analysis of different stages of *Plasmodium falciparum*, the major cause of fatal malaria, identified genes that are selectively expressed in sporozoites within the mosquito's salivary gland, where they first become infectious for human hepatocytes. Deletion of two such genes from the *P. falciparum* genome rendered sporozoites incapable of establishing a blood-stage infection in mice, yet capable of inducing an immune response that protected mice from subsequent infection by wild-type *P. falciparum*. This protection was dependent on CD8 T cells, and to some extent on IFN-γ, indicating that cell-mediated immunity is important for protection against this parasite (Fig. 16.9). This highlights once again the importance of being able to generate vaccines that are capable of inducing strong cell-mediated immunity.

16-7 Conjugate vaccines rely on linked recognition between T and B cells.

Many bacteria have an outer capsule composed of polysaccharides that are species- and type-specific for particular strains of the bacterium. Such bacteria include *Neisseria meningitidis* (meningococcus), *Streptococcus pneumoniae*

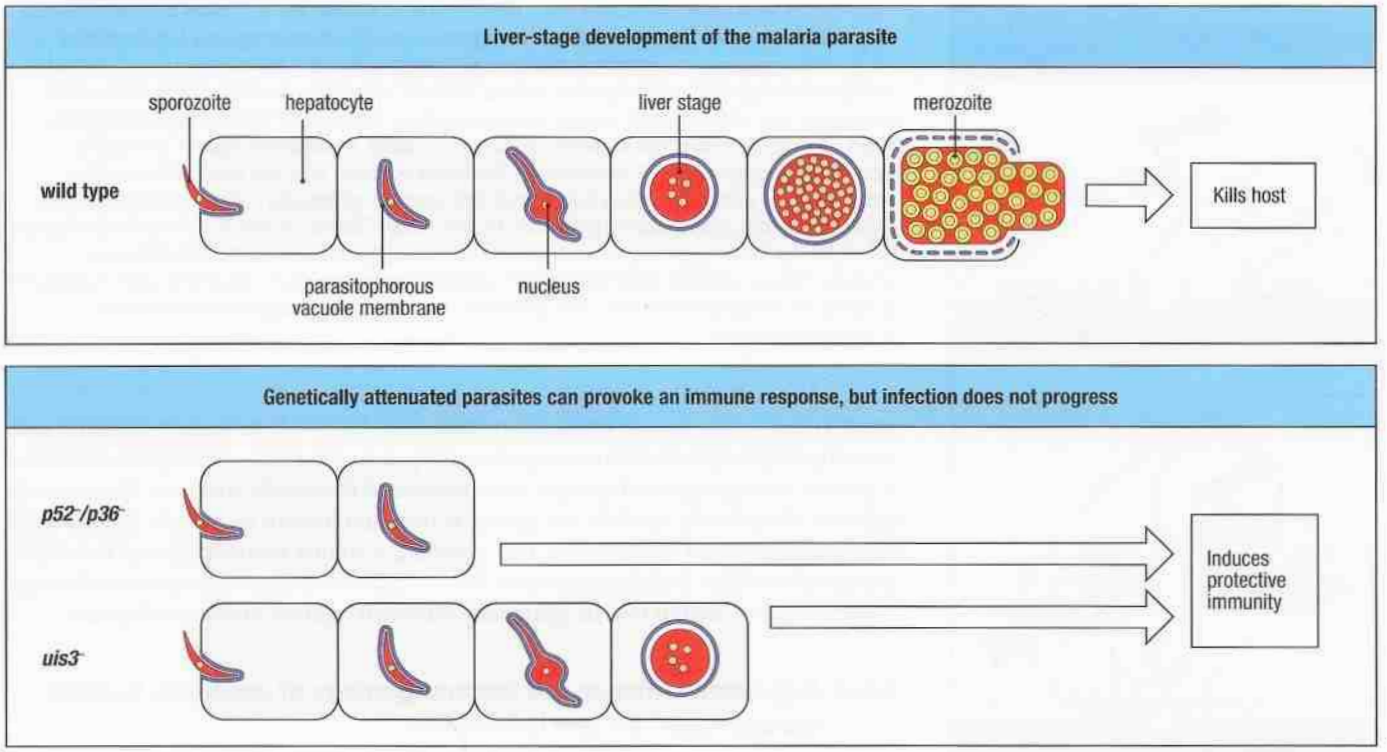

Fig. 16.9 Genetically attenuated parasites can be engineered as live vaccines to provide protective immunity. Top panel: Wild-type *Plasmodium* sporozoites transmitted through the bite of an infected mosquito enter the bloodstream and are carried to the liver, where they infect hepatocytes. Each sporozoite multiplies in the liver, killing the infected cell and releasing thousands of merozoites, the next stage in infection. Bottom panel: In mice immunized with sporozoites with targeted disruption of key genes [for example, *p52* and *p36* (*p52*$^-$/*p36*$^-$) or *uis3* (*uis3*$^-$)], the sporozoites circulate in the bloodstream and mimic an early infection but cannot establish a productive infection in the liver. The mice do, however, produce an immune response against the sporozoites and are protected against a subsequent infection by wild-type sporozoites.

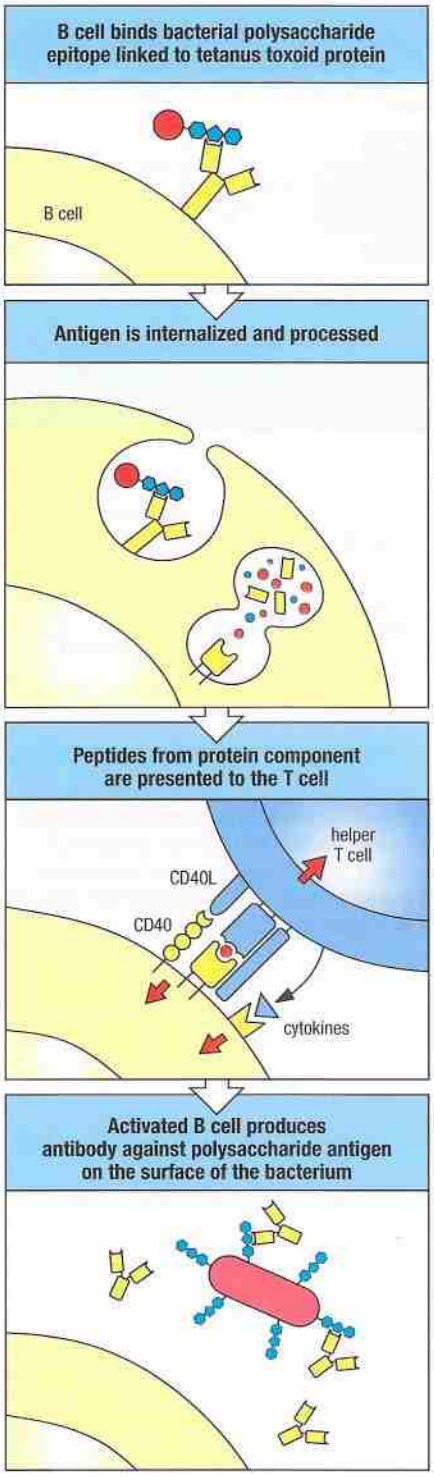
(pneumococcus), and *Haemophilus influenzae*. The most effective defense against these microorganisms is opsonization of the polysaccharide coat with antibody. The aim of vaccination for these organisms is therefore to elicit antibodies against the polysaccharide capsules of the bacteria. However, effective acellular vaccines cannot be made from a single isolated constituent of a microorganism, because generation of an effective antibody response requires the participation of several types of cells, and this fact has led to the development of **conjugate vaccines** (Fig. 16.10).

Capsular polysaccharides can be harvested from bacterial growth medium and, because they are T cell–independent antigens (see Section 10-1), they can be used on their own as vaccines. However, young children under the age of 2 years cannot make good T cell–independent antibody responses and cannot be vaccinated effectively with polysaccharide (PS) vaccines. An efficient way of overcoming this problem is to conjugate bacterial polysaccharides chemically to protein carriers (see Fig. 16.10). This carrier protein provides peptides that can be recognized by antigen-specific T cells, thus converting a T cell–independent response into a T cell–dependent antipolysaccharide antibody response. Using this approach, various conjugate vaccines have been developed against *H. influenzae* type b, an important cause of serious childhood chest infections and meningitis, and against *N. meningitidis* serogroup C, an important cause of meningitis, and these are now widely applied. The success of the latter vaccine in the United Kingdom is illustrated in Fig. 16.11, which shows that the incidence of meningitis C has been markedly reduced in comparison with meningitis B, against which there is currently no vaccine. Endemic meningitis B is due to diverse serogroup B strains, so an ideal vaccine



B cell binds bacterial polysaccharide epitope linked to tetanus toxoid protein

cytokines
Activated B cell produces antibody against polysaccharide antigen on the surface of the bacterium

Fig. 16.10 Conjugate vaccines take advantage of linked recognition to boost B-cell responses against polysaccharide antigens. The Hib vaccine against *Haemophilus influenzae* type b is a conjugate of bacterial polysaccharide and the tetanus toxoid protein. The B cell recognizes and binds the polysaccharide, internalizes and degrades the whole conjugate, and then displays toxoid-derived peptides on surface MHC class II molecules. Then, the helper T cells generated in response to earlier vaccination against the toxoid recognize the peptide:MHC complex on the B-cell surface, and this recognition by the T-cell receptor delivers a signal (red arrow) that leads to expression of surface CD40 ligand (CD40L) and the production of cytokines by the T cell. CD40L on the T cell then can engage CD40 on the B cells, and this interaction produces signals downstream of CD40 (red arrows). These, together with signals from cytokine receptors, activate the B cell to produce antibody to antipolysaccharide. This antibody can then protect against infection with *H. influenzae* type b.

would target the group B capsular polysaccharide. Unfortunately, group B polysaccharide is identical to some polysialyl polysaccharides on human cells and is poorly immunogenic because of tolerance of these self antigens. Some strategies to chemically modify the group B polysaccharide for use in a conjugate vaccine have been considered, but, instead, a major focus in group B meningococcal vaccine development has been to direct immunity against noncapsular antigens, which will be generally effective against endemic disease.

16-8 Adjuvants enhance the immunogenicity of vaccines, but few are approved for use in humans.

Vaccines that are based on peptides or purified proteins require additional components to mimic how real infections activate immunity. Such components of a vaccine are known as **adjuvants**, which are defined as substances that enhance the immunogenicity of antigens (see Appendix I, Section A-1). For example, tetanus toxoid is not immunogenic in the absence of adjuvants, and so tetanus toxoid vaccines contain inorganic aluminum salts (**alum**) in the form of noncrystalline gels that bind polyvalently to the toxoid by ionic interactions. Pertussis toxin has adjuvant properties in its own right and, when given mixed as a toxoid with tetanus and diphtheria toxoids, it not only protects against whooping cough but also acts as an additional adjuvant for the other two toxoids. This mixture makes up the DTaP triple vaccine given to infants in the first year of life.

The antigenic components and adjuvants in a vaccine are not approved for use on their own; they are approved only in the context of the specific vaccine in which they are formulated. At present, there are relatively few adjuvants approved by the U.S. Food and Drug Administration (FDA) for use in human vaccines marketed in the United States (Fig. 16-12). Alum is the common name for certain inorganic aluminum salts, of which aluminum hydroxide and aluminum phosphate are most frequently used as adjuvants. Monophosphoryl lipid A (MPL) is combined with alum for use in Cervarix, a vaccine against human papilloma virus isotypes 16 and 18, which are associated with a risk for cervical cancer, although this vaccine is no longer marketed in the United States. In Europe, in addition to the alum adjuvants, an oil (squalene)-in-water emulsion called **MF-59** is used as an adjuvant in a formulation of influenza vaccine and was approved for this use by the FDA in 2020. Alum seems to act as an adjuvant by stimulating one of the innate immune system's bacterial sensor mechanisms, **NLRP3**, thus activating the inflammasome and the inflammatory reactions that are a prerequisite for an effective adaptive immune response.

Several other adjuvants are widely used experimentally in animals but are not approved for use in humans. Many of these are sterile constituents of bacteria, particularly their cell walls. **Freund's complete adjuvant** is an oil-in-water emulsion containing killed mycobacteria. The peptidoglycan muramyl dipeptide and the glycolipid trehalose dimycolate (TDM) found in mycobacterial

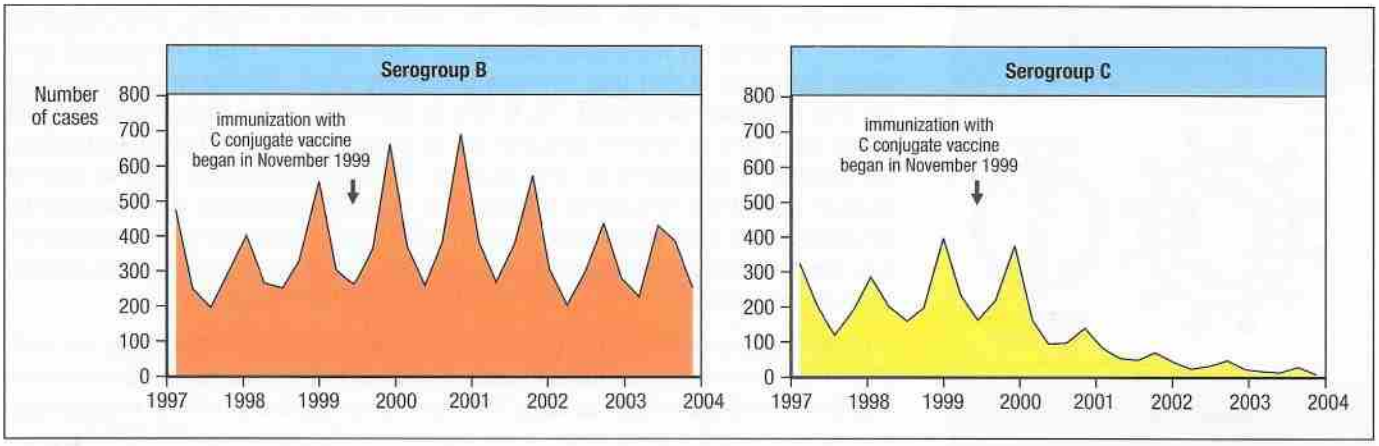

Fig. 16.11 The effect of vaccination against group *C Neisseria meningitidis* (meningococcus) on the number of cases of group B and group C meningococcal disease in England and Wales. Meningococcal infection affects roughly 5 in 100,000 people a year in the United Kingdom, with groups B and C meningococci accounting for almost all the cases. Before the introduction of the meningitis C vaccine, group C disease was the second most common cause of meningococcal disease, accounting for about 40% of cases. Group C disease now accounts for less than 10% of cases, with group B disease accounting for more than 80% of cases. After the introduction of the vaccine, there was a significant decrease in the number of laboratory-confirmed cases of group C disease in all age groups. The impact was greatest in the immunized groups, with reductions of more than 90% in these groups. An impact has also been seen in the unimmunized age groups, with a reduction of about 70%, suggesting that this vaccine has had a herd immunity effect.

cell walls contain much of the adjuvant activity of the whole killed organism. Other bacterial adjuvants include killed *Bordetella pertussis*, bacterial polysaccharides, bacterial heat-shock proteins, and bacterial DNA. Many of these adjuvants cause quite marked inflammation and are not suitable for use in vaccines for humans.

Many adjuvants seem to work by triggering viral and bacterial sensor pathways, such as the TLR and NOD-like receptor families expressed by various innate immune cells, such as dendritic cells that activate naive T cells (see Chapter 3). The TLR-4 agonist **lipopolysaccharide (LPS)** has adjuvant effects, but its use is limited by its toxicity. Small amounts of injected LPS can induce a state of shock and systemic inflammation that mimics Gram-negative sepsis, raising the question whether its adjuvant effect can be separated from its toxic effects. Monophosphoryl lipid A, an LPS derivative and TLR-4 ligand, partly achieves this by retaining adjuvant effects but being associated with much lower toxicity than that of LPS. Both unmethylated CpG dinucleotides, which activate TLR-9, and **imiquimod**, a small-molecule drug that acts as a TLR-7 agonist, can provide adjuvant activity experimentally, but neither is approved as an adjuvant in human vaccines.

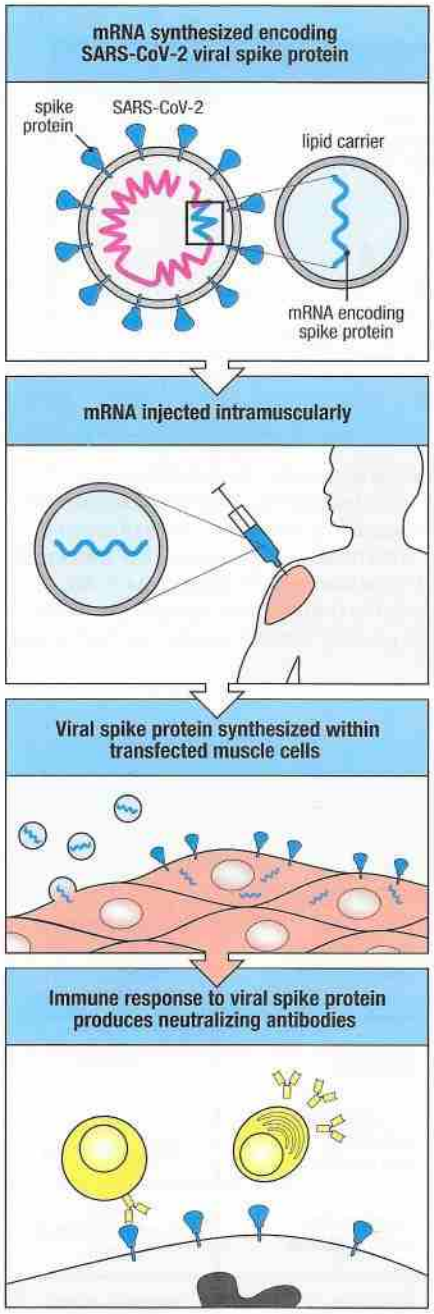
Adjuvants used in FDA-approved vaccines

Adjuvant	Vaccine
Alum (various aluminum salts)	Diphtheria/tetanus/whooping cough Pneumococcal conjugate vaccine
Aluminum hydroxide	Cervarix
D,L-alpha-tocopherol (vitamin E) and squalene	H5N1 influenza vaccine
Squalene and water emulsion	Fluad (seasonal influenza vaccine)
CpG 1018 (synthetic DNA)	Hepatitis vaccine (Heplisav-B)
Quillaja saponaria (lipid from evergreen tree)	Shingrix (shingles vaccine for elderly)

Fig. 16.12 Adjuvants used in FDA-approved vaccines. Adjuvants are not individually approved for use in the same way as conventional drugs. Rather, adjuvants are tested in combination with specific vaccines and are approved for use in that configuration.

16-9 Protective immunity can be induced by RNA- and DNA-based vaccination.

When bacterial plasmids were used to express proteins *in vivo* for gene therapy, some were found to stimulate an immune response. Later, it was found that DNA encoding a viral immunogen, when injected intramuscularly in mice, induced antibody responses and cytotoxic T cells that could protect against subsequent infection from the live virus. This response does not seem to damage the muscle tissue, is safe and effective, and, because it uses only a single microbial gene or a stretch of DNA encoding sets of antigenic peptides, does not carry the risk of active infection. This procedure, termed **DNA vaccination**, can be carried out in various ways. In one approach, DNA coated onto minute metal particles is administered by a 'gene gun,' so that particles penetrate the skin and potentially some underlying muscle, but other approaches, such as



mRNA synthesized encoding SARS-CoV-2 viral spike protein
spike protein
SARS-CoV-2
lipid carrier
mRNA encoding spike protein
mRNA injected intramuscularly
Viral spike protein synthesized within transfected muscle cells
Immune response to viral spike protein produces neutralizing antibodies

Fig. 16.13 RNA-based vaccines are being developed for COVID-19. Until 2020, there were no approved vaccines based on mRNA. The COVID-19 pandemic and the urgency for a vaccine has led to design and clinical testing of at least two RNA-based vaccines directed against the SARS-CoV-2 viral spike protein. In some configurations, mRNA produced *in vitro* is encapsulated in a lipid-based carrier and injected intramuscularly. Fusion of the lipid carrier with muscle cells releases the mRNA into the cells' cytoplasm, where it directs the translation of the spike protein, inducing an immune response and resulting in antibody response against the spike protein.

electroporation, are also possible. Because of DNA's stability, DNA vaccination is suitable for mass immunization. One problem with DNA-based vaccines, however, is that they are comparatively weak. Mixing in plasmids that encode cytokines such as IL-12, IL-23, or GM-CSF makes immunization with genes encoding protective antigens much more effective. In DNA vaccination, the antigen is produced by cells that are directly transfected, such as skin or muscle, but CD8 T-cell activation requires cross-presentation of the antigen by dendritic cells. Current approaches are identifying how best to transfect DNA into these dendritic-cell populations. DNA vaccines are being tested in human trials for malaria, influenza, HIV infection, and breast cancer.

A related approach to vaccine design involves RNA-based vaccines. As with DNA-based vaccines, the idea of using RNA to express the antigens in a vaccine is not new and dates back at least 20 years. However, this platform for vaccination has received a great deal of attention recently due to the COVID-19 pandemic. As of this writing, at least two RNA-based vaccines against SARS-CoV-2 have succeeded in clinical trials and are authorized for use in the general population. Like DNA-based vaccines, RNA vaccines are introduced into muscle cells, which then produce the encoded proteins. While inflammation caused by this process may serve as an adjuvant, the lipids selected to encapsulate the RNA also appear to exert a direct adjuvant effect, by activation of an inflammasome pathway, to enhance production of antibodies against the encoded proteins. The antigens encoded by the RNA vaccines against SARS-CoV-2 are forms of the coronavirus spike protein, which is bound to the viral membrane and serves to bind to host cellular receptors to initiate infection (Fig. 16.13). The receptor for this spike protein is the human angiotensin-converting enzyme 2 (ACE2), a membrane protein expressed by lung epithelial cells among others. The purpose of such vaccines is to induce antibodies capable of binding the spike protein, thus both neutralizing the virus and preventing cellular infection. Whether these vaccines will induce efficient T cell–mediated immunity is not yet clear. Recent analysis of convalescent COVID-19 patients suggests that the majority of T-cell epitopes against SARS-CoV-2 are derived from proteins other than the spike protein, such as nucleocapsid N protein or ORF1ab, the largest protein made by the virus. Compared to DNA vaccination and other conventional vaccines, RNA vaccines have the drawback of needing to be stored at very low temperatures from their production to the time of use, due to their relative instability, thus increasing the cost of their delivery.

16-10 The route of vaccination is an important determinant of success.

The ideal vaccination induces host defense at the point of entry of the infectious agent. Stimulation of mucosal immunity is therefore an important goal for vaccination against the many organisms that enter through mucosal surfaces. Still, most vaccines are given by injection, even though this route has several disadvantages. Injections are painful and unpopular, reducing vaccine uptake, and they are expensive, requiring needles, syringes, and a trained injector. Mass vaccination by injection is laborious. There is also the immunological drawback that injection may not be the most effective way of stimulating an appropriate immune response because it does not mimic the usual route of entry of the majority of pathogens against which vaccination is directed.

Many important pathogens infect mucosal surfaces or enter the body through mucosal surfaces. Examples include respiratory microorganisms such as *B. pertussis*, rhinoviruses, and influenza viruses, as well as enteric microorganisms such as *Vibrio cholerae*, *Salmonella enterica* serovar Typhi, enteropathogenic *Escherichia coli*, and *Shigella*. Likewise, infection with *Salmonella* stimulates a powerful mucosal and systemic immune response. The intranasally administered live-attenuated vaccine against influenza virus induces

mucosal antibodies, which are more effective than systemic antibodies in the control of upper respiratory tract infection. However, the systemic antibodies induced by injection are effective in controlling lower respiratory tract disease, which is responsible for the severe morbidity and mortality due to this disease. Thus, a realistic goal of any pandemic influenza vaccine is to prevent the lower respiratory tract disease but accept the fact that mild illness may not be prevented.

The power of mucosal vaccination is illustrated by the effectiveness of live-attenuated polio vaccines. The Sabin oral polio vaccine consists of three attenuated poliovirus strains that are highly immunogenic. As we described in Section 16-5, these vaccine strains can be transmitted from one individual to another by the fecal–oral route by contamination of public swimming pools or other failures of hygiene, just as poliovirus itself is transmitted.

16-11 *Bordetella pertussis* vaccination illustrates the importance of the perceived safety of a vaccine.

The public perception of a vaccine's safety can influence its eventual effectiveness. The history of vaccination against the bacterium that causes whooping cough, *Bordetella pertussis*, illustrates not only the challenges of developing an effective vaccine but also the public appeal of acellular conjugate vaccines over attenuated live organisms. At the beginning of the 20th century, whooping cough killed about 0.5% of American children under the age of 5 years. In the early 1930s, a trial of a killed, whole bacterial cell vaccine on the Faroe Islands provided evidence of a protective effect. In the United States, systematic use of a whole-cell pertussis vaccine in combination with diphtheria and tetanus toxoids (the DTaP vaccine) during the 1940s resulted in a decline in the annual infection rate from 200 to fewer than 2 cases per 100,000 of the population. The first vaccination with DTaP was typically given at the age of 3 months.

Whole-cell pertussis vaccine causes side effects, typically redness, pain, and swelling at the site of the injection; less commonly, vaccination is followed by high temperature and persistent crying. Very rarely, fits and temporary sleepiness or a floppy unresponsive state ensue. During the 1970s, widespread concern developed after several anecdotal observations that encephalitis leading to irreversible brain damage might very rarely follow pertussis vaccination. In Japan, in 1972, about 85% of children were given the pertussis vaccine, and fewer than 300 cases of whooping cough and no deaths were reported. However, as a result of two deaths after vaccination in Japan in 1975, the use of DTaP was temporarily suspended and then reintroduced with the first vaccination at 2 years of age rather than at 3 months. In 1979, there were about 13,000 cases of whooping cough and 41 deaths. The possibility that pertussis vaccine very rarely causes severe brain damage has been studied extensively, and expert consensus is that pertussis vaccine is not a primary cause of brain injury. There is no doubt that there is greater morbidity from whooping cough than from the vaccine.

The perception that whole-cell pertussis vaccination might be unsafe provided a powerful incentive to develop safer pertussis vaccines. The natural immune response to *B. pertussis* infection induced antibodies against four components of the bacterium—pertussis toxin, filamentous hemagglutinin, pertactin, and fimbrial antigens. Immunization of mice with these antigens in purified form protected them against challenge with pertussis. This has led to the development of **acellular pertussis vaccines**, which contain purified pertussis toxoid; that is, toxin inactivated by chemical treatment, for example with hydrogen peroxide or formaldehyde, or more recently by genetic engineering of the toxin. Some pertussis vaccines also contain filamentous hemagglutinin, pertactin, and/or fimbrial antigens, either alone or in any combination of the

three. Current evidence shows that these vaccines are probably as effective as whole-cell pertussis vaccine while lacking its common minor side effects. The acellular vaccine is more expensive, however, thus restricting its use in poorer countries, and there is continuing interest and current work to improve new live-attenuated pertussis vaccines.

The history of pertussis vaccination illustrates that, first and foremost, vaccines must be extremely safe and free of side effects; second, the public and the medical profession must perceive the vaccine to be safe; and third, careful study of the nature of the protective immune response can lead to acellular vaccines that are as effective as whole-cell vaccines but also safer. Still, public concerns about vaccination remain high. Unwarranted fears of a link between the combined live-attenuated MMR vaccine and autism saw the uptake of MMR vaccine in England fall from a peak of 92% of children in 1995–1996 to 84% in 2001–2002. Small clustered outbreaks of measles and mumps in London since 2002 illustrate the importance of maintaining high uptake of vaccine to maintain herd immunity.

16-12 Peptide-based vaccines can elicit protective immunity, but they require adjuvants and must be targeted to the appropriate cells and cell compartment to be effective.

Another vaccine strategy relies on identifying the T-cell peptide epitopes that stimulate protective immunity. These can be identified by testing overlapping peptides from immunogenic proteins for their ability to stimulate protective immunity or by predicting candidate peptide epitopes on the basis of the genome sequence of the pathogen. The latter approach has been applied to malaria by using the complete sequence of the *Plasmodium falciparum* genome. The starting point was the association between the human MHC class I molecule HLA-B53 and resistance to cerebral malaria, a relatively infrequent, but usually fatal, complication of infection by *P. falciparum*. It was thought that HLA-B53 might protect against cerebral malaria because it could present peptides that are particularly good at activating naive cytotoxic T lymphocytes. Peptides eluted from HLA-B53 frequently contain a proline as the second of their nine amino acids. On the basis of this information, reverse genetic analysis identified candidate protective peptides from four proteins of *P. falciparum* expressed in the early phase of hepatocyte infection—an important phase of infection to target in an effective immune response. One of the candidate peptides, from liver-stage antigen-1, has been shown to be recognized by cytotoxic T cells when bound to HLA-B53 and may be a useful peptide for use in vaccination.

Peptide-based vaccines have several drawbacks. First, a particular peptide may not bind to all the MHC molecules present in the population. Because humans are highly polymorphic in the MHC, a large panel of protective peptides would be needed for coverage of most individuals. Second, some direct exchange of short peptides on MHC molecules can occur without physiological antigen processing. Loading of antigenic peptides onto MHC molecules on cells other than dendritic cells may not stimulate immunity and may induce tolerance instead. Third, exogenous proteins and peptides delivered by a synthetic vaccine are efficiently processed for presentation by MHC class II molecules but require 'cross-presentation' in specific types of dendritic cells to be loaded onto MHC class I molecules (see Section 6-5). Directing peptide-based vaccines to cross-presenting dendritic cells may be required to enhance vaccine efficacy.

Recent peptide-based vaccines have already shown promise in human clinical trials. Individuals with established vulvar intraepithelial neoplasia, an early form of vulvar cancer caused by human papilloma virus (HPV), were treated with a vaccine consisting of long peptides covering the entire length

of two oncoproteins of HPV-16—E6 and E7—and delivered in an oil-in-water emulsion as adjuvant. By using very long peptides, around 100 amino acids in length, multiple candidate peptide epitopes can be delivered that may also be presented by different MHC alleles. These peptides seem to be too long for direct exchange with peptides on cell surfaces and require processing by dendritic cells in order to be loaded onto MHC class I molecules. This vaccine induced complete clinical remission in one-quarter of the recipients, and about half of the treated patients showed significant clinical responses that correlated with *in vitro* evidence of enhanced cell-mediated immunity.

16-13 Vaccination and checkpoint blockade may be useful in controlling existing chronic infections.

There are many chronic diseases in which infection persists because of a failure of the immune system to eliminate disease. Such infections can be divided into two groups: those in which there is an obvious immune response that fails to eliminate the organism, and those that seem to be invisible to the immune system and evoke a barely detectable immune response.

In the first category, the immune response is often partly responsible for the pathogenic effects. Infection by the helminth *Schistosoma mansoni* is associated with a powerful T_H2-type response, characterized by high levels of IgE, circulating and tissue eosinophilia, and a harmful fibrotic response to schistosome ova in the liver, leading to hepatic fibrosis. Other common parasites, such as *Plasmodium* and *Leishmania* species, cause damage because they are not eliminated effectively by the immune response. The mycobacterial agents of tuberculosis and leprosy cause a persistent intracellular infection; a T_H1 response helps to contain these infections but also causes granuloma formation and tissue necrosis (see Fig. 11.13).

Among viruses, hepatitis B and hepatitis C infections are commonly followed by a persistent viral burden and hepatic injury, resulting in eventual death from hepatitis or from hepatocellular carcinoma. Infection with HIV, as we have seen in Chapter 13, also persists despite an ongoing immune response.

In the second category of chronic infection, which is predominantly viral, the immune response fails to clear the infection because of the relative invisibility of the infectious agent to the immune system. A good example is herpes simplex virus type 2, which is transmitted venereally, becomes latent in nerve tissue, and causes genital herpes, which is frequently recurrent. The invisibility of this virus seems to be caused by a viral protein, ICP-47, which binds to the TAP complex (see Section 6-3) and inhibits peptide transport into the endoplasmic reticulum in infected cells. Thus, viral peptides are not presented to the immune system by MHC class I molecules. A similar example in this category of chronic infection is genital warts, caused by certain papilloma viruses that evoke very little immune response, particularly a cell-mediated response. As discussed earlier, the results of a recent clinical trial showed that use of long-peptide vaccines against HPV-16 was effective in increasing the strength of cell-mediated immune responses to viral antigens and in reducing or eliminating precancerous lesions associated with the HPV infection (see Section 16-12). These results suggest that vaccines that enhance the T cell–mediated responses to other pathogens may be similarly effective.

Summary.

Vaccination is arguably the greatest success of immunology, having eradicated or virtually eliminated several human diseases. It is the single most successful manipulation of the immune system so far, because it takes advantage of the immune system's natural specificity and inducibility. But important human infectious diseases remain that lack effective vaccines. Most effective vaccines

are based on attenuated live microorganisms, but such vaccines carry some risk and are potentially lethal to immunosuppressed or immunodeficient individuals. The live-attenuated polio vaccines can undergo revertant mutations that can enhance their virulence, but new molecular engineering is being applied to reduce the frequency of these events. New techniques are also being developed to generate genetically attenuated pathogens for use as vaccines, particularly for malaria and tuberculosis. Many bacterial vaccines are based on components of the microorganism, including components of the toxins that it produces. Protective responses to carbohydrate antigens, which in very young children do not provoke lasting immunity, can be enhanced by conjugation of the carbohydrate to a protein. Vaccines based on DNA, RNA, and very long peptides are just emerging from the experimental stage and are beginning to be tested in humans. In particular, RNA-based vaccines were developed during 2020 for use against COVID-19. A vaccine's immunogenicity often depends on adjuvants that can help, directly or indirectly, to activate antigen-presenting cells that are necessary for the initiation of immune responses. Adjuvants activate these cells by engaging the innate immune system and providing ligands for TLRs and other innate sensors on antigen-presenting cells.

Using the immune response to attack tumors.

Cancer is one of the leading causes of death in industrialized nations, the others being heart disease and stroke, and chronic respiratory diseases. As treatments for infectious diseases and cardiovascular diseases improve, and average life expectancy increases, cancer may become the most common fatal disease in these countries. Cancers are caused by the uncontrolled growth of the progeny of transformed cells. A major problem in treating cancer is controlling **metastasis**, or the spread of cancerous cells from one part of the body to unconnected parts. Curing cancer therefore requires that all the malignant cells be removed or destroyed without killing the patient. An attractive way of achieving this would be to induce an immune response against the tumor that would discriminate between tumor cells and their normal-cell counterparts, as vaccination induces a immune response that selectively targets only a particular pathogen. Immunological approaches to cancer treatment have been considered for more than a century. However, the remarkable progress over the past two decades in large part has resulted from the application of biologics—such as antibodies or cytokines—and their application to regulation of the adaptive immune response.

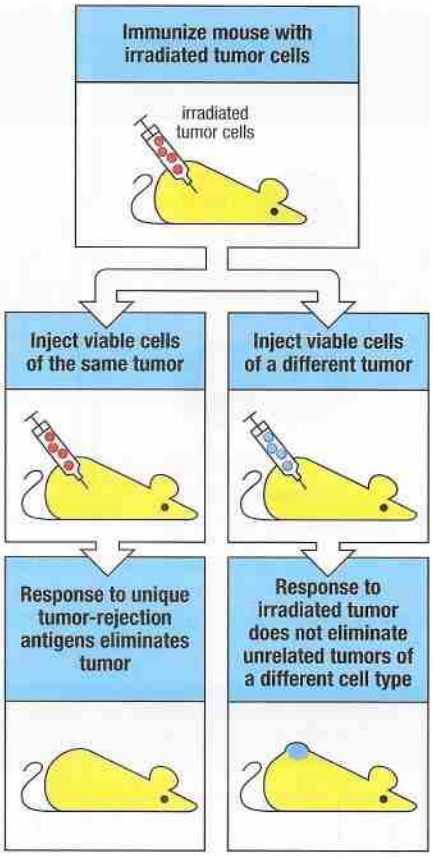
16-14 The development of transplantable tumors in mice led to the discovery of protective immune responses to tumors.

The finding that tumors could be induced in mice after treatment with chemical carcinogens or irradiation, coupled with the development of inbred strains of mice, made it possible to undertake the key experiments that led to the discovery of immune responses to tumors. These tumors could be transplanted between mice. The experimental study of tumor rejection has generally been based on such tumors. If they bear MHC molecules foreign to the mice into which they are transplanted, the tumor cells are readily recognized and destroyed by the immune system, a fact that was exploited to develop the first MHC-congenic strains of mice. Specific immunity to tumors must therefore be studied within inbred strains, so that host and tumor can be matched for their MHC type.

In mice, transplantable tumors exhibit a variable pattern of growth when injected into syngeneic recipients. Most tumors grow progressively and

eventually kill the host. However, if mice are injected with irradiated tumor cells that cannot grow, they are frequently protected against subsequent injection with a normally lethal dose of viable cells from the same tumor (Fig. 16.14). There seems to be a spectrum of immunogenicity among transplantable tumors: injections of irradiated tumor cells seem to induce varying degrees of protective immunity against a challenge injection of viable tumor cells at a distant site. These protective effects are not seen in T cell–deficient mice but can be conferred by adoptive transfer of T cells from immune mice, showing the need for T cells to mediate these effects.

These observations indicate that the tumors express antigens that can become targets of a tumor-specific T-cell response that rejects the tumor. These **tumor-rejection antigens** are expressed by experimentally induced murine tumors (in which they are often termed tumor-specific transplantation antigens) and are usually specific for an individual tumor. Thus, immunization with irradiated tumor cells from one tumor usually protects a syngeneic mouse from challenge with live cells from that same tumor, but not from challenge with a different syngeneic tumor (see Fig. 16.14).



Immunize mouse with irradiated tumor cells
irradiated tumor cells
Inject viable cells of the same tumor
Inject viable cells of a different tumor
Response to unique tumor-rejection antigens eliminates tumor
Response to irradiated tumor does not eliminate unrelated tumors of a different cell type

Fig. 16.14 Tumor-rejection antigens are specific to individual tumors. Mice immunized with irradiated tumor cells and challenged with viable cells of the same tumor can, in some cases, reject a lethal dose of that tumor (left panels). This is the result of an immune response to tumor-rejection antigens. If the immunized mice are challenged with viable cells of a different tumor, there is no protection and the mice die (right panels).

16-15 Tumors are 'edited' by the immune system as they evolve and can escape rejection in many ways.

Paul Ehrlich, who received the 1908 Nobel Prize for his work in immunology, was perhaps the first to propose that the immune system could be used to treat established tumors, suggesting that the molecules we call antibodies might be used to deliver toxins to cancer cells. In the 1950s, Frank Macfarlane Burnet, recipient of the 1960 Nobel Prize, and Lewis Thomas formulated the '**immune surveillance**' hypothesis, according to which cells of the immune system would detect and destroy tumor cells. Since then, it has become clear that the relationship between the immune system and cancer is considerably more complex, and this hypothesis has been modified to consider three phases of interactions between the immune system and a tumor. Many tumors are characterized by a loss of genome stability, in which not only is growth regulation disturbed, but so are the processes that ensure the faithful replication of the genome during cell division. Because of this, many tumors acquire mutations in proteins that may be recognized as 'foreign' by the immune system. Also, tumors can express ligands for NK-cell receptors such as NKG2D, which normally indicate cellular stress or infection (see Figure 6.26). For these reasons, early tumors may be recognized by innate cells, such as NK cells, and by T cells that react to '**neoantigens**,' or **neoepitopes**—antigens created by mutations. At this stage, the immune system may recognize and destroy potential tumor cells. This is the '**elimination phase**,' which was the phenomenon previously referred to as immune surveillance (Fig. 16.15). If elimination is not completely successful, what follows is an '**equilibrium phase**,' in which the proliferation of tumor cells causes additional changes or mutations. The selection pressure imposed by the immune system influences which of these new tumor cells can survive and which will be eliminated. During the equilibrium phase, a process known as **cancer immunoediting** continually shapes the properties of the tumor cells that survive. In the final '**escape phase**,' tumor cells that have acquired the ability to elude the attention of the immune system and grow unimpeded become clinically detectable.

Experimental evidence that these processes influence the development of certain types of tumors is based on observations of tumor growth in mice that have various targeted gene deletions or have been treated with antibodies to inhibit particular components of immunity. For example, mice lacking perforin, part of the killing mechanism of NK cells and cytotoxic CD8 T cells (see Section 9-22), show an increased frequency of lymphomas—tumors of the lymphoid system. Also, the frequency of fibrosarcomas induced by the

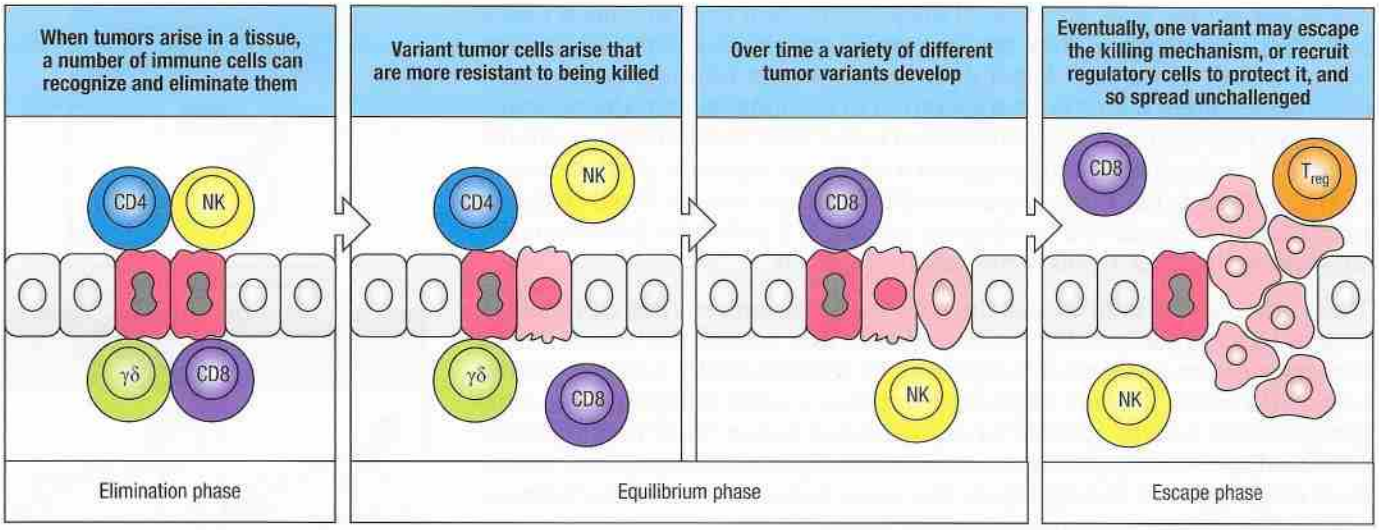


Fig. 16.15 Malignant cells can be controlled by immune surveillance. Some types of tumor cells are recognized by a variety of immune-system cells, which can eliminate them (left panel). If the tumor cells are not completely eliminated, variants occur that eventually escape the immune system and proliferate to form a tumor.

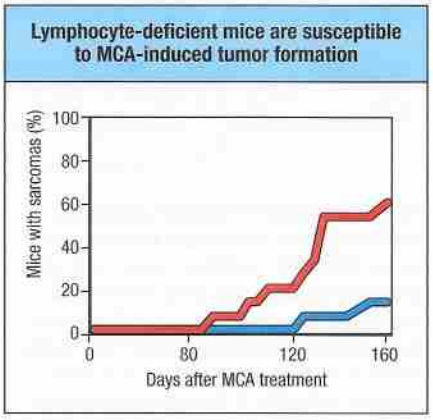

Fig. 16.16 Immune surveillance by lymphocytes reduces MCA-induced tumor formation. The idea that immune surveillance might protect against tumors is quite old, but direct experimental evidence of this process is relatively recent. This research relied on strains of mice engineered to lack lymphocytes or specific immune signaling pathways. In the experiment shown here, mice deficient in the gene *Rag2* (red line), and thus lacking T and B cells, were prospectively compared with wild-type mice (blue line) of the same genetic background for the rate of development of fibrosarcomas after treatment with the carcinogen methylcholanthrene (MCA). The absence of adaptive immunity was seen to cause an increased frequency in tumor formation.

chemical carcinogen methylcholanthrene (MCA) is greater in mice lacking the RAG-2 protein, which is necessary for the development of T cells and B cells (Fig. 16.16). MCA-induced tumor frequency is further increased in mice lacking both RAG-2 and STAT1, the latter a transcription factor that mediates signaling by receptors for IFN-γ and IFN-α/β. Mice lacking T lymphocytes expressing γδ receptors show markedly increased susceptibility to skin tumors induced by the topical application of carcinogens, illustrating a role for intraepithelial γδ T cells (see Section 6-20) in surveying and killing abnormal epithelial cells. Studies of the various effector cells of the immune system show that γδ T cells are a major source of IFN-γ, which may explain their importance in the removal of cancer cells.

According to the immunoediting hypothesis, those tumor cells that survive the equilibrium phase have acquired additional changes, such as mutations during the equilibrium phase, that prevent their elimination by the immune system. In an immunocompetent individual, the equilibrium phase of the immune response continually removes tumor cells, delaying tumor growth; if the immune system is compromised, the equilibrium phase quickly turns into an escape phase, as no tumor cells at all are removed. An excellent clinical example of the presence of tumor cells in the equilibrium phase is the occurrence of cancer in recipients of organ transplants. One study reported the development of melanoma between 1 and 2 years after transplantation in two individuals who had received kidneys from the same donor, a woman who had been successfully treated for malignant melanoma 16 years before her death. Presumably, melanoma cells, which are known to spread easily to other organs, were present in the donor kidneys at the time of transplantation but were in equilibrium phase with the immune system. If so, this would indicate that the melanoma cells had not been completely eliminated by the immunocompetent immune system of the donor, but instead had simply been held in check. Because the recipients' immune systems were immunosuppressed to prevent graft rejection, the melanoma cells were released from equilibrium and began to divide rapidly and spread to other parts of the body.

Another situation in which the suppression of immunity can lead to tumor development is in **post-transplant lymphoproliferative disorder**, which can occur when patients are immunosuppressed after, for example, solid organ transplantation. It usually takes the form of a B-cell expansion driven by Epstein–Barr virus (EBV) in which the B cells can undergo mutations and

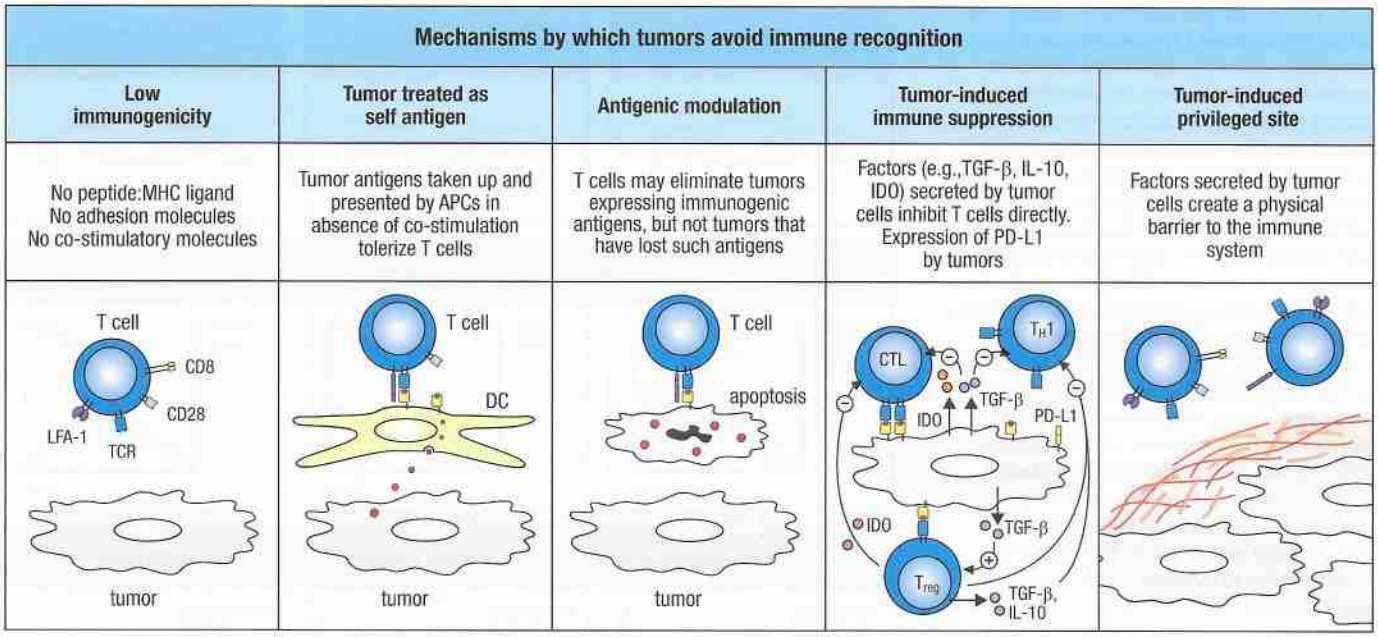

Fig. 16.17 Tumors can avoid immune recognition in a variety of ways. First panel: Tumors can have low immunogenicity. Tumors may lack antigens recognized by T cells, may have lost one or more MHC molecules, or may express inhibitory molecules that repress T-cell function, such as programmed death ligand-1 (PD-L1). Second panel: Tumor-specific antigens may be cross-presented by dendritic cells without co-stimulatory signals, inducing a tolerant state in T cells. Third panel: Tumors can initially express antigens to which the immune system responds. Such tumors may be eliminated. The genetic instability of tumors allows antigenic change, part of an equilibrium phase, during which tumor cells lacking immunogenic antigens can expand. Fourth panel: Tumors often produce molecules, such as TGF-β, IL-10, indoleamine 2,3-dioxygenase (IDO), and PD-L1, that suppress immune responses directly or recruit regulatory T cells that can secrete immunosuppressive cytokines. Fifth panel: Tumor cells can secrete molecules such as collagen that form a physical barrier around the tumor, preventing lymphocyte access.

become malignant. Here, antiviral immunity functions as a form of cancer immunosurveillance, as it normally eliminates the EBV that leads to B-cell transformation.

Acute Infectious Mononucleosis

Tumors can avoid stimulating an immune response or can evade it when it occurs by means of numerous mechanisms, which are summarized in Fig. 16.17. Spontaneous tumors may initially lack mutations that produce new tumor-specific antigens that elicit T-cell responses (see Fig. 16.17, first panel). Lack of co-stimulatory signals expressed by the antigen-presenting cells (APCs) presenting neoantigens to T cells may cause a failed response, or lead to tolerance (see Fig. 16.17, second panel). How long such tumors are treated as 'self' is unclear. Recent sequencing of entire tumor genomes reveals that mutations may generate as many as 10–15 unique antigenic peptides that could be recognized as 'foreign' by T cells. In addition, cellular transformation is frequently associated with induction of MHC class Ib proteins (such as ULBPs, MIC-A and MIC-B) that are ligands for NKG2D, thus allowing tumor recognition by NK cells (see Section 6-17). But cancer cells tend to be genetically unstable, so that clones that are not recognized by an immune response may be able to escape elimination.

Some tumors, such as colon and cervical cancers, lose the expression of a particular MHC class I molecule, perhaps through immune selection by T cells specific for a peptide presented by that MHC class I molecule (see Fig. 16.17, third panel). In experimental studies, when a tumor loses expression of all MHC class I molecules, it can no longer be recognized by cytotoxic T cells, although it might become susceptible to NK cells (Fig. 16.18). Tumors that lose only one MHC class I molecule might be able to avoid recognition by specific cytotoxic CD8 T cells while still remaining resistant to NK cells, conferring a selective advantage *in vivo*.

Fig. 16.18 Tumors that lose expression of all MHC class I molecules as a mechanism of escape from immune surveillance are more susceptible to being killed by NK cells. Regression of transplanted tumors is largely due to the actions of cytotoxic T lymphocytes (CTLs), which recognize novel peptides bound to MHC class I antigens on the surface of the cell (left panels). NK cells have inhibitory receptors that bind MHC class I molecules, so variants of the tumor that have low levels of MHC class I, although less sensitive to cytotoxic CD8 T cells, become susceptible to NK cells (center panels). Although *nude* mice lack T cells, they have higher than normal levels of NK cells, and so tumors that are sensitive to NK cells grow less well in *nude* mice than in normal mice. Transfection with MHC class I genes can restore both resistance to NK cells and susceptibility to cytotoxic CD8 T cells (right panels).

Tumors also seem to be able to evade immune attack by creating a microenvironment that is generally immunosuppressive (see Fig. 16.17, fourth panel). Many tumors make immunosuppressive cytokines. Transforming growth factor-β (TGF-β) was first identified in the culture supernatant of a tumor (hence its name), and, as we have seen, it tends to suppress the inflammatory T-cell responses and cell-mediated immunity that are needed to control tumor growth. Recall that TGF-β promotes the development of peripheral regulatory T cells (pT_{reg} cells; see Section 9-15), which have been found in a variety of cancers and might expand specifically in response to tumor antigens. In mouse models, removal of T_{reg} cells increases resistance to cancer, whereas their transfer into a T_{reg}-negative recipient allows cancer cells to proliferate.

The microenvironments of some tumors also contain populations of myeloid cells, collectively called **myeloid-derived suppressor cells (MDSCs)**, which can inhibit T-cell activation within the tumor. MDSCs may be heterogeneous, comprising both monocytic and polymorphonuclear cells, and are still incompletely characterized. Several tumors of different tissue origins, such as melanoma, ovarian carcinoma, and B-cell lymphoma, have also been shown to produce the immunosuppressive cytokine IL-10, which can reduce dendritic-cell activity and inhibit T-cell activation.

Tumors can express cell-surface proteins that directly inhibit immune responses (see Fig. 16.17, fourth panel). For example, some tumors express **programmed death ligand-1 (PD-L1)**, a B7 family member and ligand for the inhibitory receptor **PD-1** expressed by activated T cells (see Section 7-25). Tumors can also produce enzymes that suppress local immune responses. The enzyme **indoleamine 2,3-dioxygenase (IDO)** catabolizes tryptophan, an essential amino acid, in order to produce the immunosuppressive metabolite kynurenine. IDO seems to function in maintaining a balance between immune responses and tolerance during infections, but it can be induced during the equilibrium phase of tumor development. Finally,

tumor cells can produce materials such as collagen, creating a physical barrier to interaction with cells of the immune system (see Fig. 16.17, last panel).

16-16 Tumor-rejection antigens can be recognized by T cells and form the basis of immunotherapies.

Several categories of tumor-rejection antigens can be distinguished (Fig. 16.19). One category of tumor-rejection antigens comprises peptides derived from tumor-cell proteins presented by MHC molecules to T cells. Some peptides of this category can also be present on normal tissues yet become the targets of a tumor-specific T-cell response. For example, immunotherapy in people with melanoma can produce vitiligo, an autoimmune destruction of pigmented cells in healthy skin. Other peptides in this category may become **tumor-specific antigens** as a result of gene mutations or rearrangements that alter specific amino acid residues and produce a peptide epitope for T cells that are already able to bind to MHC class I molecules or that allow mutant peptides to bind *de novo* to MHC class I molecules. Such neoantigens, or neoepitopes, are newly immunogenic versions of normal proteins and may evoke a new T-cell response against the tumor. In B- and T-cell tumors, which are derived from single clones of lymphocytes, a special class of tumor-specific antigen comprises the unique rearranged antigen receptor expressed by the clone. However, not all mutated peptides may be properly processed or be able to associate with MHC molecules and thus ensure that they stimulate an effective response.

Potential tumor-rejection antigens have a variety of origins

Class of antigen	Antigen	Nature of antigen	Tumor type
Tumor-specific mutated oncogene or tumor suppressor gene	Cyclin-dependent kinase 4	Cell-cycle regulator	Melanoma
	β-Catenin	Relay in signal transduction pathway	Melanoma
	Caspase 8	Regulator of apoptosis	Squamous-cell carcinoma
	Surface Ig/ idiotype	Specific antibody after gene rearrangements in B-cell clone	Lymphoma
Cancer-testis antigens	MAGE-1 MAGE-3 NY-ESO-1	Normal testicular proteins	Melanoma Breast Glioma
Differentiation	Tyrosinase	Enzyme in pathway of melanin synthesis	Melanoma
Abnormal gene expression	HER-2/neu	Receptor tyrosine kinase	Breast Ovary
	WT1	Transcription factor	Leukemia
Abnormal post-translational modification	MUC-1	Underglycosylated mucin	Breast Pancreas
Abnormal post-transcriptional modification	NA17	Retention of introns in the mRNA	Melanoma
Oncoviral protein	HPV type 16, E6 and E7 proteins	Viral transforming gene products	Cervical carcinoma

Fig. 16.19 Proteins selectively expressed in human tumors are candidate tumor-rejection antigens. The molecules listed here represent the various categories of tumor-rejection antigens. For surface Ig, 'idiotype' refers to the unique protein structure of the particular antibody clone expressed by the lymphoma cells. These molecules have been shown to be recognized by cytotoxic T lymphocytes raised from patients with the tumor type listed.

A second category of tumor-rejection antigens is the **cancer-testis antigens**. These are proteins encoded by genes that are normally expressed only in male germ cells in the testis. Male germ cells do not express MHC molecules, and therefore peptides from these molecules are not normally presented to T lymphocytes. Tumor cells can show widespread abnormalities of gene expression, including the activation of genes encoding cancer-testis antigens, such as the **melanoma-associated antigens (MAGEs)** (see Fig. 16.19). When expressed by tumor cells, peptides derived from these 'germ-cell' proteins can now be presented to T cells by MHC class I molecules. Therefore, these proteins are effectively tumor-specific in their expression as antigens. Perhaps the cancer-testis antigen best characterized immunologically is **NY-ESO-1** (New York esophageal squamous-cell carcinoma-1), which is highly immunogenic and is expressed by a variety of human tumors, including melanomas.

A third category of tumor-rejection antigens is the class of **differentiation antigens** encoded by genes that are expressed only in particular types of tissues. Examples of these are the differentiation antigens expressed in melanocytes and melanoma cells, which include several proteins in the pathways that produce the black pigment melanin, and the CD19 antigen expressed by B cells. A fourth category of tumor-rejection antigens consists of antigens that are strongly overexpressed in tumor cells compared with their normal counterparts. An example is **HER-2/neu** (also known as c-Erb-2), which is a receptor tyrosine kinase homologous to the epidermal growth factor receptor. HER-2/neu is overexpressed in many adenocarcinomas, including breast and ovarian cancers, where it is associated with a poor clinical prognosis. CD8 T lymphocytes have been found infiltrating solid tumors overexpressing HER-2/neu but are not capable of destroying such tumors *in vivo*. A fifth category of tumor-rejection antigens consists of molecules that display abnormal post-translational modifications. An example is underglycosylated mucin, MUC-1, which is expressed by several tumors, including breast and pancreatic cancers. A sixth category of tumor-rejection antigens consists of novel proteins that are generated when one or more introns are retained in the mRNA transcribed from a gene, which occurs in melanoma. A seventh category of tumor-rejection antigens comprises proteins encoded by viral oncogenes. These oncoviral proteins can have a critical role in the oncogenic process, and because they are foreign, they can evoke a T-cell response. Examples are the human papilloma virus type 16 proteins E6 and E7, which are expressed in cervical carcinoma (see Section 16-20).

In melanoma, tumor-specific antigens were discovered by culturing irradiated tumor cells with autologous lymphocytes, a technique known as the mixed lymphocyte–tumor cell culture. From such cultures, cytotoxic T cells were identified that were reactive against melanoma peptides and would kill tumor cells bearing the relevant tumor-specific antigen. Such studies have revealed that melanomas carry at least five different antigens that can be recognized by cytotoxic T lymphocytes. It seems that cytotoxic T lymphocytes reactive against melanoma antigens are not effective *in vivo*, perhaps due to deficient priming and insufficient effector function or to downstream resistance mechanisms. However, melanoma-specific T cells can be isolated from peripheral blood, lymph nodes, or directly from lymphocytes infiltrating the tumor and propagated *in vitro*. These T cells do not recognize the products of mutant proto-oncogenes or tumor suppressor genes, but instead recognize antigens derived from the protein products of other mutant genes or from normal proteins that are now displayed on tumor cells at levels detectable by T cells for the first time. Cancer-testis antigens such as the MAGEs discussed earlier probably represent early developmental antigens reexpressed in the process of tumorigenesis. Only a minority of people with melanoma have T cells reactive to the MAGEs, indicating

that these antigens either are not expressed or are not immunogenic in most cases.

The most common melanoma antigens are peptides from the enzyme **tyrosinase** or from three other proteins—gp100, MART1, and gp75. These are differentiation antigens specific to the melanocyte lineage. It is likely that overexpression of these antigens in tumor cells leads to an abnormally high density of specific peptide:MHC complexes, and it is this that makes them immunogenic. Tumor-rejection antigens are usually presented as peptides by MHC class I molecules, but tyrosinase can also stimulate CD4 T-cell responses in some melanoma patients, likely presented by MHC class II molecules. Both CD8 and CD4 T cells are likely to be important in achieving immunological control of tumors. CD8 cells can kill the tumor cells directly, while CD4 T cells have a role in promoting the activation of cytotoxic CD8 T cells by helping to fully activate antigen-presenting cells, usually dendritic cells, that prime CD8 T cells. CD4 T cells may also kill tumor cells by means of the cytokines that they secrete, such as TNF-α.

Other potential tumor-rejection antigens include the products of mutated cellular oncogenes or tumor suppressors, such as Ras and p53, and also fusion proteins, such as the **Bcr–Abl tyrosine kinase** that results from the chromosomal translocation, t(9;22), found in chronic myeloid leukemia (CML). When present on CML cells, the HLA class I molecule HLA-A*0301 can display a peptide derived from the fusion site between Bcr and Abl. This peptide was detected by a powerful technique known as 'reverse immunogenetics,' in which endogenous peptides were eluted from the MHC binding groove, and their sequence was determined by highly sensitive mass spectrometry. This technique has identified HLA-bound peptides from other tumor antigens, such as the MART1 and gp100 tumor antigens of melanomas, as well as candidate peptide sequences for vaccination against infectious diseases.

T cells specific for the Bcr–Abl fusion peptide can be identified in peripheral blood from individuals with CML by using tetramers of HLA-A*0301 carrying the peptide as specific ligands for the antigen-specific T-cell receptor. Cytotoxic T lymphocytes specific for this and other tumor antigens can be selected *in vitro* by using peptides derived from the mutated or fused portions of these oncogenic proteins; these cytotoxic T cells are able to recognize and kill tumor cells.

After a bone marrow transplant to treat CML, mature lymphocytes from the bone marrow donor infused into the patient can help to eliminate any residual tumor. This technique is known as **donor lymphocyte infusion (DLI)**. At present, it is not clear to what extent the clinical response is due to a graft-versus-host effect, in which the donor lymphocytes are responding to general alloantigens expressed on the leukemia cells (see Section 15-25), or whether a specific antileukemic response is important. It is encouraging that it has been possible to separate T lymphocytes *in vitro* that mediate either a graft-versus-host effect or a graft-versus-leukemia effect. The ability to prime the donor cells against leukemia-specific peptides offers the prospect of enhancing the antileukemic effect while minimizing the risk of graft-versus-host disease.

16-17 Checkpoint blockade can augment immune responses to existing tumors.

Various approaches to harnessing the immune system to treat tumors have been tried. Some have aimed at making the tumor itself more immunogenic by inducing the expression of co-stimulatory molecules on tumor cells and

using these cells to activate tumor-specific naive T cells. Similarly, tumor cells have been transfected with the gene encoding cytokines, such as granulocyte–macrophage colony-stimulating factor (GM-CSF), in an attempt to induce the maturation of tumor-proximal monocytes into monocyte-derived dendritic cells. Once these cells have differentiated and capture antigens from the tumor, it was hoped they would migrate to the local lymph nodes and activate tumor-specific T cells. No approved therapies have yet emerged from these approaches.

A different approach to cancer immunotherapy is to block the normal inhibitory signals that regulate lymphocytes, called **checkpoint blockade**. Immune responses are controlled by several positive and negative immunological checkpoints. A positive checkpoint for T cells is controlled by the co-stimulatory receptors, such as CD28 and members of the TNF receptor superfamily, such as CD27 and 4-1BB. These activating receptors are stimulated by engagement of their ligands expressed by antigen-presenting cells such as dendritic cells. Negative immunological checkpoints are provided by inhibitory receptors such as CTLA-4 and PD-1. CTLA-4 imposes a critical checkpoint for potentially autoreactive T cells by binding to B7 molecules on dendritic cells and effectively providing a negative signal that must be overcome by other signals before T cells can become activated. Blocking CTLA-4 with antibodies may therefore lower the threshold for T-cell activation. Some evidence also indicates that anti-CTLA-4 antibodies may augment immune responses by eliminating regulatory T cells, which constitutively express a high level of CTLA-4 on their surface. Whatever the mechanism, the absence of this checkpoint causes self-reactive T cells that are normally held in check to become activated and to produce a multi-tissue autoimmune reaction, as seen in CTLA-4–deficient mice.

Checkpoint blockade based on the anti-CTLA-4 antibody **ipilimumab** has now been shown to be effective in treating metastatic melanoma and was approved by the FDA for this indication in 2015. Patients with metastatic melanoma who were treated with ipilimumab showed an increase in the number and activity of T cells recognizing NY-ESO-1, a cancer-testis antigen expressed by melanoma. Overall, only about 15% of recipients exhibited a response to ipilimumab, but the treatment appeared to induce long-term remission in some responding patients. One side effect of ipilimumab in these patients seemed to be an increased risk of autoimmune phenomena, in line with the role of CTLA-4 in maintaining tolerance of self-reactive T cells.

Another checkpoint involves the inhibitory receptor PD-1 and its ligands PD-L1 and PD-L2 (Fig. 16.20). PD-L1 is expressed on a wide variety of human tumors; in renal-cell carcinoma, PD-L1 expression is associated with a poor prognosis. In mice, transfection of the gene encoding PD-L1 into tumor cells increased their growth *in vivo* and reduced their susceptibility to lysis by cytotoxic T cells. These effects were reversed by an antibody against PD-L1. In humans, the anti-PD-1 antibody **pembrolizumab** has been shown to be effective in previously treated melanoma patients, giving a nearly 30% response rate. It is FDA-approved for use in treatment of several types of cancers, including melanoma, a particular form of lung cancer, certain squamous-cell cancers of the head and neck, and others, usually in combination with other types of treatments, and the indications continue to broaden. Another anti-PD-1 antibody, **nivolumab**, is also approved for treatment of metastatic melanoma and is being considered for use in treatment of Hodgkin's lymphoma. Because PD-1 is an inhibitory receptor, it is important that the antibodies used in this therapy act only to block the interaction of PD-1 with its ligands and do not trigger PD-1 signaling in T cells, which would inhibit their responses rather than activate them. Checkpoint blockade using antibodies to PD-L1 has been

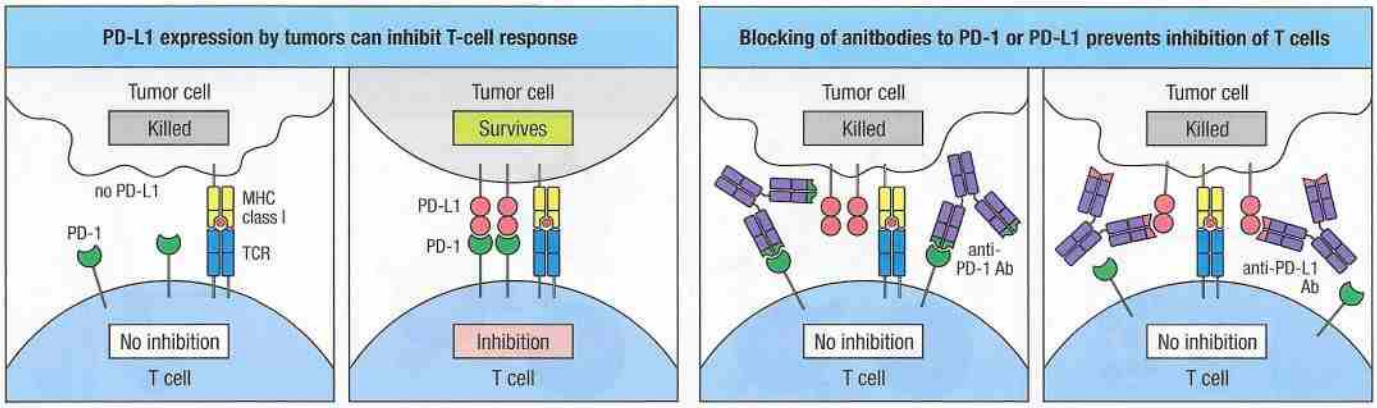

Fig. 16.20 Checkpoint blockade enhances ongoing T-cell responses to tumors expressing ligands for inhibitory receptors. Some, but not all, tumors express ligands for PD-1, such as PD-L1 or PD-L2. Left panels: T cells reacting to tumors without PD-1 ligands do not encounter the inhibitory signal from PD-1 and may deliver their cytotoxic action when recognizing tumor-specific antigens. In contrast, tumors expressing PD-1 ligands can repress T cells and be protected from cytotoxicity. Right panels: For tumors expressing PD-1 ligands, checkpoint blockade can be achieved by antagonistic antibodies against PD-1 or against the ligand, PD-L1 in this case.

FDA-approved for various indications. The PD-L1 antibody atezolizumab was approved in 2015 for treating metastatic urothelial cancer that failed to respond to prior chemotherapy, and the PD-L1 antibody avelumab was approved for treatment of an aggressive form of neuroendocrine skin cancer, Merkel-cell carcinoma.

Checkpoint blockade relies on activation of the patient's own immune system against tumors, and so its effects are not immediately evident. The delay between the initiation of treatment and clinical response presented a challenge in evaluating clinical responses to this therapy. Guidelines for evaluating clinical responses were previously based on the immediate effects of chemotherapeutic drugs or radiation, whereas checkpoint blockade requires more time for reversing immune inhibition and expanding tumor-specific T cells, which then exert their effects within the tumor. Once such issues were considered, it became possible to design clinical trials that could document the effects of checkpoint blockade used in combination with traditional anticancer therapies. For their contributions to the discovery of checkpoint blockade, James P. Allison and Tasuku Honjo received the 2018 Nobel Prize in Physiology or Medicine. Checkpoint blockade is an extremely active area of translational research, and the clinical landscape continues to change rapidly.

16-18 T cells expressing chimeric antigen receptors are an effective treatment in some leukemias.

Adoptive T-cell therapy involves *ex vivo* expansion of tumor-specific T cells to large numbers and the infusion of those T cells into patients. Cells are expanded *in vitro* by various methods, such as treatment with IL-2, anti-CD3 antibodies, and allogeneic antigen-presenting cells, to provide a co-stimulatory signal. Adoptive T-cell therapy is more effective when the patient is immunosuppressed before treatment and IL-2 is then administered systemically. Another approach that has elicited much interest is the use of retroviral vectors to transfer tumor-specific T-cell receptor (TCR) genes into a patient's T cells before reinfusion. This can have long-lasting effects as a result of the ability of T cells to become memory cells, and there is no requirement for histocompatibility because the transfused cells are derived from the patient.

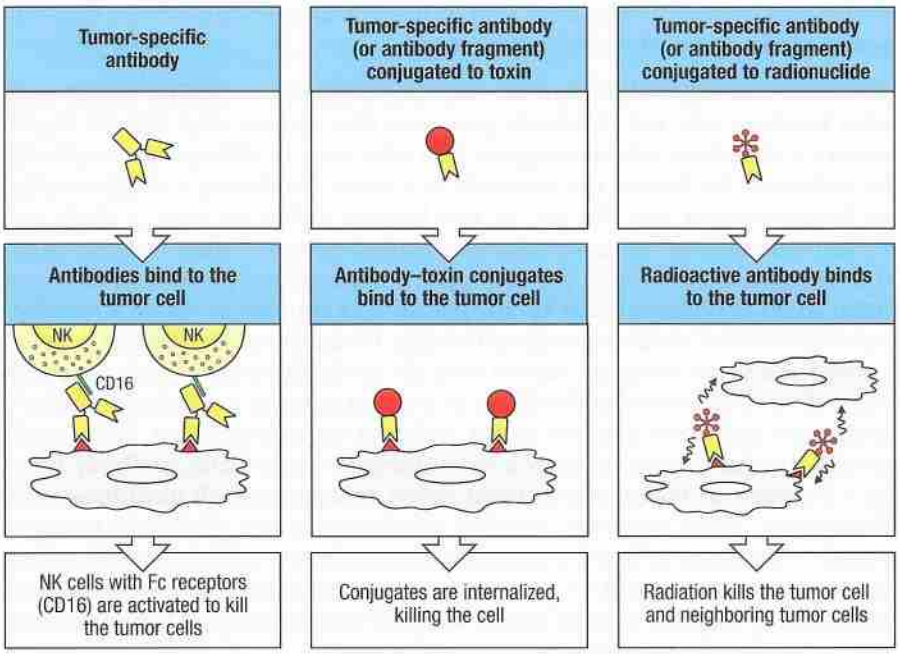
Fig. 16.21 Chimeric antigen receptors (CARs) expressed in T cells can confer antitumor specificity to lymphocytes. Bottom panel: A chimeric antigen receptor, CART-19, is composed of an extracellular single-chain antibody that binds to CD19, which is fused to intracellular signaling domains from 4-1BB and the CD3ζ chain. Top row of panels: A lentivirus, a type of retrovirus, is used to express the gene encoding CART-19 in the T cells harvested from a patient diagnosed with acute lymphocytic leukemia (ALL). After *in vitro* activation and expansion, the transfected CART-19 cells are infused into the patient and exert cytotoxic actions against CD19-expressing tumor cells as well as nontransformed B cells.

Another form of adoptive immunotherapy also uses a viral vector to introduce genes into a patient's T cells but involves expressing a novel type of receptor, known as a **chimeric antigen receptor (CAR)**. As we introduced in Section 7-27, CARs are fusion receptors containing extracellular antigen-specific domains fused to intracellular domains that provide signals for activation and co-stimulation. These receptors are introduced stably into T cells using lentiviral or retroviral vectors to produce so-called CARL T cells. This approach differs from conventional adoptive T-cell therapies, as use of a CAR allows the T cell's target specificity to be almost any molecule recognizable by an antibody (or other receptors), rather than use of a TCR that recognizes a specific peptide:MHC complex. This approach has been used to target CD19 as a tumor-rejection antigen in treating acute lymphocytic leukemia (ALL), an aggressive cancer of transformed B cells (Fig. 16.21). The CAR used in this case had an extracellular domain of an antibody that recognizes human CD19. The intracellular domain had three ITAMs from the ζ chain of the T-cell receptor CD3 complex (see Chapter 7) fused with a co-stimulation domain from 4-1BB, a member of the TNF receptor superfamily. These CART-19 transduced T cells were expanded *in vitro* and transferred into a patient. The results of this case combined with others have demonstrated that CD8 T cells expressing CART-19 (see Fig. 16.21) are effective at achieving complete clinical remissions in many individuals with ALL. This approach is not without its side effects, however, as it also eliminates normal B cells in patients, and they therefore require treatment with intravenous immunoglobulin (IVIG). This cell-based therapy is an example of 'personalized medicine' because it requires the modification of each patient's T cells, which are expanded and introduced back only into that same individual. This treatment was approved by the FDA in 2017, under the trade name **Kymriah**, for the treatment of certain adults with diffuse large B-cell lymphoma who have either relapsed or who were refractory to conventional therapy altogether.

16-19 Monoclonal antibodies against tumor antigens, alone or linked to toxins, can control tumor growth.

A tumor-specific antigen must be expressed on the tumor's cell surface to allow a monoclonal antibody to direct the activity of a cytotoxic cell, toxin, or radioactive nuclide to the tumor cell (Fig. 16.22). Some of the cell-surface molecules



Tumor-specific antibody

Fig. 16.22 Monoclonal antibodies that recognize tumor-specific antigens have been used to help eliminate tumors. Tumor-specific antibodies of the correct isotypes can lyse tumor cells by recruiting effector cells such as NK cells and activating them via their Fc receptors (left panels). Another strategy has been to couple the antibody to a powerful toxin (center panels). When the antibody binds to the tumor cell and is endocytosed, the toxin is released from the antibody and can kill the tumor cell. If the antibody is coupled to a radioisotope (right panels), binding of the antibody to a tumor cell will deliver a dose of radiation sufficient to kill the tumor cell. In addition, nearby tumor cells could also receive a lethal radiation dose, even though they do not bind the antibody. Antibody fragments have started to replace whole antibodies for coupling to toxins or radioisotopes.

targeted in clinical trials are shown in Fig. 16.23, and some of these treatments have now been licensed. The monoclonal antibody **trastuzumab** (Herceptin) was approved in 1998 for treatment of patients whose breast cancer is positive for the receptor human epidermal growth factor receptor 2, also called HER-2/neu. This receptor is overexpressed in about one-quarter of individuals with breast cancer and is associated with a poor prognosis. Herceptin is thought to act by blocking the binding of the natural ligand to this receptor and by down-regulating the level of expression of the receptor. The effects of this antibody can be enhanced when it is combined with conventional chemotherapy. Experiments in mice suggest that some of trastuzumab's antitumor effects may also involve antibody-dependent cell-mediated cytotoxicity (ADCC) or the induction of antitumor T-cell responses. A monoclonal antibody that has yielded excellent results in the treatment of non-Hodgkin's B-cell lymphoma is the anti-CD20 antibody **rituximab**, which triggers the apoptosis of B cells upon binding to CD20 on their surface (see Section 16-28). ADCC may be another

Tumor tissue origin	Type of antigen	Antigen	Tumor type

mechanism by which rituximab acts, as its clinical efficacy has been linked to polymorphisms in activating Fc receptors.

However, monoclonal antibodies may be inefficient in killing tumor cells after binding, may not efficiently penetrate into tumors, and may be inactivated by abundant soluble antigens. The efficiency in killing tumor cells can be enhanced by linking the antibody to a toxin, producing a reagent called an **immunotoxin** (see Fig. 16.22): two favored toxins are ricin A chain and *Pseudomonas* toxin. The antibody must be internalized to allow cleavage of the toxin from the antibody in the endocytic compartment, permitting the freed toxin chain to penetrate and kill the cell. Toxins coupled to native antibodies have had limited success in cancer therapy. However, molecules can be engineered as a single chain to contain only the antibody variable region, or fragment (Fv), while retaining the ability to bind an antigen. Such single-chain Fv molecules may show promise in the design of an immunotoxin. An example of a successful immunotoxin is a recombinant Fv anti-CD22 antibody fused to a fragment of *Pseudomonas* toxin called **moxetumomab pasudotox-tdfk (Lumoxiti)**, which induced complete remissions in two-thirds of a group of people with a type of B-cell leukemia known as hairy-cell leukemia in whom the disease was resistant to conventional chemotherapy. This treatment was approved by the FDA in 2018, under the trade name Lumoxiti, for this indication in those with relapsed or refractory disease.

Monoclonal antibodies can also be conjugated to chemotherapeutic drugs or to radioisotopes. In the case of a drug-linked antibody, the binding of the antibody to a cell-surface antigen concentrates the drug to the site of the tumor. After internalization, the drug is released in the endosomes and exerts its cytostatic or cytotoxic effect. For example, the antibody trastuzumab has been linked to the cytotoxic agent mertansine, a drug that inhibits the assembly of microtubules, in a conjugate called **T-DM1**. Because HER-2 is overexpressed only in cancer cells, T-DM1 selectively delivers the toxin specifically to tumor cells. Another drug–antibody conjugate, brentuximab vedotin, links an anti-CD30 antibody with a different microtubule inhibitor and is approved for certain forms of relapsed lymphomas.

A variation on this approach is to link an antibody to an enzyme that metabolizes a nontoxic pro-drug to the active cytotoxic drug, a technique known as **antibody-directed enzyme/pro-drug therapy (ADEPT)**. With this technique, a small amount of enzyme localized by the antibody can generate much larger amounts of active cytotoxic drug in the immediate vicinity of tumor cells. Monoclonal antibodies linked to radioisotopes (see Fig. 16.22) have been successful in treatment of refractory B-cell lymphoma by using anti-CD20 antibodies linked to yttrium-90 (ibritumomab tiuxetan). These approaches have the advantage of also killing neighboring tumor cells, because the released drug or radioactive emissions can affect cells adjacent to those that bind the antibody. Monoclonal antibodies coupled to γ-emitting radioisotopes have also been used successfully to image tumors for the purposes of diagnosis and monitoring of tumor spread.

16-20 Enhancing the immune response to tumors by vaccination holds promise for cancer prevention and therapy.

Another approach to cancer immunotherapy is based on the idea that tumors are intrinsically poorly immunogenic, and that a vaccine may supply the missing immunogenicity. Some cancers are associated with viral infections, and vaccines that prevent these infections can reduce cancer risk. Human papilloma virus (HPV) is such a virus, and infections with two HPV strains, HPV-16 and HPV-18, are associated with 70% of cervical cancers. A major breakthrough in anticancer therapy occurred in 2005 with the completion of a clinical trial involving 12,167 women who tested a vaccine against HPV. This

trial showed that a recombinant vaccine against HPV was 100% effective in preventing cervical cancer caused by HPV-16 and HPV-18.

The vaccine most likely prevents infection of cervical epithelium by HPV by inducing anti-HPV antibodies (Fig. 16.24). Although the 2005 trial involving 12,167 women showed the potential of vaccines to prevent cancer, attempts to use vaccines to treat existing tumors—called **therapeutic vaccination**—have been less effective. In the case of HPV, certain types of vaccines that have increased immunogenicity for eliciting T-cell responses are beginning to show effectiveness in treating existing intraepithelial neoplasia caused by the virus. Similarly, the majority of liver cancers are associated with chronic hepatitis caused by several viruses. The vaccine against hepatitis B can reduce primary liver cancer that is due to this virus, although the vaccine will not protect against cancers caused by infections by other viruses such as hepatitis C.

Vaccines based on tumor antigens, in principle, could provide a basis for T cell–mediated cancer immunotherapy, but they are difficult to develop. While the relevant antigens are known for HPV, the relevant neoantigens for most spontaneous tumors would require a sequence analysis to identify potential candidates, and these would not be the same in different patients' tumors. Further, the suitability of the epitopes would depend on the individual's particular MHC alleles. Practically, tumor vaccines may require a range of tumor antigens and might be effective only when the tumor burden is low, such as after surgery and chemotherapy.

The sources of antigens for cell-based cancer vaccines are the individual patients' tumors removed at surgery. These vaccines are prepared by mixing either irradiated tumor cells or tumor extracts with killed bacteria such as bacillus Calmette-Guérin (BCG) or *Corynebacterium parvum*, which act as adjuvants to enhance the immunogenicity of the tumor antigens (see Appendix I, Section A-1). Vaccination using BCG adjuvants has had variable results in the past, but renewed interest is based on recent appreciation of their interaction with Toll-like receptors (TLRs). Stimulation of TLR-4 by BCG and other ligands has been tested against melanoma and other solid tumors. CpG DNA, which binds to TLR-9, has also been used to increase the immunogenicity of cancer vaccines. In cases where candidate tumor-rejection antigens have been identified (for example, in melanomas), experimental vaccination strategies have included the use of whole proteins; peptide vaccines based on sequences recognized by cytotoxic T lymphocytes and helper T lymphocytes (either administered alone or presented by the patient's own dendritic cells); and recombinant viruses encoding these peptide epitopes. One cell-based cancer vaccine, **sipuleucel-T (Provenge)**, was approved in 2010 for treatment of metastatic prostate cancer. In this therapy, a patient's monocytes are extracted from peripheral blood and cultured with a fusion protein containing the antigen **prostatic acid phosphatase (PAP)**, which is expressed by most prostate cancers, and the cytokine granulocyte-macrophage colony-stimulating factor (GM-CSF), which induces monocytes to undergo maturation to monocyte-derived dendritic cells. The resulting cells are reinfused into the patient in the hope of inducing an immune response specific to the PAP antigen. This treatment reduced the risk of death by 22% and improved survival by about 4 months relative to a placebo group. However, this approach has not had the same clinical impact as other therapies, such as checkpoint blockade.

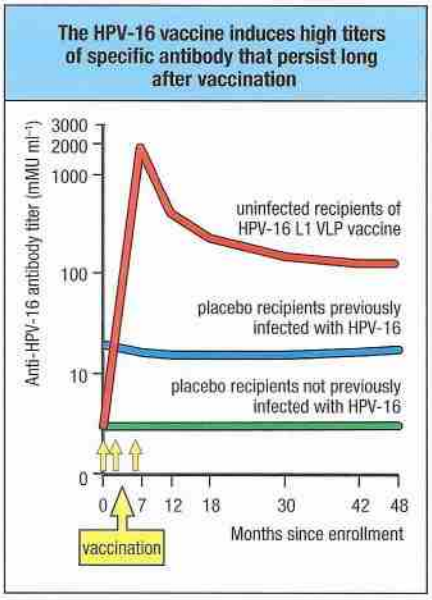

Fig. 16.24 An effective vaccine against human papilloma virus (HPV) induces antibodies that protect against HPV infection. Serotype 16 of HPV (HPV-16) is highly associated with the development of cervical cancer. In a clinical trial, 755 healthy uninfected women were immunized with a vaccine generated from highly purified noninfectious 'viruslike particles' (VLPs) consisting of the capsid protein L1 of HPV-16 and formulated with an alum adjuvant (in this case, aluminum hydroxyphosphate sulfate). In comparison with the very low titers of antibody in placebo-treated uninfected women (green line) or in women previously infected with HPV who received placebo (blue line), the women treated with the viruslike particle vaccine (red line) developed high titers of antibody against the L1 capsid protein. None of these immunized women subsequently became infected by HPV-16. An anti-HPV vaccine marketed as Gardasil is now available and recommended for use in girls and young women as a protection from cervical cancer caused by HPV serotypes 6, 11, 16, and 18. mMU, milli-Merck units.

Summary.

Some tumors elicit specific immune responses that suppress or modify their growth. Tumors evade or suppress these responses in several ways, passing through various stages of a process known as immunological editing. Understanding how the immune system promotes and prevents cancer growth has led to new therapies now deployed in the clinic. Checkpoint

blockade strategies for CTLA-4 and PD-1 have been approved for treating melanoma, and related strategies are being developed for other biologic targets to stimulate antitumor immune responses or block inhibitory mechanisms that suppress such responses. The possibility of eradicating cervical cancer has been brought closer by an effective vaccine against the specific HPV strains associated with cancer that prevents infection. CAR T cells engineered to recognize CD19 expressed on B cells can be an effective treatment for acute lymphocytic leukemia. Monoclonal antibodies can be used for tumor immunotherapy, including an anti-CD20 antibody used to treat B-cell lymphoma and anti-HER-2/neu for treatment of certain types of breast cancers. Attempts are also being made to develop vaccines incorporating antigens from a patient's tumor in order to generate effective cytotoxic and helper T-cell responses. One vaccine using monocyte-derived dendritic cells has been approved for treatment of prostate cancer. A current trend in cancer therapy has been to incorporate immunotherapy with other traditional anticancer treatments to take advantage of the specificity and power of the immune system.

Treatment of unwanted immune responses.

Unwanted immune responses occur in many settings, such as autoimmune disease, transplant rejection, and allergy, which present different therapeutic challenges. The goal of treatment in all cases is to prevent tissue damage and disruption of tissue function. Some unwanted immune responses can be anticipated in advance, as with tissue transplantation, so that preventive measures may be taken. Other unwanted responses may be undetectable until after they become established, as is the case with autoimmune diseases or allergic reactions. The relative difficulty of suppressing established immune responses is seen in animal models of autoimmunity, in which treatments that could have prevented induction of the disease are usually unable to halt it once it is established.

Conventional immunosuppressive drugs—meaning natural or synthetic small-molecule compounds—can be divided into several different categories (Fig. 16.25). There are the powerful anti-inflammatory drugs of the corticosteroid family, such as prednisone; cytotoxic drugs, such as azathioprine and cyclophosphamide; and noncytotoxic fungal and bacterial derivatives,

Fig. 16.25 Conventional immunosuppressive drugs in clinical use.

Conventional immunosuppressive drugs in clinical use	
Immunosuppressive drug	**Mechanism of action**
Corticosteroids	Inhibit inflammation; inhibit many targets including cytokine production by macrophages
Azathioprine, cyclophosphamide, mycophenolate	Inhibit proliferation of lymphocytes by interfering with DNA synthesis
Cyclosporin A, tacrolimus (FK506)	Inhibit the calcineurin-dependent activation of NFAT; block IL-2 production by T cells and proliferation by T cells
Rapamycin (sirolimus)	Inhibits proliferation of effector T cells by blocking Rictor-dependent mTOR activation
Fingolimod (FTY720)	Blocks lymphocyte trafficking out of lymphoid tissues by interfering with signaling by the sphingosine 1-phosphate receptor
Jakinibs	Inhibit the Janus kinases (JAKs) that mediate the signaling of various cytokine receptors

such as cyclosporin A, tacrolimus (FK506 or fujimycin), and rapamycin (sirolimus), which inhibit intracellular signaling pathways within T lymphocytes. A relatively new drug, **fingolimod**, interferes with signaling by the sphingosine 1-phosphate receptor that controls the egress of B and T cells from lymphoid organs, thus preventing effector lymphocytes from reaching peripheral tissues. Most of these drugs exert broad inhibition of the immune system and suppress helpful as well as harmful responses. Opportunistic infection is therefore a common complication of immunosuppressive drug therapy. A recently developed class of drugs called **JAK inhibitors**, or '**jakinibs**,' are kinase inhibitors that block signaling by a variety of cytokine receptors and provide somewhat greater selectivity in the form of inhibition.

Besides conventional small-molecule drugs, there are now many biopharmaceuticals—or **biologics**—that can be used to manipulate the immune response. The most immediate way of inhibiting a particular part of the immune response is by using antibodies that act on specific proteins expressed on or secreted by immune cells. Monoclonal antibodies directed against cytokines, such as the drug **infliximab** (anti-TNF-α) used in the treatment of rheumatoid arthritis, can neutralize local excesses of cytokines or chemokines or target natural cellular regulatory mechanisms to inhibit unwanted immune responses. Proteins other than antibodies are also in use to control immune responses, an example being **abatacept**, a fusion protein consisting of the Fc region of an immunoglobulin fused to the extracellular domain of CTLA-4. Abatacept reduces co-stimulation of T cells by binding to B7 molecules and blocking their interactions with CD28. It is currently used to treat rheumatoid arthritis in individuals who fail to respond to anti-TNF-α therapy.

16-21 Corticosteroids are powerful anti-inflammatory drugs that alter the transcription of many genes.

Corticosteroid drugs are powerful anti-inflammatory and immunosuppressive agents that are used widely to attenuate the harmful effects of autoimmune or allergic immune responses (see Chapters 14 and 15), as well as responses against transplanted organs. **Corticosteroids** are derivatives of the glucocorticoid family of steroid hormones that play a crucial role in maintaining the body's homeostasis; one of the most widely used is **prednisone**, a synthetic version of the hormone cortisol. Corticosteroids cross the cell's plasma membrane and bind to intracellular receptors of the nuclear receptor family. Activated glucocorticoid receptors are transported to the nucleus, where they bind to DNA and regulate a large number of genes expressed in leukocytes. The response to steroid therapy is complex, given the large number of genes regulated in leukocytes and in other tissues. With respect to immunosuppression, corticosteroids exert multiple anti-inflammatory effects, which are briefly summarized in Fig. 16.26.

Corticosteroids target the pro-inflammatory functions of monocytes and macrophages and reduce the number of CD4 T cells. They can induce the expression of certain anti-inflammatory genes, such as *AnxaI*, which encodes a protein inhibitor of phospholipase A_2 and thereby prevents this enzyme from generating pro-inflammatory **prostaglandins** and **leukotrienes** (see Section 3-3 and Section 14-6). Conversely, corticosteroids can also suppress the expression of pro-inflammatory genes, including those encoding the cytokines IL-1β and TNF-α.

The therapeutic effects of corticosteroid drugs are due to their presence at much higher concentrations than the natural concentration of glucocorticoid hormones, causing exaggerated responses with both toxic and beneficial effects. Adverse effects include fluid retention, weight gain, diabetes, bone mineral loss, and thinning of the skin, requiring a careful balance to

Corticosteroid therapy	
Effect on	**Physiological effects**
↓ IL-1, TNF-α, GM-CSF ↓ IL-3, IL-4, IL-5, CXCL8	↓ Inflammation caused by cytokines
↓ NOS	↓ NO
↓ Phospholipase A_2 ↓ Cyclooxygenase-2 ↑ Annexin-1	↓ Prostaglandins ↓ Leukotrienes
↓ Adhesion molecules	Reduced emigration of leukocytes from vessels
↑ Endonucleases	Induction of apoptosis in lymphocytes and eosinophils

Fig. 16.26 Anti-inflammatory effects of corticosteroid therapy. Corticosteroids regulate the expression of many genes, with a net anti-inflammatory effect. First, they reduce the production of inflammatory mediators, including cytokines, prostaglandins, and nitric oxide (NO). Second, they inhibit inflammatory-cell migration to sites of inflammation by inhibiting the expression of adhesion molecules. Third, corticosteroids promote the death of leukocytes by apoptosis. The layers of complexity are illustrated by the actions of annexin-1 (originally identified as a factor induced by corticosteroids and named lipocortin), which has been shown to participate in all of the effects of corticosteroids listed on the right. NOS, NO synthase.

be maintained between beneficial and harmful effects. These drugs can also decrease in effectiveness over time. Despite these drawbacks, inhaled corticosteroids have proven highly beneficial in the treatment of chronic asthma (see Section 14-12). In the treatment of autoimmunity or allograft rejection, in which high doses of oral corticosteroids are needed to be effective, they are most often administered in combination with other immunosuppressant drugs to keep the corticosteroid dose and side effects to a minimum. These other drugs include cytotoxic agents that act as immunosuppressants by killing rapidly dividing lymphocytes and drugs that more specifically target lymphocyte signaling pathways.

16-22 Cytotoxic drugs cause immunosuppression by killing dividing cells and have serious side effects.

The three cytotoxic drugs most commonly used as immunosuppressants are **azathioprine**, **cyclophosphamide**, and **mycophenolate**. These drugs interfere with DNA synthesis, and their major pharmacological action is on tissues in which cells are continually dividing. Developed originally to treat cancer, these drugs were found to be immunosuppressive after observations that they were cytotoxic to dividing lymphocytes. Azathioprine also interferes with CD28 co-stimulation in T cells, thus promoting T-cell apoptosis (see Section 7-22). The use of these compounds is, however, limited by their toxic effects on all tissues in which cells are dividing, such as the skin, gut lining, and bone marrow. Effects include decreased immune function, as well as anemia, leukopenia, thrombocytopenia, damage to intestinal epithelium, hair loss, and fetal death or injury. Because of their toxicity, these drugs are used at high doses only when the aim is to eliminate all dividing lymphocytes, as in the treatment of lymphoma and leukemia; in these cases, treated patients require subsequent bone marrow transplantation to restore their hematopoietic function. When used to treat unwanted immune responses such as autoimmune conditions, they are used at lower doses and in combination with other drugs such as corticosteroids.

Azathioprine is converted *in vivo* to the purine analog 6-thioguanine (6-TG), which is metabolized to 6-thioinosinic acid. Competing with inosine monophosphate, 6-thioinosinic acid blocks the *de novo* synthesis of adenosine monophosphate and guanosine monophosphate, thus inhibiting DNA synthesis. 6-TG is also incorporated into the DNA in place of guanine, and accumulation of 6-TG increases the DNA's sensitivity to mutations induced by the ultraviolet radiation in sunlight. Thus, patients treated with azathioprine have the long-term side effect of increased risk of skin cancer. Azathioprine also generates 6-thioguanine triphosphate (6-thio-GTP), which in T cells binds to the small GTPase Rac1 in place of GTP and suppresses its activity. Signaling from CD28 co-stimulation requires Rac1, and T cells therefore do not receive the anti-apoptotic signals from co-stimulation and instead undergo apoptosis. **Mycophenolate mofetil**, the 2-morpholinoethyl ester of mycophenolic acid, is the newest addition to the family of cytotoxic immunosuppressive drugs; it works in a similar fashion as azathioprine. It is metabolized to mycophenolic acid, which inhibits the enzyme inosine monophosphate dehydrogenase, thus blocking the *de novo* synthesis of guanosine monophosphate.

Azathioprine and mycophenolate are less toxic than cyclophosphamide, which is metabolized to phosphoramide mustard, which alkylates DNA. Cyclophosphamide is a member of the nitrogen mustard family of compounds, which were originally developed as chemical weapons. It has a range of highly toxic effects including inflammation of and hemorrhage from the bladder, known as hemorrhagic cystitis, and induction of bladder neoplasia.

16-23 Cyclosporin A, tacrolimus, and rapamycin are effective immunosuppressive agents that interfere with various T-cell signaling pathways.

Three noncytotoxic alternatives to the cytotoxic drugs are available as immunosuppressants and are widely used to treat transplant recipients. These are **cyclosporin A**, **tacrolimus** (previously known as **FK506**), and **rapamycin** (also known as **sirolimus**). Cyclosporin A is a cyclic decapeptide derived from a soil fungus found in Norway, *Tolypocladium inflatum*. Tacrolimus is a macrolide compound from the filamentous bacterium *Streptomyces tsukubaensis*, found in Japan; macrolides are compounds that contain a many-membered lactone ring to which is attached one or more deoxysugars. Rapamycin, another macrolide, is derived from *Streptomyces hygroscopicus*, found on Easter Island ('Rapa Nui' in Polynesian—hence the name of the drug). All three compounds exert their pharmacological effects by binding to members of a family of intracellular proteins known as the **immunophilins**, forming complexes that interfere with signaling pathways important for the clonal expansion of lymphocytes.

ANIMATION 16.1

As explained in Section 7-14, cyclosporin A and tacrolimus block T-cell proliferation by inhibiting the phosphatase activity of the Ca^{2+}-activated protein phosphatase **calcineurin**, which is required for the activation of the transcription factor NFAT. Both drugs reduce the expression of several cytokine genes that are normally induced upon T-cell activation (Fig. 16.27), including the gene encoding interleukin-2 (IL-2), which is an important factor for regulating T cells (see Section 9-15). Cyclosporin A and tacrolimus inhibit T-cell proliferation in response to either specific antigens or allogeneic cells and are used extensively in medical practice to prevent the rejection of allogeneic organ grafts. Although the major immunosuppressive effects of both drugs are probably the result of inhibition of T-cell proliferation, they also act on other cells and have a large variety of other immunological effects (see Fig. 16.27).

These two drugs inhibit calcineurin by first binding to an immunophilin molecule; cyclosporin A binds to the **cyclophilins**, and tacrolimus binds to the **FK-binding proteins (FKBPs)**. Immunophilins are peptidyl-prolyl *cis–trans* isomerases, but their isomerase activity is not relevant to the immunosuppressive activity of the drugs that bind them. Rather, the immunophilin:drug complexes bind to calcineurin and inhibit its phosphatase activity. In a normal immune response, the increase in intracellular calcium ions in response to T-cell receptor signaling activates the calcium-binding protein calmodulin; calmodulin then activates calcineurin (see Fig. 7.19). Binding of the

Immunological effects of cyclosporin A and tacrolimus

Cell type	Effects
T lymphocyte	Reduced expression of IL-2, IL-3, IL-4, GM-CSF, TNF-α Reduced proliferation after decreased IL-2 production Reduced Ca^{2+}-dependent exocytosis of granule-associated serine esterases Inhibition of antigen-driven apoptosis
B lymphocyte	Inhibition of proliferation secondary to reduced cytokine production by T lymphocytes Inhibition of proliferation after ligation of surface immunoglobulin Induction of apoptosis after B-cell activation
Granulocyte	Reduced Ca^{2+}-dependent exocytosis of granule-associated serine esterases

Fig. 16.27 Cyclosporin A and tacrolimus inhibit lymphocyte function and some granulocyte responses.

Fig. 16.28 Cyclosporin A and tacrolimus inhibit T-cell activation by interfering with the serine/threonine-specific phosphatase calcineurin. Top panel: Signaling via T-cell receptor–associated tyrosine kinases leads to opening of calcium release–activated calcium (CRAC) channels in the plasma membrane. This increases the concentration of Ca^{2+} in the cytoplasm and promotes calcium binding to the regulatory protein calmodulin (see Fig. 7.19). Calmodulin is activated by binding Ca^{2+} and can then target many downstream effector proteins such as the phosphatase calcineurin. Binding by calmodulin activates calcineurin to dephosphorylate the transcription factor NFAT (see Section 7-14), which then enters the nucleus and transcribes genes that are required for T-cell activation to progress. Bottom panel: When cyclosporin A or tacrolimus or both are present, they form complexes with their immunophilin targets, cyclophilin and FK-binding protein, respectively. These complexes bind to calcineurin, preventing it from becoming activated by calmodulin, and thereby preventing the dephosphorylation of NFAT.

immunophilin:drug complex to calcineurin prevents the latter's activation by calmodulin. Thus, the bound calcineurin is unable to dephosphorylate and activate NFAT (Fig. 16.28). Calcineurin is found in other cells besides T cells, but its levels in T cells are much lower than in other tissues. T cells are therefore particularly susceptible to the inhibitory effects of these drugs.

Cyclosporin A and tacrolimus are effective immunosuppressants but can inhibit all immune responses indiscriminately. This problem can be controlled by carefully varying the dose of drug given during the course of a response. During organ transplantation, for example, high doses are required during the time of grafting, but once the graft is established, the dose can be decreased to allow for protective immune responses while maintaining suppression of a response against the grafted tissue. Maintaining this balance requires careful monitoring of the patient. These drugs also have effects on many different tissues and thus can have broad side effects, such as injury to kidney tubule epithelial cells. Finally, treatment with these drugs is relatively expensive, because they are complex natural products that must be taken for long periods. Nevertheless, at present they are the immunosuppressants of choice in clinical transplantation, and they are also being tested in a variety of autoimmune diseases, especially those that, like graft rejection, are mediated by T cells.

Rapamycin has a different mechanism of action from either cyclosporin A or tacrolimus. Like tacrolimus, rapamycin binds to the FKBP family member of the immunophilins, but the rapamycin:immunophilin complex does not inhibit calcineurin activity. Instead, it inhibits a serine/threonine kinase known as **mTOR (mammalian target of rapamycin)**, which is involved in regulating cell growth and proliferation (see Section 7-17). The mTOR pathway can be activated by different upstream signaling pathways, including the Ras–MAPK pathway and the PI 3-kinase pathway. These pathways activate the kinase **Akt**, which phosphorylates and inactivates a regulatory complex called the tuberous sclerosis complex (**TSC**) (see Fig. 7-24). The non-phosphorylated TSC is active and normally acts as an inhibitor of the small GTPase **Rheb**. But after Akt phosphorylates TSC, Rheb becomes free to activate mTOR (see Fig. 7.24). Two distinct mTOR complexes can be formed, called **mTORC1** and **mTORC2**. These are controlled by two regulatory proteins called **Raptor** and **Rictor**, respectively, and which activate different downstream cellular pathways of mTOR (Fig. 16.29). The rapamycin:FKBP complex selectively inhibits the Raptor-dependent pathway (see Fig. 16.29), which markedly reduces T-cell proliferation, arrests cells in the G_1 phase of the cell cycle, and promotes apoptosis. Rapamycin inhibits lymphocyte proliferation driven by growth factors such as IL-2, IL-4, and IL-6, and selectively reduces the outgrowth of effector T cells while apparently enhancing the formation of memory T cells.

Although not directly acting on T-cell activation, one recently introduced drug regulates the migration of effector cells to the sites of a graft or of autoimmune disease. In Section 9-5, we described how emigration of lymphocytes out of the lymphoid tissues requires recognition of the lipid molecule

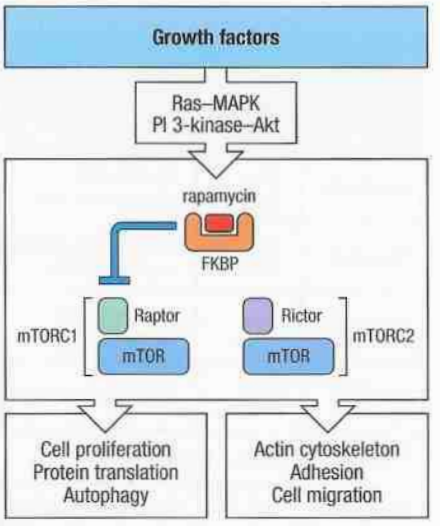

Fig. 16.29 Rapamycin inhibits cell growth and proliferation by selectively blocking activation of the kinase mTOR by Raptor. Rapamycin binds FK-binding protein (FKBP), the same immunophilin protein that binds to tacrolimus (FK506). The rapamycin:FKBP complex does not inhibit calcineurin, but instead blocks one of two complexes that activate mTOR, a large kinase that regulates many metabolic pathways. mTOR is activated downstream of various growth factor signaling pathways and becomes associated with either of two proteins, Raptor (regulatory-associated protein of mTOR) or Rictor (rapamycin-insensitive companion of mTOR). The complex with Raptor, mTORC1, promotes cell proliferation, translation of proteins, and autophagy, and the complex with Rictor, mTORC2, influences cell adhesion and migration by controlling the actin cytoskeleton. The rapamycin:FKBP complex acts to inhibit the Raptor-associated mTORC1, and thereby selectively reduces cell growth and proliferation.

sphingosine 1-phosphate (S1P) by the G protein–coupled receptor S1PR1. Fingolimod (FTY720), a sphingosine 1-phosphate analog, causes the retention of effector lymphocytes in lymphoid organs, thus preventing these cells from mediating their effector activities in target tissues. Fingolimod was approved in 2010 for treatment of the autoimmune disease multiple sclerosis and has shown promise in the treatment of kidney graft rejection and asthma.

16-24 JAK inhibitors can be used to treat autoimmune and inflammatory diseases.

Cytokines activate many aspects of the immune response. Many cytokine receptors use **Janus kinases (JAKs)** in their signal transduction (see Section 3-16), but they use different combinations of JAK proteins (Fig. 16.30). The four JAK family members, Jak1, Jak2, Jak3, and Tyk2, bind and phosphorylate the cytoplasmic regions of cytokine receptors and initiate the activation of different STAT transcription factors. Selective JAK inhibitors have been developed over the past decade that can block the kinase activity of one or more members of this family. Because different JAKs binds to different cytokine receptors, JAK inhibitors, or 'jakinibs,' can exert potentially specific effects on the quality of T-cell development.

The development of selective JAK inhibitors has advanced rapidly over the past several years, and there are currently eight drugs of this class approved in various countries for use in treating various inflammatory diseases (Fig. 16.31). For example, **tofacitinib** inhibits Jak3, interfering with signaling by IL-2 and IL-4, and somewhat more weakly Jak1, interfering with signaling by IL-6. Tofacitinib is approved for treatment of rheumatoid arthritis. **Ruxolitinib** inhibits Jak1 and Jak2 and has been approved for treating myelofibrosis, an abnormal proliferation of bone marrow progenitor cells that causes fibrosis. Jakinibs have been developed that selectively inhibit Jak1, including upadacitinib, which was recently approved by the FDA for the treatment of rheumatoid arthritis.

Cytokine receptors and JAKs	
Cytokine	**JAKs used by receptors**

16-25 Antibodies against cell-surface molecules can be used to eliminate lymphocyte subsets or to inhibit lymphocyte function.

All the drugs discussed so far exert a general inhibition on immune responses and can have severe side effects, but antibodies can act in a more specific manner and with less direct toxicity. The initial therapeutic use of antibodies extends back to the late 1800s with the development of equine sera for treatment of diphtheria and tetanus. Today, intravenous immunoglobulin (IVIG), a collection of polyvalent IgG antibodies pooled from many blood donors, is still widely used as a treatment for various primary and acquired immune deficiencies. It is also used in some acute infections, where it likely works by neutralizing certain pathogens or their toxins. Finally, IVIG is also used to treat

Drug-Induced Serum Sickness

JAK inhibitors approved for use in autoimmune conditions		
Jakinib	**JAKs targeted**	**Indication**
Ruxolitinib	Jak1/ Jak2	Myelofibrosis, polycythemia vera
Tofacitinib	Jak1/ Jak3	Rheumatoid arthritis, psoriatic arthritis
Oclacitinib	Jak1	Pruritus, atopic dermatitis (dogs)
Baricitinib	Jak1/ Jak2	Rheumatoid arthritis
Fedratinib	Jak2	Myelofibrosis
Upadacitinib	Jak1	Rheumatoid arthritis
Filgotinib	Jak1	Rheumatoid arthritis (EU/Japan)
Peficitinib	Jak3	Rheumatoid arthritis (Japan)

Fig. 16.31 Several JAK inhibitors are approved for use in autoimmune conditions. Shown are the targeted Janus kinases (JAKs) and the approved clinical indication for each drug. Some are approved only in the European Union (EU) or Japan, as indicated.

certain autoimmune and inflammatory diseases, such as immune thrombocytopenia and Kawasaki disease. In these cases, IVIG exerts an immunomodulatory effect that seems to operate through interactions with inhibitory Fc receptors that inhibit immune-cell activation.

The relatively recent expansion in the use of antibodies as therapeutic agents has extended their use beyond simply targeting pathogens to acting on components of the immune system itself. For example, the potential of antibodies to eliminate unwanted lymphocytes is demonstrated by **anti-lymphocyte globulin**, a preparation of polyclonal immunoglobulin from rabbits (and previously horses) immunized with human lymphocytes, which has been used for many years to treat episodes of acute graft rejection. Anti-lymphocyte globulin does not, however, discriminate between useful lymphocytes and those responsible for the unwanted responses and therefore leads to global immunosuppression. Foreign immunoglobulins are also highly antigenic in humans, and the large doses of anti-lymphocyte globulin used in therapy often cause a condition called **serum sickness**, resulting from the formation of immune complexes of the animal immunoglobulin and human antibodies against it (see Section 14-14).

Anti-lymphocyte globulin is nevertheless still used to treat acute rejection, and this has stimulated the quest for monoclonal antibodies (see Appendix I, Section A-8) that would achieve more specifically targeted effects. One such antibody is **alemtuzumab** (marketed as Campath-1H), which is directed at the cell-surface protein CD52 expressed by most lymphocytes. It has actions similar to those of anti-lymphocyte globulin, causing long-standing lymphopenia. It is also used to eliminate cancer cells in the treatment of chronic lymphocytic leukemia.

Immunosuppressive monoclonal antibodies act by one of two general mechanisms. Some, such as alemtuzumab, trigger the destruction of lymphocytes *in vivo* and are referred to as **depleting antibodies**, whereas others are **nondepleting** and act by blocking the function of their target protein without killing the cell that bears it. Depleting monoclonal IgG antibodies bind to lymphocytes and target them to macrophages and NK cells, which bear Fc receptors and kill the lymphocytes by phagocytosis or ADCC, respectively. Complement-mediated lysis may also play a part in lymphocyte destruction.

16-26 Antibodies can be engineered to reduce their immunogenicity in humans.

A major impediment to therapy with monoclonal antibodies in humans has been that these antibodies are most readily made by immunizing nonhuman species, such as the mouse, to generate antibodies of the desired specificity (see Appendix I, Section A-8). Humans may develop an antibody response against such nonhuman antibodies, because aggregated forms of foreign antibodies can be immunogenic. Such a reaction not only interferes with the therapeutic actions of the antibodies but also leads to allergic reactions and, if treatment is continued, may result in **anaphylaxis** (see Section 14-1). Once a patient has made a response to an antibody, it can no longer be used for treatment. In principle, this problem can be avoided by making antibodies that are not recognized as foreign by the human immune system, a process called **humanization**.

Various approaches have been tried to humanize antibodies. The variable regions encoding the antigen-recognition determinants from a murine antibody can be spliced onto the Fc regions of human IgG by gene manipulation. Antibodies of this type are called chimeric antibodies. However, this approach leaves regions within the murine variable regions that could potentially induce immune responses (Fig. 16.32). Genetically engineered mice that harbor human immunoglobulin genes inserted into their immunoglobulin

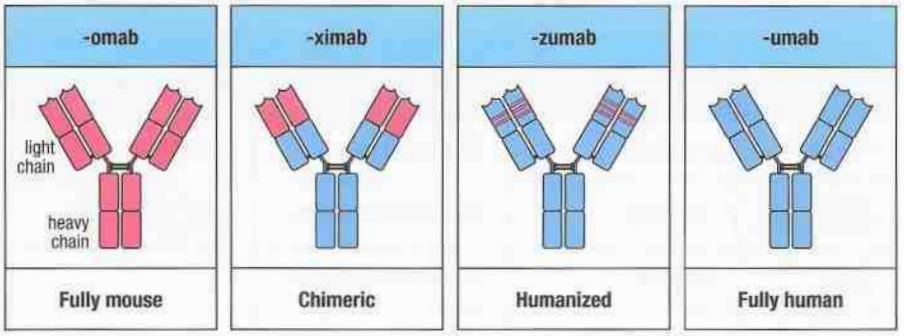

Fig. 16.32 Monoclonal antibodies used to treat human diseases can be engineered to decrease immunogenicity but maintain their antigen specificity. Antibodies that are derived fully from mice, named with the suffix *-omab*, are immunogenic in humans. This causes patients to generate antibodies against them, limiting their usefulness over time. This immunogenicity can be reduced by making chimeric antibodies in which the V regions from the mouse are spliced onto human antibody constant regions; such antibodies are named with the suffix *-ximab*. Humanization is the process of splicing in just the complementarity-determining regions from the mouse antibody, further reducing immunogenicity; humanized antibodies are named with the suffix *-zumab*. New techniques allow fully human (*-umab*) monoclonal antibodies to be derived, which are the least immunogenic type of antibody currently used for treating humans.

locus represent one way that human antibodies may be obtained from the immunization of mice. Newer methods are aimed at generating fully human monoclonal antibodies directly from human cells through the use of viral transformation of human primary B-cell lines or antibody-secreting plasmablasts or by generating human B-cell hybridomas.

Monoclonal antibodies belong to a new class of therapeutic compounds called biologics, which includes other natural proteins such as anti-lymphocyte globulin, cytokines, protein fragments, and even whole cells, the latter used, for example, in the adoptive transfer of T cells in cancer immunotherapy. Many monoclonal antibodies have been, or are in the process of being, approved for clinical use by the FDA (Fig. 16.33). A systematic naming process identifies the type of antibody. Murine monoclonal antibodies are designated by the suffix **-omab**, except for muromonab (originally called OKT3), a murine antibody against CD3, which was named before the nomenclature was established. Chimeric antibodies in which the entire variable region is spliced into human constant regions have the suffix **-ximab**, such as basiliximab, an anti-CD25 (anti-IL-2Rα) antibody approved for the treatment of transplantation rejection. Humanized antibodies in which the murine hypervariable regions have been spliced into a human antibody have the suffix **-zumab**, as in alemtuzumab and **natalizumab** (Tysabri). The latter is directed against the α_4 integrin subunit and is used to treat multiple sclerosis and Crohn's disease. Antibodies derived entirely from human sequences have the suffix **-umab**, as in adalimumab, an antibody derived from phage display (see Appendix I, Section A-9) that binds TNF-α; it is used to treat several autoimmune diseases.

16-27 Monoclonal antibodies can be used to prevent allograft rejection.

Antibodies specific for various physiological targets are being used or are under investigation to prevent the rejection of transplanted organs by inhibiting the development of harmful inflammatory and cytotoxic responses. For example, alemtuzumab, discussed in Section 16-25, is licensed for the treatment of certain leukemias but is also used in both solid organ and bone marrow transplantation. In solid organ transplantation, alemtuzumab may be given to the recipient around the time of transplantation to remove mature

Fig. 16.33 Monoclonal antibodies developed for immunotherapy. A substantial fraction of pharmaceuticals currently under development are antibodies, and additions to this list, current as of this writing, are under development and in clinical trials. BLyS, B-lymphocyte stimulator, also known as BAFF (B-cell activating factor).

Monoclonal antibodies developed for immunotherapy			
Generic name	**Specificity**	**Mechanism of action**	**Approved indication**
Rituximab	Anti-CD20	Eliminates B cells	Non-Hodgkin's lymphoma
Alemtuzumab (Campath-1H)	Anti-CD52	Eliminates lymphocytes	Chronic lymphocytic leukemia
Muromonab (OKT3)	Anti-CD3	Inhibits T-cell activation	Kidney transplantation
Daclizumab	Anti-IL-2Rα	Reduces T-cell activation	
Basiliximab	Anti-IL-2Rα	Reduces T-cell activation	
Infliximab	Anti-TNF-α	Inhibit inflammation induced by TNF-α	Crohn's disease
Certolizumab	Anti-TNF-α		Rheumatoid arthritis
Adalimumab	Anti-TNF-α		
Golimumab	Anti-TNF-α		
Tocilizumab	Anti-IL-6R	Blocks inflammation induced by IL-6 signaling	
Canakinumab	Anti-IL-1β	Blocks inflammation caused by IL-1	Muckle–Wells syndrome
Denosumab	Anti-RANKL	Inhibits activation of osteoclasts by RANKL	Bone loss
Ustekinumab	Anti-IL-12/23	Inhibits inflammation caused by IL-12 and IL-23	Psoriasis
Efalizumab	Anti-CD11a (α_L integrin subunit)	Block lymphocyte trafficking	Psoriasis (withdrawn from use in United States and European Union)
Natalizumab	Anti-α_4 integrin		Multiple sclerosis
Omalizumab	Anti-IgE	Removes IgE antibody	Chronic asthma
Belimumab	Anti-BLyS (BAFF)	Reduces B-cell responses	Systemic lupus erythematosus (pending approval)
Ipilimumab	Anti-CTLA-4	Increases CD4 T-cell responses	Metastatic melanoma
Raxibacumab	Anti-*Bacillus anthracis* protective antigen (the cell-binding moiety of anthrax toxin)	Prevents action of anthrax toxins	Anthrax infection (pending approval)

T lymphocytes from the circulation. In bone marrow transplantation, alemtuzumab can be used *in vitro* to deplete donor bone marrow of mature T cells before its infusion into a recipient or used *in vivo* to treat the recipient after infusion. Elimination of mature T cells from donor bone marrow is very effective at reducing the incidence of graft-versus-host disease (see Section 15-25). In this disease, the T lymphocytes in the donor bone marrow recognize the recipient as foreign and mount a damaging response, causing rashes, diarrhea, and hepatitis, which can occasionally be fatal. Bone marrow transplantation is also used as a treatment for leukemia, as T cells in the graft can have a so-called

graft-versus-leukemia effect where they recognize the leukemic cells as foreign and destroy them. It was originally thought that elimination of mature donor T cells during such procedures would be disadvantageous, as the antileukemic action of the donor T cells could be lost, but this seems to not be the case when alemtuzumab is used as the depleting agent.

Graft-Versus-Host Disease

Specific antibodies directed against T cells have been used to treat episodes of graft rejection that occur after transplantation. The murine antibody **muromonab** (OKT3) targets the CD3 complex and leads to T-cell immunosuppression by inhibiting signaling through the T-cell receptor. It has been used clinically in solid organ transplantation but is often associated with a dangerous side effect, namely, the stimulation of pro-inflammatory cytokine release, and its use is declining. This cytokine release is related to muromonab's intact Fc region, which can activate Fc receptors via cross-linking and activate the cells that bear these receptors. In an antibody against the CD3? chain called teplizumab, or OKT3γ1 Ala-Ala, the amino acids 234 and 235 in the human IgG1 Fc region have been changed to alanines, and this antibody no longer stimulates cytokine release.

Two other antibodies, **daclizumab** and **basiliximab**, approved for treating kidney transplant rejection, are directed against CD25 (a subunit of the IL-2 receptor), reducing T-cell activation, presumably by blocking the growth-promoting signals delivered by IL-2.

A primate model of kidney transplant rejection showed promising effects for a humanized monoclonal antibody against the **CD40 ligand** expressed by T cells (see Section 9-20). A possible mechanism of protection by this antibody is blockade of the activation of dendritic cells by helper T cells that recognize donor antigens. Only preliminary studies of anti-CD40 ligand antibodies have been performed in humans. One antibody was associated with thromboembolic complications and was withdrawn; a different anti-CD40 ligand antibody was administered to patients with the autoimmune disease systemic lupus erythematosus (SLE) without significant complications, but also with little evidence of efficacy.

In experimental models, monoclonal antibodies against other targets have also had some success in preventing graft rejection, including nondepleting antibodies that bind the CD4 co-receptor or the co-stimulatory receptor CD28 on lymphocytes. Similarly, abatacept, a soluble recombinant CTLA-4–Ig fusion protein that binds to the co-stimulatory B7 molecules on antigen-presenting cells and prevents their interaction with CD28 on T cells, is approved for the treatment of rheumatoid arthritis.

Systemic Lupus Erythematosus

Rheumatoid Arthritis

16-28 Depletion of autoreactive lymphocytes can treat autoimmune disease.

In addition to their use in preventing transplantation rejection, monoclonal antibodies can be used to treat certain autoimmune diseases, and in the next few sections we discuss the different immune mechanisms targeted. Here we will discuss the use of depleting and nondepleting antibodies to remove lymphocytes nonspecifically. The anti-CD20 monoclonal antibody rituximab was originally developed to treat B-cell lymphomas but has also been tried in treating certain autoimmune diseases. By ligating CD20, rituximab (Rituxan; MabThera) transduces a signal that induces lymphocyte apoptosis and depletes B cells for several months. Certain autoimmune diseases are believed to involve autoantibody-mediated pathogenesis. There is evidence for the efficacy of rituximab in some individuals with autoimmune hemolytic anemia, SLE, rheumatoid arthritis, or type II mixed cryoglobulinemia, all of which have autoantibodies as a part of their clinical presentation. Although CD20 is not expressed on antibody-producing plasma cells, their B-cell precursors are

targeted by anti-CD20, resulting in a substantial reduction in the short-lived, but not the long-lived, plasma-cell population.

Alemtuzumab, discussed earlier as a treatment for leukemia and in transplant rejection, has shown some beneficial effect in studies of small numbers of people with multiple sclerosis. However, immediately after its infusion, most multiple sclerosis patients suffered a frightening, although fortunately brief, flare-up of their illness, illustrating another potential complication of antibody therapy. Alemtuzumab was acting as intended, killing cells by complement- and Fc-dependent mechanisms. However, it also stimulated the release of cytokines, including TNF-α, IFN-γ, and IL-6, which transiently block nerve conduction in nerve fibers previously affected by demyelination. This caused the transient but dramatic exacerbation of symptoms. Nevertheless, alemtuzumab may be useful at early stages of the disease, when the inflammatory response is maximal, but this has yet to be determined.

Treatment of rheumatoid arthritis and multiple sclerosis with anti-CD4 antibodies has been tried, but with disappointing results. In controlled studies, the antibodies showed only small therapeutic effects but caused depletion of T lymphocytes from peripheral blood for more than 6 years after treatment. The likely explanation for the failure seems to be that these antibodies failed to delete already primed CD4 T cells secreting pro-inflammatory cytokines, and may thus have missed their target. This cautionary tale shows that it is possible to deplete large numbers of lymphocytes and yet completely fail to kill the cells that matter.

16-29 Biologics that block TNF-α, IL-1, or IL-6 can alleviate autoimmune diseases.

Anti-inflammatory therapy can attempt to eliminate an autoimmune response altogether, as with immunosuppressive drugs or depleting antibodies, or try to reduce the tissue injury caused by the immune response. This second category of treatment is called **immunomodulatory therapy** and is illustrated by the use of conventional anti-inflammatory agents such as aspirin, nonsteroidal anti-inflammatory drugs, or low-dose corticosteroids. A newer avenue of immunomodulatory therapy using biologics is illustrated by several FDA-approved antibodies that block the activity of powerful pro-inflammatory cytokines such as TNF-α, IL-1, and IL-6.

Rheumatoid Arthritis
Multiple Sclerosis
Crohn's Disease

Anti-TNF therapy was the first specific biological therapeutic to enter the clinic. Anti-TNF-α antibodies induced striking remissions in rheumatoid arthritis (Fig. 16.34) and reduced inflammation in Crohn's disease, an inflammatory bowel disease (see Section 15-5). Two types of established biologics are used to antagonize TNF-α in clinical practice. The first type comprises the anti-TNF-α antibodies, such as infliximab and adalimumab, which bind to TNF-α and block its activity. The second type is a recombinant human TNF receptor (TNFR) subunit p75–Fc fusion protein called **etanercept**, which also binds TNF-α, neutralizing its activity. These are extremely potent anti-inflammatory agents, and the number of diseases in which they have been shown to be effective is growing as further clinical trials are performed. In addition to rheumatoid arthritis, the rheumatic diseases **ankylosing spondylitis**, **psoriatic arthropathy**, and juvenile idiopathic arthritis (other than the systemic-onset subset) respond well to blockade of TNF-α, and this treatment is now routine in many cases.

An illustration of the importance of TNF-α in defending against infection is the observation that TNF-α blockade carries a small but increased risk of serious infections, including tuberculosis (see Section 3-20). Anti-TNF-α therapy has not been successful in all diseases. TNF-α blockade as a treatment for **experimental autoimmune encephalomyelitis (EAE)**, a mouse model of multiple sclerosis, led to amelioration of the disease, but in human patients with

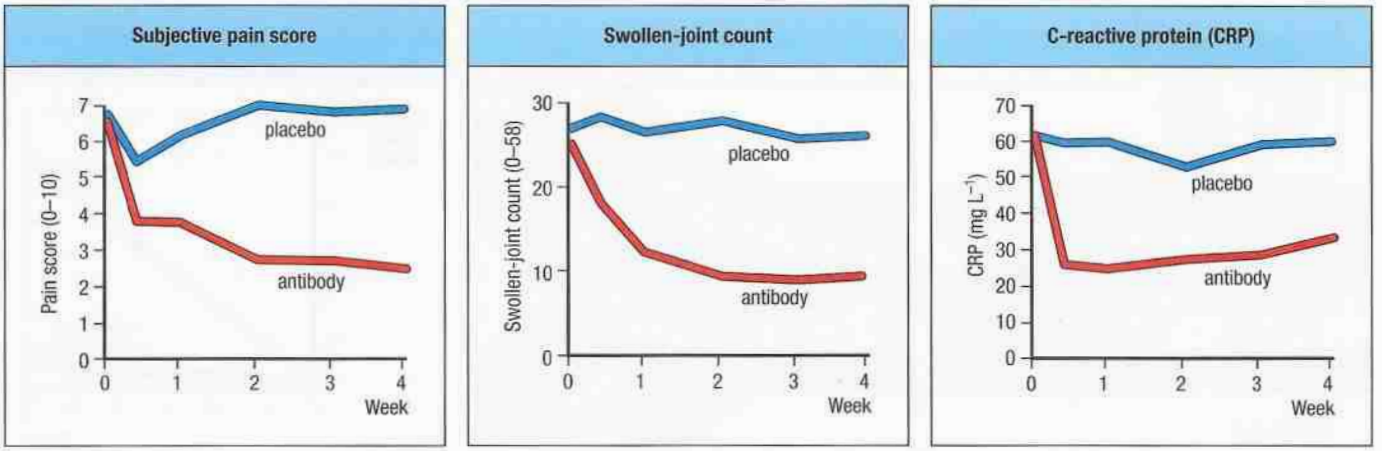

Fig. 16.34 Anti-inflammatory effects of anti-TNF-α therapy in rheumatoid arthritis. The clinical course of 24 patients was followed for 4 weeks after treatment with either a placebo or a monoclonal antibody against TNF-α at a dose of 10 mg kg^{-1}. The antibody therapy was associated with a reduction in both subjective and objective parameters of disease activity (as measured by pain score and swollen-joint count, respectively) and in the systemic inflammatory acute-phase response, measured as a fall in the concentration of the acute-phase C-reactive protein (CRP).

multiple sclerosis treated with anti-TNF-α, relapses became more frequent, possibly because of an increase in T-cell activation.

Antibodies and recombinant proteins against the pro-inflammatory cytokine IL-1 and its receptor have not proved as effective as TNF-α blockade for treating rheumatoid arthritis in humans, despite being equally powerful in animal models of arthritis. An antibody against the cytokine IL-1 has been licensed for clinical use against the hereditary autoinflammatory disease Muckle–Wells syndrome (see Section 13-18), and blockade of the IL-1β receptor by the recombinant protein **anakinra** (Kineret) has also proven useful in adults with moderate to severe rheumatoid arthritis.

Another cytokine antagonist in clinical use is the humanized antibody **tocilizumab**; by virtue of being directed against the IL-6 receptor, it blocks the effects of the pro-inflammatory cytokine IL-6. This seems to be as effective as anti-TNF-α in individuals with rheumatoid arthritis and also shows promise in treating systemic-onset juvenile idiopathic arthritis, an autoinflammatory condition.

Interferon-β (Avonex) is used to treat diseases of viral origin on the basis of its ability to enhance immunity, but it is also effective in treating multiple sclerosis, attenuating its course and severity and reducing the occurrence of relapses. Until recently, it was unclear how IFN-β could reduce rather than enhance immunity. In Section 3-11, we described the inflammasome, in which innate sensors of the NLR family activate caspase 1 to cleave the IL-1 pro-protein into the active form of the cytokine (see Fig. 3.20). We now know that IFN-β acts at two levels to reduce IL-1 production. It inhibits the activity of the NALP3 (NLRP3) and NLRP1 inflammasomes and also reduces expression of the IL-1 pro-protein, reducing the substrate available to caspase 1. Thus, IFN-β limits the production of a powerful pro-inflammatory cytokine, which may explain its observed effects on the symptoms of multiple sclerosis.

Hereditary Periodic Fever Syndromes

Systemic Juvenile Idiopathic Arthritis

16-30 Biologics can block cell migration to sites of inflammation and reduce immune responses.

Effector lymphocytes expressing the **integrin $\alpha_4\beta_1$** (VLA-4) bind to VCAM-1 on endothelium in the central nervous system, while those expressing **integrin $\alpha_4\beta_7$** (lamina propria–associated molecule 1) bind to MAdCAM-1 on the endothelium in the gut. The humanized monoclonal antibody **natalizumab** is

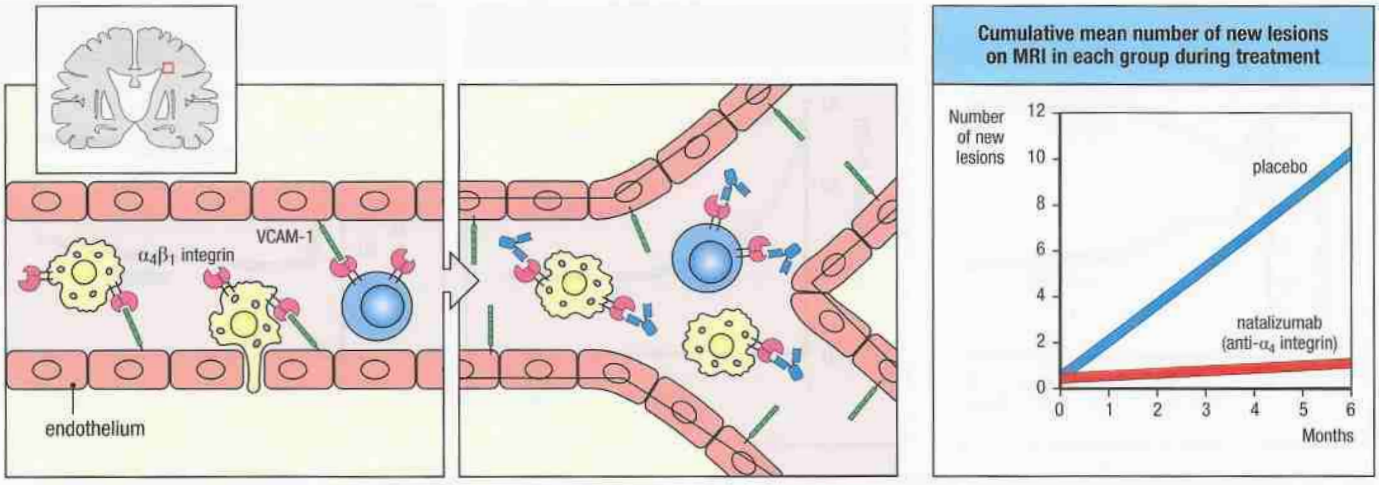

Fig. 16.35 Treatment with an anti-α_4 integrin humanized monoclonal antibody reduces relapses in multiple sclerosis. Left panel: Interaction between $\alpha_4\beta_1$ integrin (VLA-4) on lymphocytes, monocytes, and macrophages and VCAM-1 expressed on endothelial cells permits the adhesion of these cells to brain endothelium. This facilitates the migration of these cells into the plaques of inflammation in multiple sclerosis. Center panel: The monoclonal antibody natalizumab (blue) binds to the α_4 chain of the integrin and blocks adhesive interactions between lymphocytes, monocytes, and macrophages and VCAM-1 on endothelial cells, thus preventing the cells from entering the tissue and exacerbating the inflammation. The future of this treatment is unclear because of the development of a rare infection as a side effect (see the text). Right panel: The number of new lesions detected on magnetic resonance imaging (MRI) of the brain is greatly reduced in patients treated with natalizumab compared with those treated with placebo.

specific for the α_4 integrin subunit and binds both VLA-4 and $\alpha_4\beta_7$, preventing their interaction with their ligands (Fig. 16.35). This antibody has shown therapeutic benefit in placebo-controlled trials in individuals with Crohn's disease and those with multiple sclerosis. The early signs that this treatment could be successful illustrate the fact that disease depends on the continuing emigration of lymphocytes, monocytes, and macrophages from the circulation into the tissues of the brain in multiple sclerosis, and into the gut wall in Crohn's disease. However, blockade of $\alpha_4\beta_1$ integrin is not specific and, like anti-TNF therapy, could lead to reduced defense against infection. Rarely, patients treated with natalizumab have developed **progressive multifocal leukoencephalopathy (PML)**, an opportunistic infection caused by the JC virus, a very common and normally harmless virus. This led to the temporary withdrawal of natalizumab from the market in 2005, but in June 2006 it was again allowed to be prescribed for multiple sclerosis and for Crohn's disease.

A similar problem with multifocal leukoencephalopathy led to the 2009 withdrawal from the market in the United States and Europe of another anti-integrin antibody, efalizumab; this drug targets the α_L subunit (CD11a) and had shown promise in treating **psoriasis**, an inflammatory skin disease driven primarily by T cells that produce pro-inflammatory cytokines.

16-31 Blockade of co-stimulatory pathways that activate lymphocytes can be used to treat autoimmune disease.

Blocking co-stimulatory pathways, as noted earlier in connection with the prevention of transplantation rejection (see Section 16-27), has also been applied to autoimmune diseases. For example, CTLA-4–Ig (abatacept) blocks the interaction of the B7 expressed by antigen-presenting cells with the CD28 expressed by T cells. This drug is approved for the treatment of rheumatoid arthritis and also seems to be beneficial in treating psoriasis. When CTLA-4–Ig was given to individuals with psoriasis, there was an improvement in the psoriatic rash and histological evidence of loss of activation of keratinocytes, T cells, and dendritic cells within the damaged skin.

Another co-stimulatory pathway that has been targeted in psoriasis is the interaction between the adhesion molecule CD2 on T cells and CD58 (LFA-3) on antigen-presenting cells. A recombinant CD58–IgG1 fusion protein, called **alefacept** (Amevive), inhibits the interaction between CD2 and CD58 and is now a routine and effective treatment for psoriasis. Although memory T cells are targeted by this therapy, responses to vaccination such as anti-tetanus remain intact.

16-32 Some commonly used drugs have immunomodulatory properties.

Certain existing medications, such as the statins and angiotensin-converting enzyme (ACE) inhibitors widely used in the prevention and treatment of cardiovascular disease, can also modulate the immune response in experimental animals. **Statins** are very widely prescribed drugs that block the enzyme **3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase**, thereby reducing cholesterol levels. They also reduce the increased level of expression of MHC class II molecules in some autoimmune diseases. These effects may be due to an alteration in the cholesterol content of membranes, thereby influencing lymphocyte signaling. In animal models, these drugs also seem to cause T cells to switch from a more pathogenic T_H1 response to a more protective T_H2 response, although whether this occurs in humans is not clear.

The hormone vitamin D_3, essential for bone and mineral homeostasis, also exerts immunomodulatory effects. It decreases IL-12 production by dendritic cells and leads to a decrease in IL-2 and IFN-γ production by CD4 T cells. Protective effects have been demonstrated in a variety of animal models of autoimmunity, such as EAE (see Section 15-3) and diabetes, as well as in transplantation. The major drawback of vitamin D_3 is that its immunomodulatory effects are seen only at dosages that would lead to hypercalcemia and bone resorption in humans. There is a major search under way for structural analogs of vitamin D_3 that retain the immunomodulatory effects but do not cause hypercalcemia.

Multiple Sclerosis

16-33 Controlled administration of antigen can be used to manipulate the nature of an antigen-specific response.

In some diseases, the target antigen of an unwanted immune response can be identified. It can be possible, then, to use the antigen itself, rather than drugs or antibodies, to treat the disease, because the manner of antigen presentation can alter the immune response and reduce or eliminate its pathogenic features. As discussed in Section 14-12, this principle has been applied with some success to the treatment of allergies caused by an IgE response to very low doses of antigen. Repeated treatment of allergic individuals with increasing doses of allergen seems to divert the allergic response to one dominated by T cells that favor the production of IgG and IgA antibodies from B cells. These antibodies are thought to desensitize the patient by binding the small amounts of allergen normally encountered and preventing it from binding to IgE.

There has been considerable interest in using peptide antigens to suppress pathogenic responses in T cell–mediated autoimmune disease. The type of CD4 T-cell response induced by a peptide depends on the way in which it is presented to the immune system (see Section 9-14). For instance, peptides given orally tend to induce regulatory T cells through production of TGF-β but do not induce T_H1 cells or systemic antibody production (see Section 12-7). Experiments in animals indicate that oral antigens can protect against induced autoimmune disease. Diseases resembling multiple sclerosis or rheumatoid arthritis can be induced in mice by the injection of myelin basic protein

(MBP) or type II collagen, respectively, in Freund's complete adjuvant (see Section 16-8). Oral administration of MBP or type II collagen inhibits the development of these diseases in animals, but oral administration of the whole protein in individuals with multiple sclerosis or rheumatoid arthritis has had marginal therapeutic effects. Similarly, no protective effect was found in a large study that examined whether giving low-dose parenteral insulin could delay the onset of diabetes in people at high risk of developing the disease.

Other approaches using antigen to shift the autoimmune T-cell response to a less damaging T_H2 response have been more effective in humans. The peptide drug glatiramer acetate (Copaxone) is approved for treating multiple sclerosis, in which it may reduce relapse rates by up to 30%. It is a polymer consisting of the four amino acids glutamic acid, alanine, tyrosine, and lysine in ratios that mimic their composition in MBP, and it induces a T_H2-type protective response. A more refined strategy uses **altered peptide ligands (APLs)**, in which amino acid substitutions have been made in specific amino acids at the T-cell receptor contact positions of an antigenic peptide. APLs can be designed to act as partial agonists or antagonists or to induce regulatory T cells. But despite the success of APLs in treating EAE in mice, a trial of these peptides for multiple sclerosis in some patients led to exacerbated disease or to allergic reaction associated with a vigorous T_H2 response, and so their value in humans remains to be seen.

Summary.

Treatments for unwanted immune responses, such as graft rejection, autoimmunity, or allergic reactions, include conventional drugs—anti-inflammatory, cytotoxic, and immunosuppressive drugs and JAK inhibitors—as well as biologic agents such as monoclonal antibodies and immunomodulatory proteins. Anti-inflammatory drugs, of which the most potent are the corticosteroids, have a broad spectrum of actions and a wide range of toxic side effects. Their dose must be carefully controlled, and they are normally used in combination with either cytotoxic or immunosuppressive drugs. The cytotoxic drugs kill dividing cells and prevent lymphocyte proliferation but suppress all immune responses indiscriminately and also kill other types of dividing cells. The immunosuppressive drugs, such as cyclosporin A and rapamycin, interfere in specific signaling pathways and are generally less toxic but are more expensive and still suppress the immune response somewhat indiscriminately.

Several types of biologic agents are now established in the clinic for treating transplant rejection and autoimmune diseases (Fig. 16.36). Many monoclonal antibodies approved for human use deplete lymphocytes either generally or selectively, or inhibit lymphocyte activation through receptor blockade, or prevent lymphocyte migration into tissues. Immunomodulatory agents also include monoclonal antibodies or fusion proteins that inhibit the inflammatory actions of TNF-α, a notable success for immunotherapy.

Summary to Chapter 16.

Arguably, the greatest achievement of immunology has been the development of vaccines to control or prevent the threat of infectious diseases. The global COVID-19 pandemic has brought this aspect of immunology's contributions to the forefront, as new technologies have been rapidly applied on the basis of a deep understanding of the mechanisms of protective immunity. The current armamentarium of therapeutic technologies is vast, ranging from rather old approaches that used live but attenuated virus strains, through an array of subunit and conjugate vaccines, to the newly developed and rapidly deployable mRNA-based vaccines that hold the promise of keeping up with quickly evolving viral variants. Even today, the original oral Sabin vaccines are undergoing

Therapeutic agents used to treat human autoimmune diseases				
Target	**Therapeutic agent**	**Disease**	**Disease outcome**	**Disadvantages**
Integrins	$\alpha_4\beta_1$ integrin–specific monoclonal antibody (mAb)	Relapsing/ remitting multiple sclerosis (MS) Rheumatoid arthritis (RA) Inflammatory bowel disease	Reduction in relapse rate; delay in disease progression	Increased risk of infection; progressive multifocal encephalopathy
B cells	CD20-specific mAb	RA Systemic lupus erythematosus (SLE) MS	Improvement in arthritis, possibly in SLE	Increased risk of infection
HMG-coenzyme A reductase	Statins	MS	Reduction in disease activity	Hepatotoxicity; rhabdomyolysis
T cells	CD3-specific mAb	Type 1 diabetes mellitus	Reduced insulin use	Increased risk of infection
	CTLA-4–immuno-globulin fusion protein	RA Psoriasis MS	Improvement in arthritis	
Cytokines	TNF-specific mAb and soluble TNFR fusion protein	RA Crohn's disease Psoriatic arthritis Ankylosing spondylitis	Improvement in disability; joint repair in arthritis	Increased risk of tuberculosis and other infections; slight increase in risk of lymphoma
	IL-1 receptor antagonist	RA	Improves disability	Low efficacy
	IL-15–specific mAb	RA	May improve disability	Increased risk of opportunistic infection
	IL-6 receptor–specific mAb	RA	Decreased disease activity	Increased risk of opportunistic infection
	Type I interferons	Relapsing/ remitting MS	Reduction in relapse rate	Liver toxicity; influenza-like syndrome is common

Fig. 16.36 Therapeutic agents for human autoimmunity. The immunosuppressive agents listed in Fig 16.33 can act in one of three general ways. First (red), they can act by depleting cells from inflammatory sites, causing global cell-specific depletion, or by blocking integrin interactions, thereby inhibiting lymphocyte trafficking. Second (blue), agents may block specific cellular interactions or inhibit various co-stimulatory pathways. Third (green), agents may target the terminal effector mechanisms, such as by neutralizing various pro-inflammatory cytokines.

modernization with molecular design aimed at reducing their potential for reversion, a feature that still challenges the goal of global polio eradication. A future challenge in immunology is to control the immune system so that unwanted immune responses can be suppressed and desirable responses elicited. Current methods of suppressing unwanted responses rely heavily on drugs that suppress adaptive immunity indiscriminately and are thus inherently flawed. We have seen in this book that the immune system can suppress its own responses in an antigen-specific manner and that, by studying these endogenous regulatory events, it has been possible to devise strategies to manipulate specific responses while sparing general immune competence. New treatments, including many monoclonal antibodies and new classes of drugs, such as the jakinibs, have emerged as clinically important therapies to selectively suppress the responses that lead to allergy, autoimmunity, or the rejection of grafted organs. Similarly, as we understand more about tumors and infectious agents, better strategies to mobilize the immune system against cancer and infection are becoming possible. To achieve all this, we need to learn more about the induction of immunity and the biology of the immune system and to apply what we have learned to human disease.

Discussion Questions

16.1 The earliest vaccines developed were live pathogens, such as cowpox variolation and the live-attenuated oral Sabin vaccines for polio. Compare vaccination using live-attenuated pathogens to vaccination using killed or conjugate vaccines.

16.2 The live oral Sabin vaccines for polio were generated during a time when characterization of the mutations responsible for attenuation was not possible, and yet they were tested and used without such knowledge. Discuss the issues that affect the development of a live-attenuated vaccine for COVID-19 using such approaches today.

16.3 What are the benefits and/or drawbacks in using solely the SARS-CoV-2 spike protein as an antigen in vaccines against COVID-19?

16.4 Discuss the importance of herd immunity. Should vaccination against important pathogens such as polio or SARS-CoV-2 be mandatory?

16.5 In cancer treatment, what types of clinical issues must be considered when evaluating the efficacy of checkpoint blockade therapies compared to that of conventional cytotoxic drug therapies? If the tumor continues to be viable 1 week after checkpoint blockade, has the treatment necessarily failed?

16.6 Antibodies against PD-1 were available long before PD-1 checkpoint blockade was recognized as an effective treatment for cancers in mice. What properties of an antibody against an inhibitory receptor are required for it to be useful in checkpoint blockade? What other information might be required?

16.7 Explain how the drug cyclosporin A can still exert effects selectively on T cells, even though the immunophilin to which it binds is ubiquitous and is expressed at even higher levels by other tissues.

16.8 Rapamycin inhibits mTORC1 and supresses the emergence of effector T cells. How could it be potentially useful in augmenting the action of a vaccine?

16.9 Anti-TNF-α antibodies are useful in treating rheumatoid arthritis. What is the downside of this therapy?

The Immunologist's Toolbox

A-1 Immunization.

Natural immune responses are normally directed at antigens borne by pathogenic microorganisms. The immune system can also be induced to respond to simple nonliving antigens, and experimental immunologists have focused on the responses to these simple antigens in developing our understanding of the immune response. The deliberate induction of an immune response is known as **immunization**. Experimental immunizations are routinely carried out by injecting the test antigen into the animal or human subject. The route, dose, and form in which antigen is administered can profoundly affect whether a response occurs and the type of response that is produced. The induction of protective immune responses against common microbial pathogens is often called vaccination, although this term originally referred to the induction of immune responses against smallpox by immunizing with the cross-reactive virus, vaccinia.

To determine whether an immune response has occurred and to follow its course, the immunized individual is monitored for the appearance of immune reactants. Immune responses to most antigens include soluble factors, such as cytokines and specific antibodies, and cellular responses, such as the generation of specific effector T cells. Monitoring the cytokine and antibody responses usually involves the analysis of relatively crude preparations of **antiserum** (plural: **antisera**). **Serum** is the fluid phase of clotted blood, which, if taken from an individual immunized against a particular antigen, is called antiserum. To study immune responses mediated by T cells, blood lymphocytes or cells from lymphoid organs such as the spleen are tested; T-cell responses are more commonly studied in experimental animals than in humans.

Antisera generated by immunization with even the simplest antigen will contain many different antibody molecules that bind to the immunogen in slightly

different ways. In addition, antisera contain many antibodies that do not bind at all to the immunizing antigen, because they were present in the individual prior to immunization. These nonspecific antibodies often lead to technical difficulties in using antisera for detecting an immunogen. To circumvent this problem, antibodies that bind to the immunogen can be purified by affinity chromatography using immobilized antigen (see Section A-3). Alternatively, these problems can be avoided by making monoclonal antibodies (see Section A-8).

Any substance that can elicit an immune response is said to be **immunogenic** and is called an **immunogen**. There is a clear operational distinction between an immunogen and an antigen. Immunogens are substances that elicit an adaptive immune response, whereas an antigen is defined as any substance that can bind to a specific antibody. All antigens therefore have the potential to elicit specific antibodies; however, not all antigens are immunogenic. An example of this distinction is evident when considering protein antigens. In spite of the fact that antibodies against proteins are of enormous utility in experimental biology and medicine, purified proteins are not generally immunogenic. This is because purified proteins lack microbial-associated molecular patterns (MAMPs), and therefore do not elicit an innate immune response. To provoke an immune response to a purified protein, the protein must be administered together with an adjuvant (discussed shortly).

Certain properties of antigens that favor the initiation of an adaptive immune response have been defined by studying antibody responses to simple natural proteins such as hen egg-white lysozyme, to synthetic polypeptide antigens, and to small organic molecules of simple structure. The study of antibody responses to small organic molecules, such as phenyl arsonates and nitrophenyls, was essential in defining early immunological principles. These molecules do not provoke antibodies when injected by themselves. However, antibodies can be raised against them if the molecule is attached covalently, by simple chemical reactions, to a protein carrier. Such small molecules were termed **haptens** (from the Greek *haptein*, 'to fasten') by the immunologist Karl Landsteiner, who first studied them in the early 20th century. He found that animals immunized with a hapten–carrier conjugate produced three distinct sets of antibodies (Fig. A.1). One set comprised hapten-specific antibodies that reacted with the same hapten on any carrier, as well as with free hapten. The second set of antibodies was specific for the carrier protein, as shown by their ability to bind both the hapten-modified and unmodified carrier protein. Finally, some antibodies reacted only with the specific conjugate of hapten and carrier used for immunization. Landsteiner's studies focused primarily on the antibody response to the hapten, as these small molecules could be synthesized in many closely related forms. He observed that antibodies raised against a particular hapten bind that hapten but, in general, fail to bind even very closely related chemical structures. The binding of haptens by anti-hapten antibodies has played an important part in defining the precision of antigen binding by antibody molecules. Anti-hapten antibodies are also important medically because they mediate allergic reactions to penicillin and other compounds that elicit antibody responses when they attach to self proteins (see Section 14-9).

The route by which antigen is administered affects both the magnitude and the type of response obtained. The most common routes by which antigen is introduced experimentally or as a vaccine into the body are as follows: into tissue by **subcutaneous (s.c.)** injection into the fatty layer just below the dermis or by **intradermal (i.d.)** or **intramuscular (i.m.)** injection; directly into the bloodstream by **intravenous (i.v.)** injection or transfusion; into the gastrointestinal tract by oral administration; and into the respiratory tract by **intranasal (i.n.)** administration or inhalation. Antigens may also be introduced into the peritoneal cavity by **intraperitoneal (i.p.)** injection.

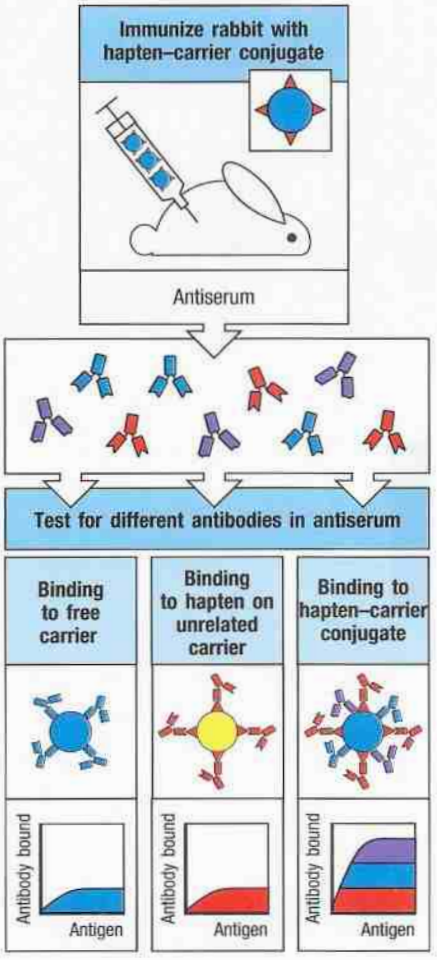

Fig. A.1 Antibodies can be elicited by small chemical groups called haptens only when the hapten is linked to an immunogenic protein carrier. After immunization with a hapten–carrier conjugate, three types of antibodies are produced. One set (blue) binds the carrier protein alone and is called carrier-specific. One set (red) binds to the hapten on any carrier or to free hapten in solution and is called hapten-specific. One set (purple) binds only the specific conjugate of hapten and carrier used for immunization, apparently binding to sites at which the hapten joins the carrier, and is called conjugate-specific. The amount of antibody of each type in this serum is shown schematically in the graphs at the bottom; note that the original antigen binds more antibody than the sum of anti-hapten and anti-carrier antibodies as a result of the additional binding of conjugate-specific antibody.

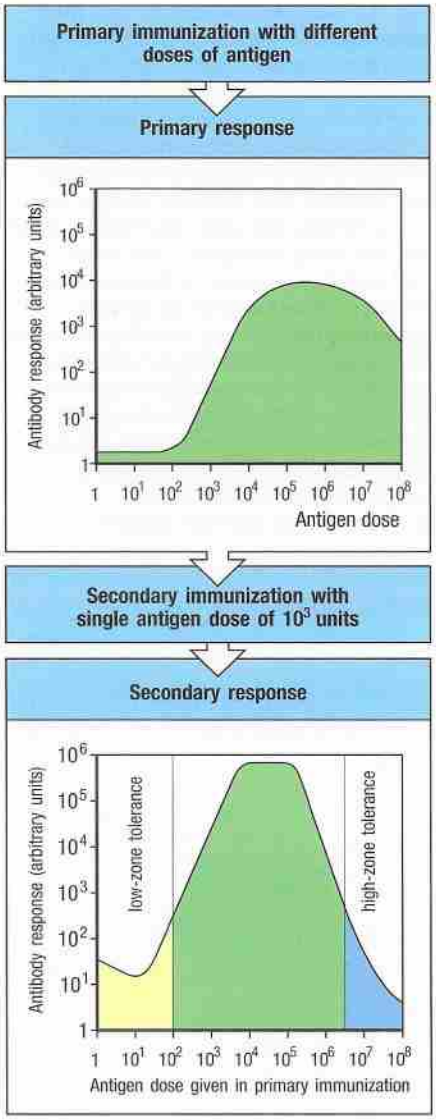

Fig. A.2 The dose of antigen used in an initial immunization affects the primary and the secondary antibody response. The typical antigen dose–response curve shown here illustrates both the influence of dose on a primary antibody response (amounts of antibody produced expressed in arbitrary units) and the effect of the dose used for priming on a secondary antibody response elicited by a dose of antigen of 10^3 arbitrary mass units. Very low doses of antigen do not cause an immune response at all. Slightly higher doses seem to inhibit specific antibody production, an effect known as low-zone tolerance. Above these doses there is a steady increase in the response with antigen dose until an optimum response is reached; this response persists across a broad range of doses. Very high doses of antigen also inhibit immune responsiveness to a subsequent challenge, a phenomenon known as high-zone tolerance.

Antigens injected subcutaneously generally elicit strong responses, most probably because the antigen is taken up by resident dendritic cells in the skin and efficiently presented in local lymph nodes, and so this is the method most commonly used when the object of the experiment is to elicit specific antibodies or T cells against a given antigen. Antigens injected or transfused directly into the bloodstream tend to induce immune unresponsiveness or tolerance unless they bind to host cells or are in the form of aggregates that are readily taken up by antigen-presenting cells.

Antigen administration via the gastrointestinal tract is used mostly in the study of allergy. It has distinctive effects, frequently eliciting a local antibody response in the intestinal lamina propria, while producing a systemic state of tolerance that manifests as a diminished response to the same antigen if subsequently administered in immunogenic form elsewhere in the body (see Chapter 12). This 'split tolerance' may be important in avoiding allergy to antigens in food, because the local response prevents food antigens from entering the body, while the inhibition of systemic immunity helps to prevent the formation of IgE antibodies, which are the cause of such allergies (see Chapter 14).

The immune response to an antigen is also influenced by the dose of immunogen administered. Below a certain threshold dose, most proteins do not elicit any immune response. Above the threshold dose, there is a gradual increase in the response as the dose of antigen is increased, until a broad plateau level is reached, followed by a decline at very high antigen doses (Fig. A.2). In general, secondary and subsequent immune responses occur at lower antigen doses and achieve higher plateau values, which is a sign of immunological memory.

Most proteins are poorly immunogenic or non-immunogenic when administered by themselves. Strong adaptive immune responses to protein antigens almost always require that the antigen be injected in a mixture known as an adjuvant. An adjuvant is any substance that enhances the immunogenicity of substances mixed with it. Commonly used adjuvants are listed in Fig. A.3.

Adjuvants generally enhance immunogenicity in two different ways. First, adjuvants convert soluble protein antigens into particulate material, which is more readily ingested by phagocytic antigen-presenting cells such as macrophages and dendritic cells. For example, the antigen can be adsorbed on particles of the adjuvant (such as alum), be made particulate by emulsification in mineral oils, or be incorporated into the colloidal particles of immune stimulatory complexes (ISCOMs). Second, and more important, adjuvants contain pathogen-associated molecular patterns (PAMPs) that elicit a strong innate immune response. When taken up by phagocytic cells, the PAMPs in the adjuvant stimulate inflammatory cytokine production and induce the activation of the antigen-presenting cell. The activated antigen-presenting cells up-regulate abundant levels of co-stimulatory molecules that are important for activating T cells. Activated antigen-presenting cells also up-regulate high levels of MHC class I and class II proteins, plus many of the proteins important for efficient antigen processing and presentation (see Section 3-12). Because of the strong local inflammatory responses induced by adjuvants that contain PAMPs, most

Fig. A.3 Common adjuvants and their use. Adjuvants are mixed with the antigen and usually render it particulate, which helps to retain the antigen in the body and promotes uptake by macrophages. Most adjuvants include bacteria or bacterial components that stimulate macrophages and dendritic cells, aiding in the induction of the immune response. ISCOMs are small micelles of the detergent Quil A; when viral proteins are placed in these micelles, they apparently fuse with the antigen-presenting cell, allowing the antigen to enter the cytosol. Thus, the antigen-presenting cell can stimulate a response to the viral protein, much as a virus infecting these cells would stimulate an antiviral response. Vaccines designed to elicit responses to purified proteins often include compounds that stimulate pattern-recognition receptors, such as Toll-like receptors (TLRs), NOD-like receptors (NLRs), or C-type lectin receptors.

Adjuvants that enhance immune responses		
Adjuvant name	**Composition**	**Mechanism of action**
Freund's incomplete adjuvant	Oil-in-water emulsion	Delayed release of antigen; enhanced uptake by macrophages
Freund's complete adjuvant	Oil-in-water emulsion with dead mycobacteria that stimulate C-type lectin receptors	Delayed release of antigen; enhanced uptake by macrophages; induction of co-stimulators in macrophages
Freund's adjuvant with MDP	Oil-in-water emulsion with muramyl dipeptide (MDP), a constituent of mycobacteria that stimulates NOD-like receptors	Similar to Freund's complete adjuvant
Alum (aluminum hydroxide)	Aluminum hydroxide gel	Delayed release of antigen; enhanced macrophage uptake
Alum plus *Bordetella pertussis*	Aluminum hydroxide gel with killed *B. pertussis*	Delayed release of antigen; enhanced uptake by macrophages; induction of co-stimulators
Immune stimulatory complexes (ISCOMs)	Matrix of Quil A containing viral proteins	Delivers antigen to cytosol; allows induction of cytotoxic T cells
TLR agonists	Lipopolysaccharide, flagellin, lipopeptides, dsRNA, unmethylated DNA	Inflammatory cytokine production, induction of co-stimulators, enhanced antigen presentation to T cells
NOD-like receptor (NLR) agonists	Muramyl dipeptide (bacterial cell wall constituent)	Inflammatory cytokine production, induction of co-stimulators, enhanced antigen presentation to T cells
C-type lectin receptor agonists	Mycobacterial cell wall component trehalose-6,6′-dimycolate	Inflammatory cytokine production

of the adjuvants commonly used in experimental animals are not approved for use in humans.

Nevertheless, some human vaccines naturally contain microbial antigens that can also act as effective adjuvants. For example, purified constituents of the bacterium *Bordetella pertussis*, which is the causative agent of whooping cough, are used as both antigen and adjuvant in the triplex DTaP (diphtheria, pertussis, tetanus) vaccine. In addition, modified TLR ligands, such as monophosphoryl lipid A, a derivative of LPS, or poly(I):poly(C12U), a derivative of polyI:C, are currently included as components of several human vaccines.

A-2 Antibody responses.

B cells contribute to adaptive immunity by secreting antibodies, and the response of B cells to an injected immunogen is usually measured by analyzing the specific antibody produced in a **humoral immune response**. This is most conveniently achieved by assaying the antibody that accumulates in the fluid phase of whole blood, or **plasma**; such antibodies are known as circulating antibodies. Circulating antibody is usually measured by collecting blood, allowing it to clot, and then isolating the serum from the clotted blood. The amount and characteristics of the antibody in the resulting antiserum are then determined using the assays described later. Because assays for antibody were originally conducted using antisera from immune individuals, they are commonly referred to as **serological assays**, and the use of antibodies in such testing is often called **serology**.

The most important characteristics of an antibody response are the specificity, amount, isotype or class, and affinity of the antibodies produced. The **specificity** determines the ability of the antibody to distinguish the immunogen from other antigens. The amount of antibody can be determined in many different ways and is a function of the number of responding B cells, their rate of antibody synthesis, and the persistence of the antibody after production. The persistence of an antibody in the plasma and extracellular fluid bathing the tissues is determined mainly by its isotype or class (see Section 4-6 and Section 10-15); each isotype has a different half-life *in vivo*. The isotypic composition of an antibody response also determines the biological functions these antibodies can perform and the sites in which antibody will be found. Finally, the strength of binding of the antibody to its antigen in terms of a single antigen-binding site binding to a monovalent antigen is termed its **affinity**; the total binding strength of a molecule with more than one binding site is called its **avidity**. Binding strength is important: the higher the affinity of the antibody for its antigen, the less antibody is required to eliminate the antigen, because antibodies with higher affinity will bind at lower antigen concentrations. All these parameters of the humoral immune response help to determine the capacity of that response to protect the host from infection.

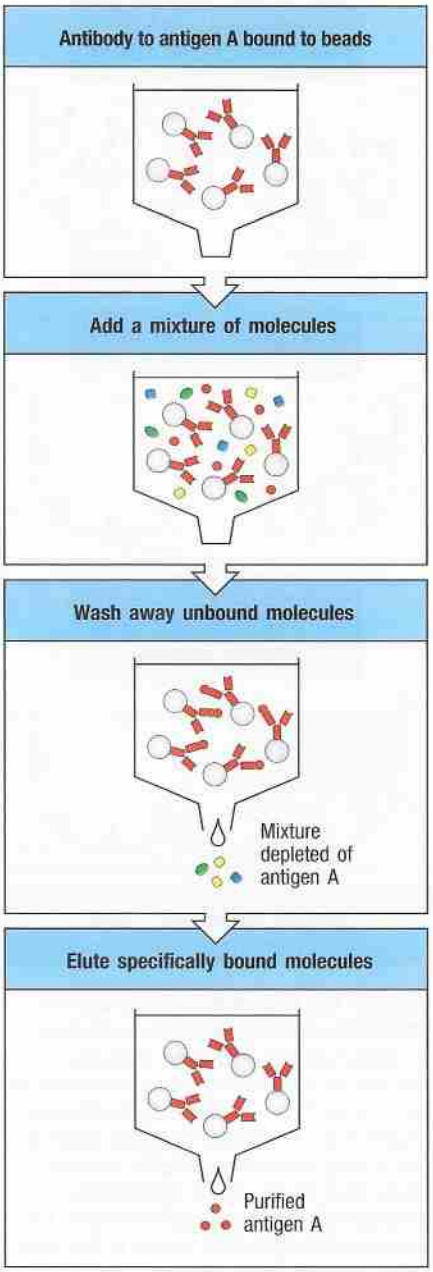
A-3 Affinity chromatography.

The specificity of antigen–antibody binding interactions can be exploited for the purification of a specific antigen from a complex mixture or alternatively for the purification of specific antibodies from antiserum containing a mixture of different antibodies. The technique employed is called **affinity chromatography** (Fig. A.4). For purification of an antigen, antigen-specific antibodies are bound, often covalently, to small, chemically reactive beads, which are loaded into a column. The antigen mixture is allowed to pass over the beads. The specific antigen binds; all the other components in the mixture can then be washed away. The specific antigen is then eluted, typically by lowering the pH to 2.5 or raising it to greater than 11. Antibodies bind stably under physiological conditions of salt concentration, temperature, and pH, but the binding is reversible because the bonds are noncovalent. Affinity chromatography can also be used to purify antibodies from complex antisera by using beads coated with specific antigen. The technique is known as affinity chromatography because it separates molecules on the basis of their affinity for one another.

A-4 Radioimmunoassay (RIA), enzyme-linked immunosorbent assay (ELISA), and competitive inhibition assay.

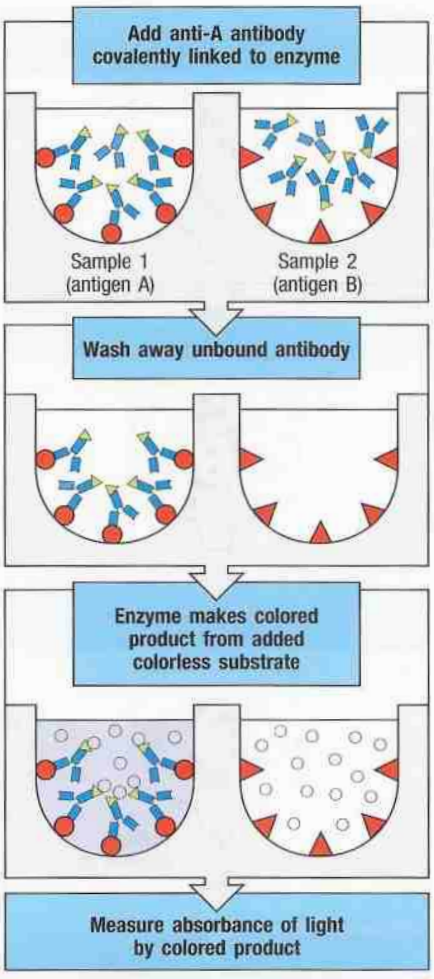
Radioimmunoassay (RIA) and **enzyme-linked immunosorbent assay (ELISA)** are direct binding assays for antigen or antibody; both work on the same principle, but the means of detecting specific binding is different. Radioimmunoassays are commonly used to measure the levels of hormones in blood and tissue fluids, while ELISAs are frequently used in viral diagnostics; for example, in detecting cases of infection with the human immunodeficiency virus (HIV), which is the cause of AIDS. For both of these methods, one needs a pure preparation of a known antigen or antibody, or both, in order to standardize the assay. We will describe the assay that is used to determine the amount of a specific antigen in a sample; for instance, the amount of HIV p24 protein in a patient's serum. For this, a preparation of pure antibody specific for the antigen is required. One can also use RIA or ELISA to determine the amount of specific antibody in a mixture, such as serum; in this case, a preparation of pure antigen is needed as a starting point.

For the most sensitive determination of antigen concentration, an RIA is used. In this technique, pure antibody against the antigen is radioactively labeled,



Antibody to antigen A bound to beads
Add a mixture of molecules
Wash away unbound molecules
Mixture depleted of antigen A
Elute specifically bound molecules
Purified antigen A

Fig. A.4 Affinity chromatography uses antigen–antibody binding to purify antigens or antibodies. To purify a specific antigen from a complex mixture of molecules, a monoclonal antibody is attached to an insoluble matrix, such as chromatography beads, and the mixture of molecules is passed over the matrix. The specific antibody binds the antigen of interest; other molecules are washed away. Specific antigen is then eluted by altering the pH, which can usually disrupt antibody–antigen bonds. Antibodies can be purified in the same way on beads coupled to antigen (not shown).



Add anti-A antibody covalently linked to enzyme
Sample 1 (antigen A)
Sample 2 (antigen B)
Wash away unbound antibody
Enzyme makes colored product from added colorless substrate
Measure absorbance of light by colored product

Fig. A.5 The principle of the enzyme-linked immunosorbent assay (ELISA). To detect antigen A, purified antibody specific for antigen A is linked chemically to an enzyme. The samples to be tested are coated onto the surface of plastic wells, to which they bind nonspecifically; residual sticky sites on the plastic are blocked by adding irrelevant proteins (not shown). The labeled antibody is then added to the wells under conditions that prevent nonspecific binding, so that only binding to antigen A causes the labeled antibody to be retained on the surface. Unbound labeled antibody is removed from all wells by washing, and bound antibody is detected by an enzyme-dependent color-change reaction. This assay allows arrays of wells known as microtiter plates to be read in fiber-optic multichannel spectrometers, greatly speeding the assay. Modifications of this basic assay allow antibody or antigen in unknown samples to be measured as shown in Figs. A.6 and A.25.

usually with ^{125}I. For ELISA, a non-radioactive approach, an enzyme is linked chemically to the antibody. The unlabeled component, which in this case would be the solution containing an unknown amount of antigen, is attached to a solid support, such as the wells of a plastic multiwell plate, which will adsorb a certain amount of any protein. After this, the labeled antibody is added to the well and allowed to bind to the unlabeled antigen under conditions in which nonspecific adsorption is blocked, and any unbound antibody and other proteins are washed away. Antibody binding in RIA is measured directly in terms of the amount of radioactivity retained by the coated wells, whereas in ELISA the binding is detected by a reaction that converts a substrate into a reaction product of a different color (Fig. A.5). The color change can be read directly in the reaction tray, making data collection very easy and providing a quantitative measurement of reaction-product concentration; furthermore, ELISA also avoids the hazards of radioactivity. This makes ELISA the preferred method for most direct-binding assays. In a variation of this assay, labeled anti-immunoglobulin antibodies can also be used in RIA or ELISA as a second layer, after the binding of unlabeled antibody to unlabeled antigen-coated plates. The use of such a second layer amplifies the signal, because at least two molecules of the labeled anti-immunoglobulin antibody are able to bind to each unlabeled antibody. As mentioned above, RIA and ELISA can also be carried out in reverse when the goal is to determine the amount of antibody in a solution; in this case, unlabeled antibody is adhered to the plates, labeled antigen is added, and the amount of labeled antigen bound after washing is measured.

A modification of ELISA known as a **capture (or sandwich) ELISA** (or more generally as an **antigen-capture assay**) is commonly used to detect secreted products such as cytokines. Rather than the antigen being directly attached to a plastic plate, antigen-specific antibodies are bound to the plate. These are able to bind antigen with high affinity, and thus concentrate it on the surface of the plate, even with antigens that are present in very low concentrations in the initial mixture. A separate labeled antibody that recognizes a different epitope from that recognized by the immobilized first antibody is then used to detect the bound antigen.

These assays illustrate two crucial aspects of all serological assays. First, at least one of the reagents must be available in a pure, detectable form in order to obtain quantitative information. Second, there must be a means of separating the bound fraction of the labeled reagent from the unbound, free fraction so that the percentage of specific binding can be determined. Normally, this separation is achieved by having the unlabeled partner trapped on a solid support. Labeled molecules that do not bind can then be washed away, leaving just the labeled partner that has bound. In Fig. A.5, the unlabeled antigen is attached to the well, and the labeled antibody is trapped by binding to it. The separation of bound reagent from the free fraction is an essential step in every assay that uses antibodies.

RIA and ELISA do not allow one to measure directly the amount of antigen or antibody in a sample of unknown composition, because both depend on the binding of a pure labeled antigen or antibody. There are various ways around this problem, one of which is to use a **competitive inhibition assay**, as shown in Fig. A.6. In this type of assay, the presence and amount of a particular test antigen in a sample of unknown composition are determined by the ability of the antigen, if present, to compete with a known amount of that antigen, but in this case labeled, for binding to an antibody attached to a plastic well. To perform this assay, an antibody specific for the antigen is adhered to an assay plate well. A standard curve is determined using a known quantity of labeled antigen, which is mixed with increasing amounts of the same antigen, but unlabeled. As the unlabeled antigen concentration increases, the binding of the labeled antigen to the antibody will decrease. In separate assay wells, the labeled antigen is mixed with increasing amounts of the sample of unknown

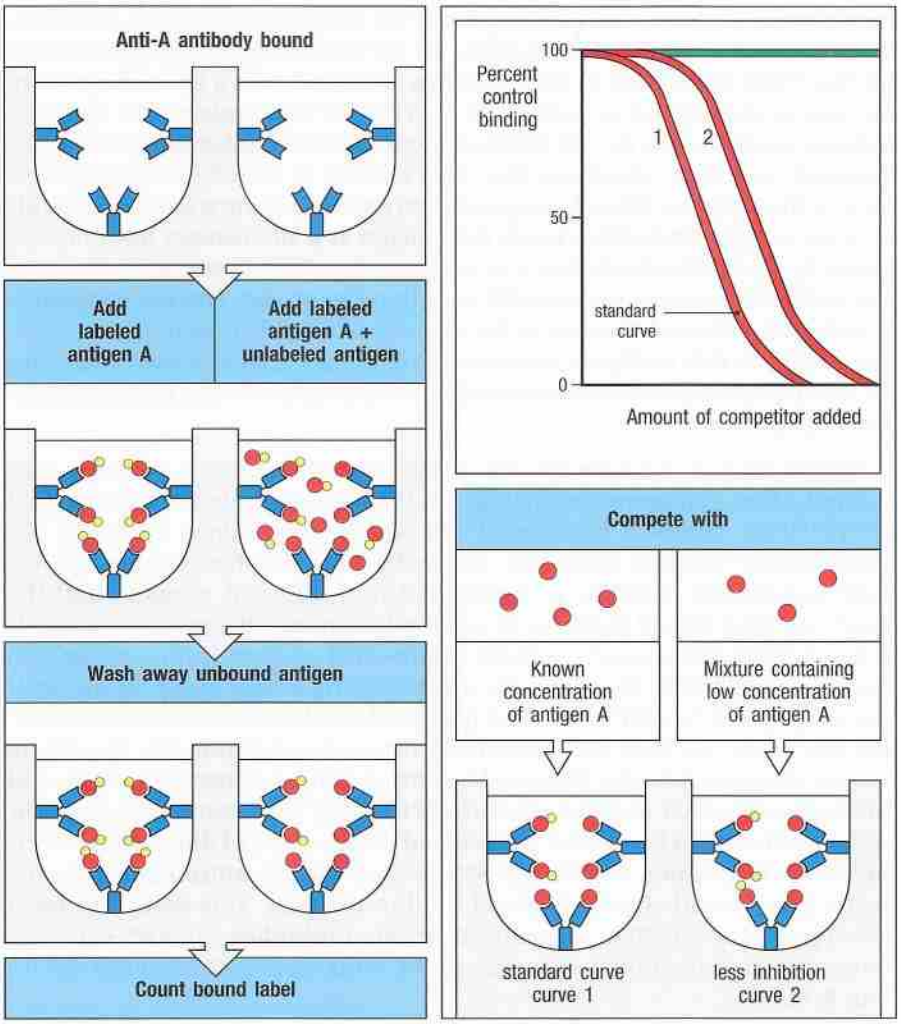


Fig. A.6 Competitive inhibition assay for antigen in samples of unknown composition. A fixed amount of unlabeled antibody is attached to a set of wells, and a standard reference preparation of a labeled antigen is bound to it. Unlabeled standard or test samples are then added in various amounts, and the displacement of labeled antigen is measured, generating characteristic inhibition curves. A standard curve is obtained by using known amounts of unlabeled antigen identical to those used for the labeled species, and comparison with this curve allows the amount of antigen in samples of unknown composition to be calculated. The green line on the graph represents a sample lacking any substance that reacts with anti-A antibodies.

composition, and the amount of labeled antigen bound to the antibody is measured to determine a binding curve for the test sample. A comparison of the two curves indicates the presence or absence of the antigen in the test sample and, if present, its concentration in the sample.

A-5 Multiplex bead assay for detection of cytokines, antibody responses, or antigens.

Another binding assay used to detect specific proteins in complex mixtures such as serum samples from humans or experimental animals is known as a **multiplex assay**. The term 'multiplex' refers to the fact multiple antigens or antibodies can simultaneously be detected and quantified in a single sample. This technique is often utilized to examine the levels of multiple cytokines or multiple antibodies when sample availability is limited, and therefore it is not feasible to measure each cytokine or antibody individually.

For this type of assay, small microspheres are differentially labeled with fluorescent dyes that can be distinguished on the basis of their distinct emission spectra. Each population of microspheres is labeled with a given fluorescent dye and is conjugated to antibodies specific for one antigen; for instance, a single cytokine. Up to 100 different populations of microspheres can be prepared, and then mixed together. This mixture is added to the sample to capture the antigens. Bound antigen is then detected using a second antibody for each antigen and which binds the antigen at a site distinct from the site bound by the first antibody that was conjugated to the microspheres. This second antibody is conjugated to a different fluorescent dye, and the magnitude of its fluorescence is a measure of the quantity of bound antigen. The machine that performs this multiplex analysis, the Luminex analyzer, then measures the amount of fluorescence associated with each differentially labeled microsphere population.

Multiplex bead assays have also been developed for analysis of serum antibodies by flow cytometry (see Section A-19). One example is the BioLegend LEGENDplex carboxyl bead assay, in which populations of beads are differentially labeled with the fluorochrome allophycocyanin (APC). Each population of beads is conjugated to a different antigen, and the beads are then mixed together in equimolar ratios. This mixture of beads is incubated with a serum sample. Antibodies present in the serum will bind to a bead in the mixture if the antibodies have specificity for the antigen conjugated to that bead. The unbound antibodies are washed away, and the beads are then incubated with biotinylated antibodies specific to human immunoglobulin, followed by streptavidin conjugated to a second fluorochrome, such as phycoerythrin (PE). After flow cytometry analysis, each population of beads can be resolved on the basis of different APC fluorescence intensities, and beads with bound human antibodies from the serum sample will show enhanced PE fluorescence. This assay has been developed as a sensitive measure of serum antibodies to SARS-CoV-2 to determine an individual's exposure to the virus responsible for COVID-19 (Fig. A.7).

A-6 Hemagglutination and blood typing.

The direct measurement of antibody binding to antigen is used in most quantitative serological assays. However, some important assays are based on the ability of antibody binding to alter the physical state of the antigen to which the antibody binds. These secondary interactions can be detected in a variety of ways. For instance, when the antigen is displayed on the surface of a large particle such as a bacterium, antibodies can cause the bacteria to clump, or **agglutinate**. The same principle applies to the reactions used in blood typing, only here the target antigens are on the surface of red blood cells, and the clumping reaction caused by antibodies against them is called **hemagglutination** (from the Greek *haima*, 'blood').

Hemagglutination is used to determine the **ABO blood group** of blood donors and transfusion recipients. Clumping or agglutination is induced by antibodies or agglutinins called anti-A or anti-B that bind to the A or B blood-group substances, respectively (Fig. A.8). These blood-group antigens are arrayed in many copies on the surface of the red blood cell, causing the cells to agglutinate when cross-linked by antibodies. Because hemagglutination involves the cross-linking of blood cells by the simultaneous binding of antibody molecules to identical antigens on different cells, this reaction also demonstrates that each antibody molecule must have at least two identical antigen-binding sites.

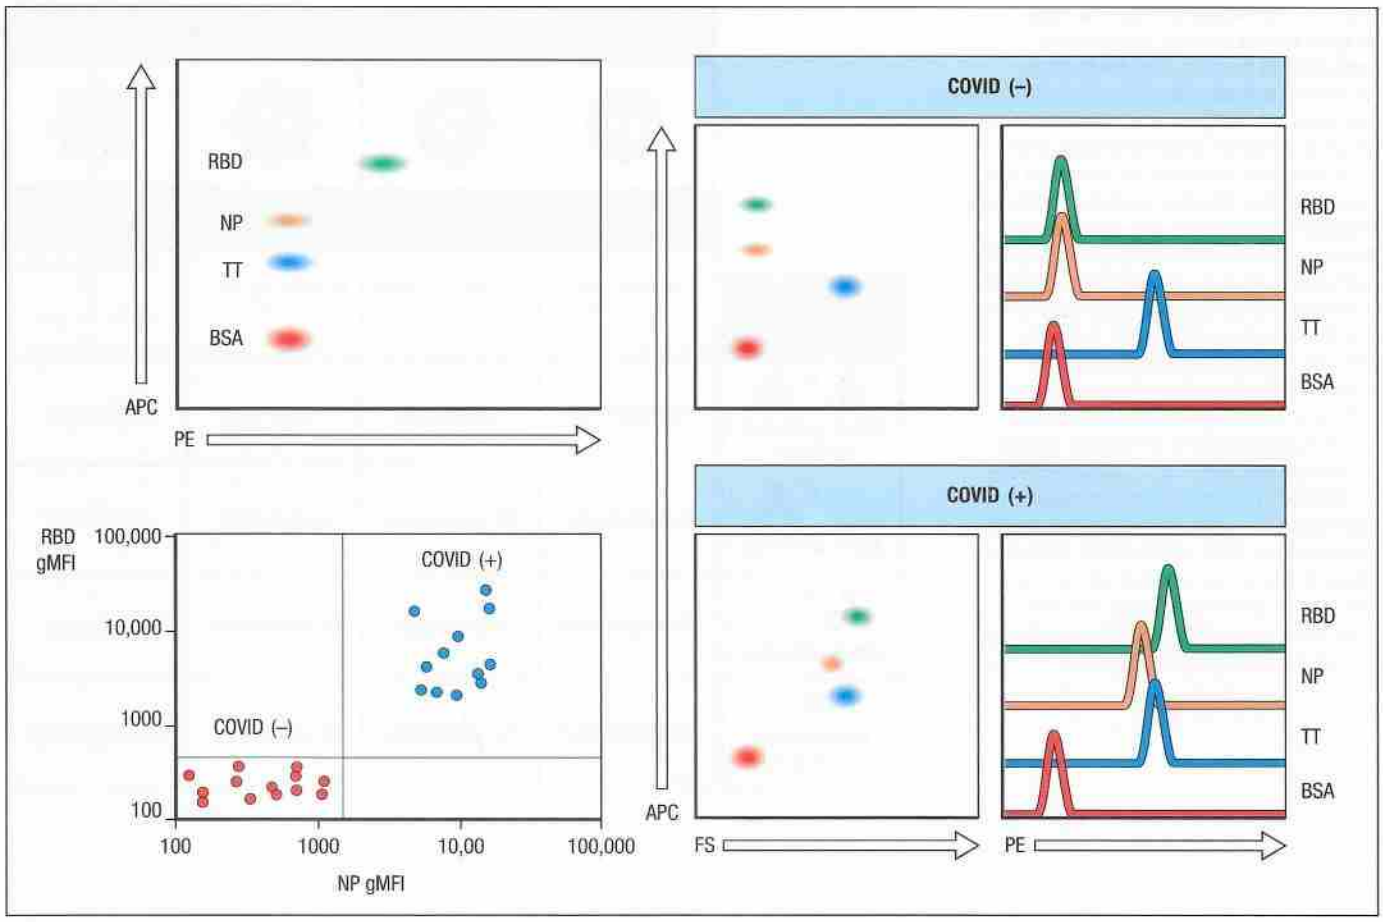

Fig. A.7. Multiplex bead assay for detection of human antibodies specific to SARS-CoV-2 spike protein and nucleoprotein. The BioLegend LEGENDplex carboxyl beads of different sizes and allophycocyanin (APC) fluorescence intensities were conjugated to bovine serum albumin (BSA), tetanus toxoid (TT), SARS-CoV-2 spike protein receptor-binding domain (RBD), and SARS-CoV-2 nucleoprotein (NP). Upper left panel: Flow cytometry analysis shows the levels of fluorescence and the forward scatter (FS; size) of the conjugated beads after mixing the four populations of beads together. Right panels: Serum samples from one healthy control individual [COVID (–)] and one individual previously infected with SARS-CoV-2 [COVID (+)] were incubated with the mixture of beads. Samples were washed and then incubated with biotinylated anti-human Ig followed by streptavidin conjugated to phycoerythrin (PE) and analyzed by flow cytometry. Plots on the left show the relative fluorescence intensities for PE versus APC, and histograms on the right show the PE fluorescence from the dot plots on the left. Lower left panel: Thirteen pre-COVID serum samples [COVID (–)] and 12 serum samples from patients that screened positive for SARS-CoV-2 [COVID (+)] were analyzed using the multiplex bead assay. The average and standard deviation for all negative samples was determined; the value of 3 times the standard deviation (3XSD) is indicated by the thin black lines. All positive samples are well above the cutoff, easily identifying the seropositive COVID-positive patients. gMFI, geometric mean fluorescence intensity. Data provided by Ross Kedl.

A-7 Coombs tests and the detection of rhesus incompatibility.

Coombs tests use anti-immunoglobulin antibodies to detect the antibodies that cause **hemolytic disease of the newborn,** or **erythroblastosis fetalis**. Anti-immunoglobulin antibodies were first developed by R. R. A. Coombs, and the test for this disease is still called the Coombs test. Hemolytic disease of the newborn occurs when a mother makes IgG antibodies specific for the **rhesus** (or **Rh**) **blood-group antigen** expressed on the red blood cells of her fetus. Rh-negative mothers make these antibodies when they are exposed at delivery to Rh-positive fetal red blood cells bearing the paternally inherited Rh antigen. During subsequent pregnancies, these anti-Rh antibodies are transported across the placenta to the fetus. The

Fig. A.8 Hemagglutination is used to type blood groups and match compatible donors and recipients for blood transfusion. Common gut bacteria bear antigens that are similar or identical to blood-group antigens, and these bacterial antigens will stimulate the formation of antibodies against blood-group antigens in individuals who do not bear the corresponding antigens on their own red blood cells (left column); thus, type O individuals, who lack A and B, have both anti-A and anti-B antibodies, whereas type AB individuals have neither. The pattern of agglutination of the red blood cells of a transfusion donor or recipient with anti-A and anti-B antibodies reveals the individual's ABO blood group. Before transfusion, the serum of the recipient is also tested for antibodies that agglutinate the red blood cells of the donor, and vice versa, a procedure called a cross-match, which may detect potentially harmful antibodies against other blood groups that are not part of the ABO system.

Serum from individuals of type	Red blood cells from individuals of type: O	A	B	AB
	Express the carbohydrate structures: R–GlcNAc–Gal (Fuc)	R–GlcNAc–Gal–GalNAc (Fuc)	R–GlcNAc–Gal–Gal (Fuc)	R–GlcNAc–Gal–GalNAc (Fuc) + R–GlcNAc–Gal (Fuc)
O — Anti-A and anti-B antibodies	No agglutination	Agglutination	Agglutination	Agglutination
A — Anti-B antibodies	No agglutination	No agglutination	Agglutination	Agglutination
B — Anti-A antibodies	No agglutination	Agglutination	No agglutination	Agglutination
AB — No antibodies to A or B	No agglutination	No agglutination	No agglutination	No agglutination

normal process of transporting maternal IgG across the placenta is generally beneficial, as it protects newborn infants against infection. However, IgG anti-Rh antibodies coat the fetal red blood cells, which are then destroyed by phagocytic cells in the liver, causing a hemolytic anemia in the fetus and newborn infant.

Rh antigens are widely spaced on the red blood cell surface, and so the IgG anti-Rh antibodies do not bind in the correct conformation to fix complement and so do not cause lysis of red blood cells *in vitro*. Furthermore, for reasons that are not fully understood, antibodies against Rh antigens do not agglutinate red blood cells, unlike antibodies against the ABO blood-group antigens. Thus, detecting anti-Rh antibodies was difficult until anti-human immunoglobulin antibodies were developed. With these, maternal IgG antibodies bound to the fetal red blood cells can be detected after washing the cells to remove unbound immunoglobulin that is present in the fetal serum. Adding anti-human immunoglobulin antibodies against the washed fetal red blood cells agglutinates any cells to which maternal antibodies are bound. This is the **direct Coombs test** (Fig. A.9), so called because it directly detects antibody bound to the surface of the fetal red blood cells. An **indirect Coombs test** is used to detect non-agglutinating anti-Rh antibody in maternal serum: the serum is first incubated with Rh-positive red blood cells, which bind the anti-Rh antibody, after which the antibody-coated cells are washed to remove unbound immunoglobulin and are then agglutinated with anti-immunoglobulin antibody (see Fig. A.9). The indirect Coombs test allows Rh incompatibilities that might lead to hemolytic disease of the newborn to be detected, and this knowledge allows the disease to be prevented. The Coombs test is also commonly used to detect antibodies against drugs that bind to red blood cells and cause hemolytic anemia.

A-8 Monoclonal antibodies.

The antibodies generated in a natural immune response or after immunization in the laboratory are a mixture of molecules of different specificities and affinities. Some of this heterogeneity results from the production of antibodies that bind to different epitopes on the immunizing antigen, but even antibodies directed at a single antigenic determinant such as a hapten can be markedly heterogeneous, as shown by **isoelectric focusing**. In this technique, proteins are separated on the basis of their isoelectric point, the pH at which their net charge is zero. By electrophoresing proteins in a pH gradient for long enough, each molecule migrates along the pH gradient until it reaches the pH at which it is neutral and is thus concentrated (focused) at that point. When antiserum containing anti-hapten antibodies is treated in this way and then transferred to a solid support such as nitrocellulose paper, the anti-hapten antibodies can be detected by their ability to bind labeled hapten. The binding of antibodies of various isoelectric points to the hapten shows that even antibodies that bind the same antigenic determinant can be heterogeneous.

Antisera are valuable for many biological purposes, but they have certain inherent disadvantages that relate to the heterogeneity of the antibodies they contain. First, each antiserum is different from all other antisera, even if raised in a genetically identical animal by using the identical preparation of antigen and the same immunization protocol. Second, antisera can be produced in only limited volumes, and thus it is impossible to use the identical serological reagent in a long or complex series of experiments or clinical tests. Finally, even antibodies purified by affinity chromatography (see Section A-3) can include minor populations of antibodies that give unexpected cross-reactions, which confound the analysis of experiments. To avoid these problems, and to harness the full potential of antibodies, it was necessary to develop a way of making an unlimited supply of antibody molecules of homogeneous structure and known specificity. This has been achieved through the production of monoclonal antibodies from cultures of hybrid antibody-forming cells or, more recently, by genetic engineering.

Starting in the 1950s, biochemists in search of a homogeneous preparation of antibody that they could subject to detailed chemical analysis turned to proteins produced by individuals with multiple myeloma, a common tumor of plasma cells. It was known that antibodies are normally produced by plasma cells, and because this disease is associated with the presence of large amounts of a homogeneous gamma globulin called **myeloma protein** in a patient's serum, it seemed likely that myeloma proteins would serve as models for normal antibody molecules. Thus, much of the early knowledge of antibody structure came from studies on myeloma proteins. These studies showed that monoclonal antibodies could be obtained from immortalized plasma cells. However, the antigen specificity of most myeloma proteins was unknown, which limited their usefulness as objects of study or as immunological tools.

This problem was solved by Georges Köhler and César Milstein, who devised a technique for producing a homogeneous population of antibodies of known antigenic specificity. They did this by fusing spleen cells from an immunized mouse to cells of a mouse myeloma to produce hybrid cells that both proliferated indefinitely and secreted antibody specific for the antigen used to immunize the spleen-cell donor. The spleen cell provides the ability to make specific antibody, while the myeloma cell provides the ability to grow indefinitely in culture and secrete immunoglobulin continually. By using a myeloma-cell partner that produces no antibody proteins itself, the antibody produced by the hybrid cells comes only from the immune spleen-cell partner. After fusion, the hybrid cells are selected using drugs that kill the myeloma parental cell, while the unfused parental spleen cells have a limited life span and soon die, so that only hybrid myeloma-cell lines, or **hybridomas**, survive. Those hybridomas

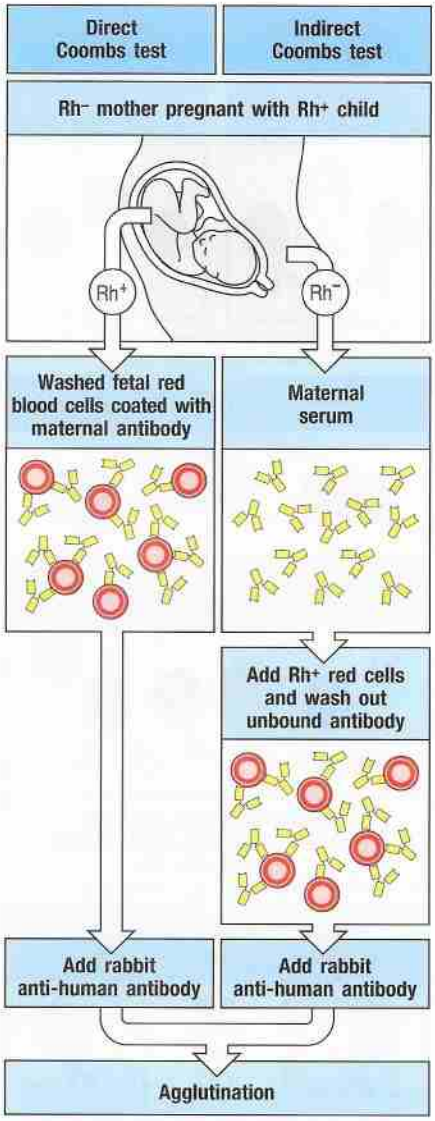

Fig. A.9 The Coombs direct and indirect anti-globulin tests for antibody against red blood cell antigens. An Rh⁻ mother of an Rh⁺ fetus can become immunized to fetal red blood cells that enter the maternal circulation at the time of delivery. In a subsequent pregnancy with an Rh⁺ fetus, IgG anti-Rh antibodies can cross the placenta and damage the fetal red blood cells. In contrast to anti-Rh antibodies, maternal anti-ABO antibodies are of the IgM isotype and cannot cross the placenta, and so do not cause harm. Anti-Rh antibodies do not agglutinate red blood cells, but their presence on the fetal red blood cell surface can be shown by washing away unbound immunoglobulin and then adding antibody against human immunoglobulin, which agglutinates the antibody-coated cells. Anti-Rh antibodies can be detected in the mother's serum in an indirect Coombs test; the serum is incubated with Rh⁺ red blood cells, and once the antibody has bound, the red blood cells are treated as in the direct Coombs test.

Clone selected hybridoma

Fig. A.10 The production of monoclonal antibodies. Mice are immunized with antigen A and given an intravenous booster immunization 3 days before they are sacrificed, in order to produce a large population of spleen cells secreting specific antibody. Spleen cells die after a few days in culture. To produce a continual source of antibody, they are fused with immortal myeloma cells by use of polyethylene glycol (PEG), resulting in a hybrid cell line called a hybridoma. The myeloma cells are selected beforehand to ensure that they are not secreting antibody themselves and that they lack the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT); without this enzyme, unfused myeloma cells are sensitive to the hypoxanthine–aminopterin–thymidine (HAT) medium, which is used to select hybrid cells. The HGPRT gene contributed by the spleen cell allows hybrid cells to survive in the HAT medium, and only hybrid cells can grow continually in culture, because of the malignant potential contributed by the myeloma cells combined with the finite life span of unfused spleen cells. Unfused myeloma cells and unfused spleen cells therefore die in the HAT medium, as shown here by cells with dark, irregular nuclei. Individual hybridomas are obtained by single-cell dilution and then screened for antibody production, and single clones that make antibody of the desired specificity can be isolated and grown. The cloned hybridoma cells are grown in bulk culture to produce large amounts of antibody. As each hybridoma is descended from a single cell, all the cells of a hybridoma cell line make the same antibody molecule, which is thus called a monoclonal antibody.

producing antibody of the desired specificity are then identified and cloned by regrowing the cultures from single cells (Fig. A.10). Because each hybridoma is a **clone** derived from fusion with a single B cell, all the antibody molecules it produces are identical in structure, including their antigen-binding site and isotype. Such antibodies are called **monoclonal antibodies**. This technology has revolutionized the use of antibodies by providing a limitless supply of antibody of a single and known specificity. Monoclonal antibodies are now used in most serological assays, as diagnostic probes, and as therapeutic agents. So far, efforts to use the same approach to make human monoclonal antibodies have met with limited success. 'Fully human' therapeutic monoclonal antibodies are currently made by using phage display technology (described in Section A-9), by using recombinant DNA technology to clone and express antibody genes from human plasma cells (see Section A-10), or by immunizing transgenic mice (see Section A-35) carrying human antibody genes.

A-9 Phage display libraries for antibody V-region production.

In a technique for producing antibody-like molecules, gene segments encoding the antigen-binding variable, or V, domains of antibodies are fused to genes encoding the coat protein of a bacteriophage. Bacteriophages containing such gene fusions are used to infect bacteria, and the resulting phage particles have coats that express the antibody-like fusion protein, with the antigen-binding domain displayed on the outside of the bacteriophages. A collection of recombinant phages, each displaying a different antigen-binding domain on the surface, is known as a **phage display library**. In much the same way that antibodies specific for a particular antigen can be isolated from a complex mixture by affinity chromatography (see Section A-3), phages expressing antigen-binding domains specific for a particular antigen can be isolated by selecting the phages in the library for binding to that antigen. The phage particles that bind are recovered and used to infect fresh bacteria. Each phage isolated in this way will produce a monoclonal antigen-binding particle analogous to a monoclonal antibody (Fig. A.11). The genes encoding the antigen-binding site, which are unique to each phage, can then be recovered from the phage DNA and used to construct genes for a complete antibody molecule by joining them to parts of immunoglobulin genes that encode the invariant parts of an antibody. When these reconstructed antibody genes are introduced into a suitable host-cell line, such as the non-antibody-producing myeloma cells used for hybridomas, the transfected cells can secrete antibodies with all the desirable characteristics of monoclonal antibodies produced from hybridomas.

Fig. A.11 The production of antibodies by genetic engineering. Short primers to consensus sequences in heavy- and light-chain variable (V) regions of immunoglobulin genes are used to generate a library of heavy- and light-chain V-region DNAs by the polymerase chain reaction (PCR), with spleen DNA as the starting material. These heavy- and light-chain V-region genes are cloned randomly into filamentous phages such that each phage expresses one heavy-chain and one light-chain V region as a surface fusion protein with antibody-like properties. The resulting phage display library is multiplied in bacteria, and the phages are then bound to a surface coated with antigen. The unbound phages are washed away; the bound phages are recovered, multiplied in bacteria, and again bound to antigen. After a few cycles, only specific high-affinity antigen-binding phages are left. These can be used like antibody molecules, or their V genes can be recovered and engineered into antibody genes to produce genetically engineered antibody molecules (not shown). This technology may replace the hybridoma technology for producing monoclonal antibodies and has the advantage that humans can be used as the source of DNA.

A-10 Generation of human monoclonal antibodies from vaccinated individuals.

In some cases, human monoclonal antibodies can be made by cloning the rearranged antibody heavy- and light-chain gene sequences from plasma cells isolated from vaccinated individuals. Based on the expression of cell-surface molecules such as CD27 and CD38, human plasma cells can be isolated from the peripheral blood of individuals who were immunized approximately 1 week earlier. Individual plasma cells are sorted into wells of microtiter plates, and the antibody heavy- and light-chain variable-region sequences are cloned from each cell by PCR. These sequences are then inserted into constructs that re-create the full-length antibody heavy- and light-chain genes, and the paired heavy- and light-chain vectors are introduced into an immortalized human cell line. Human cells are then screened to identify those secreting antibody proteins that bind to the immunizing antigen. These immortalized cells become a permanent source of the specific human antibody protein.

A-11 Microscopy and imaging using fluorescent dyes.

Because antibodies bind stably and specifically to their corresponding antigen, they are invaluable as probes for identifying a particular molecule in cells, tissues, or biological fluids. Antibody molecules can be used to locate their target molecules accurately in single cells or in tissue sections by a variety of different labeling techniques. When the antibody itself, or the anti-immunoglobulin antibody used to detect it, is labeled with a fluorescent dye (a fluorochrome or fluorophore) and then detected by microscopy, the technique is known as **immunofluorescence microscopy**. As in all serological techniques, the antibody binds stably to its antigen, allowing unbound antibody to be removed by thorough washing. Because antibodies against proteins recognize the surface features of the native, folded protein, the native structure of the protein being sought usually needs to be preserved, either by using only the most gentle chemical fixation techniques or by using frozen tissue sections that are fixed only after the antibody reaction has been performed. Some antibodies,

Excitation and emission wavelengths of some commonly used fluorochromes

Rhodamine	550	573

Fig. A.12 Excitation and emission wavelengths for common fluorochromes.

however, bind proteins even if they are denatured, and such antibodies will bind specifically even to protein in fixed tissue sections.

The fluorescent dye can be covalently attached directly to the specific antibody; however, the bound antibody is more commonly detected by fluorescently labeled anti-immunoglobulin, a technique known as **indirect immunofluorescence**. The dyes chosen for immunofluorescence are excited by light of one wavelength, usually blue or green, and emit light of a different wavelength in the visible spectrum. The most commonly used fluorochromes are fluorescein, which emits green light; Texas Red and peridinin chlorophyll protein (PerCP), which emit red light; and rhodamine and phycoerythrin (PE), which emit orange-red light (Fig. A.12). By using selective filters, only the light coming from the fluorochrome used is detected in the fluorescence microscope (Fig. A.13). Although Albert Coons devised this technique to identify the plasma cell as the source of antibody, it can be used to detect the distribution of any protein. By attaching different dyes to different antibodies, the distribution of two or more molecules can be determined in the same cell or tissue section (see Fig. A.13).

The development of the **confocal fluorescent microscope**, which uses computer-aided techniques to produce ultrathin optical sections of a cell or tissue, gives very high resolution (sub-micrometer) fluorescence microscopy without the need for elaborate sample preparation. The light source for excitation (a laser) is focused onto a particular plane in the specimen, and the emitted light is refocused through a 'pinhole' so that only light from the desired plane reaches the detector, thus removing out-of-focus emissions from above or below the plane. This gives a sharper image than conventional fluorescence microscopy, and a three-dimensional picture can be built up from successive optical sections taken along the 'vertical' axis. Confocal microscopy can be used on fixed cells stained with fluorescently tagged antibodies or on living cells expressing proteins tagged with naturally fluorescent proteins. The first of these fluorescent proteins to come into wide use was green fluorescent protein (GFP), isolated from the jellyfish *Aequorea victoria*. The list of fluorescent proteins in routine use now includes those emitting red, blue, cyan, or yellow fluorescence. By using cells transfected with genes encoding different fusion

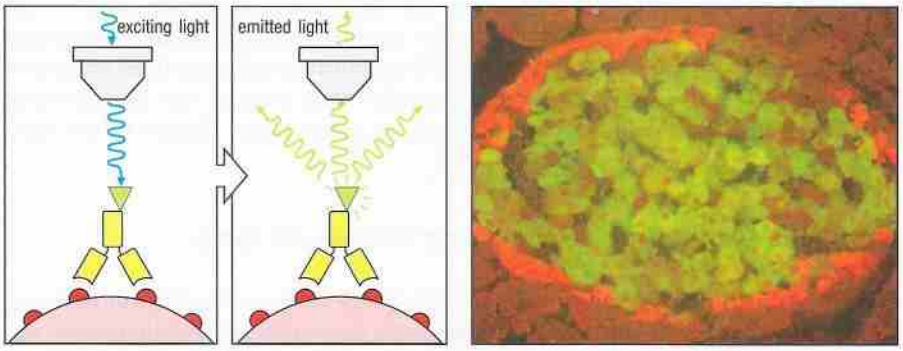

Fig. A.13 Immunofluorescence microscopy. Antibodies labeled with a fluorescent dye such as fluorescein (green triangle) are used to reveal the presence of their corresponding antigens in cells or tissues. The stained cells are examined using a microscope that exposes them to blue or green light to excite the fluorescent dye. The excited dye emits light at a characteristic wavelength, which is captured by viewing the sample through a selective filter. This technique is applied widely in biology to determine the location of molecules in cells and tissues. Different antigens can be detected in tissue sections by labeling antibodies with dyes of distinctive color. Here, antibodies against the protein glutamic acid decarboxylase (GAD) coupled to a green dye are shown to stain the β cells of pancreatic islets of Langerhans. The α cells do not make this enzyme and are labeled with antibodies against the hormone glucagon coupled with an orange fluorescent dye. GAD is an important antigen in type 1 diabetes mellitus, a disease in which the insulin-secreting β cells of the islets of Langerhans are destroyed by an immune attack on self tissues (see Chapter 15).

proteins, it has been possible to visualize the redistribution of T-cell receptors, co-receptors, adhesion molecules, and other signaling molecules, such as CD45, that takes place when a T cell makes contact with a target cell (see Fig. 9.40).

Confocal microscopy, however, can penetrate only around 80 μm into a tissue, and at the wavelengths typically used for excitation, the source light will soon bleach the fluorescent label and damage the specimen. This means the technique is not suitable for imaging a live specimen over a period of time sufficient, for example, to track the movements of cells in a tissue. The more recently developed technique of **two-photon scanning fluorescence microscopy** overcomes some of these limitations. In this technology, ultrashort pulses of laser light of much longer wavelength (and thus with photons of lower energy) are used for excitation, and two of these lower-energy photons arriving nearly simultaneously are required to excite the fluorophore. Excitation will therefore occur in only a very small region at the focus of the microscope, where the beam of light is most intense, and so fluorescence emission will be restricted to the plane of focus, producing a sharp, high-contrast image. The longer-wavelength light (typically in the near infrared) is also less damaging to living tissue than the blue and ultraviolet wavelengths typically used in confocal microscopy, and so imaging can be carried out over a longer period. More of the emitted light is collected than in confocal microscopy, and because single photons scattering within the tissue cannot cause fluorescence and consequent background haze, imaging to greater depths (several hundred micrometers) is possible. Like confocal microscopy, two-photon microscopy produces thin optical sections from which a three-dimensional image can be built up.

To track the movements of molecules or cells over time, confocal or two-photon microscopy is combined with **time-lapse video imaging** using sensitive digital cameras. In immunology, time-lapse two-photon fluorescence imaging has been particularly valuable for tracking the movements of individual T cells and B cells expressing fluorescent proteins in intact lymphoid organs and observing where they interact (see Chapter 10).

A-12 Immunoelectron microscopy.

Antibodies can be used to detect the intracellular location of structures or particular proteins at high resolution by electron microscopy, a technique known as immunoelectron microscopy. Antibodies against the required antigen are labeled with gold particles and then applied to ultrathin sections, which are then examined in the transmission electron microscope. Antibodies labeled with gold particles of different diameters enable two or more proteins to be studied simultaneously (see Fig. 6.12). The difficulty with this technique is in staining the ultrathin section adequately, because few molecules of antigen are present in each section.

A-13 Immunohistochemistry.

An alternative to immunofluorescence (see Section A-11) for detecting a protein in tissue sections is **immunohistochemistry**, in which the specific antibody is chemically coupled to an enzyme that converts a colorless substrate into a colored reaction product *in situ*. The localized deposition of the colored product where antibody has bound can be directly observed under a light microscope. The antibody binds stably to its antigen, allowing unbound antibody to be removed by thorough washing. This method of detecting bound antibody is analogous to ELISA (see Section A-4) and frequently uses the same coupled enzymes, the difference in detection being primarily that in immunohistochemistry the colored products are insoluble and precipitate at the site where they are formed. Horseradish peroxidase and alkaline phosphatase

are the two enzymes most commonly used in these applications. Horseradish peroxidase oxidizes the substrate diaminobenzidine to produce a brown precipitate, while alkaline phosphatase can produce red or blue dyes depending on the substrates used; a common substrate is 5-bromo-4-chloro-3-indolyl phosphate plus nitroblue tetrazolium (BCIP/NBT), which gives rise to a dark blue or purple stain. As with immunofluorescence, the native structure of the protein being sought usually needs to be preserved so that it will be recognized by the antibody. Tissues are fixed by the most gentle chemical fixation techniques or frozen tissue sections are used that are fixed only after the antibody reaction has been performed.

A-14 Immunoprecipitation and co-immunoprecipitation.

To raise antibodies against membrane proteins and other cellular structures that are difficult to purify, mice are often immunized with whole cells or crude cell extracts. Antibodies against the individual molecules are then obtained by using these immunized mice to produce hybridomas making monoclonal antibodies (see Section A-8) that bind to the cell type used for immunization. To characterize the molecules identified by the antibodies, cells of the same type are labeled with radioisotopes and dissolved in nonionic detergents that disrupt cell membranes but do not interfere with antigen–antibody interactions. This allows the labeled protein to be isolated by binding to the antibody in a reaction known as **immunoprecipitation**. The antibody is usually attached to a solid support, such as the beads that are used in affinity chromatography (see Section A-3), or to Protein A, a protein derived from the cell wall of *Staphylococcus aureus* that binds tightly to the Fc region of IgG antibodies. Cells can be labeled in two main ways for immunoprecipitation analysis. All the proteins in a cell can be labeled metabolically by growing the cell in a medium containing radioactive amino acids that are then incorporated into cellular proteins (Fig. A.14). Alternatively, one can label only the cell-surface

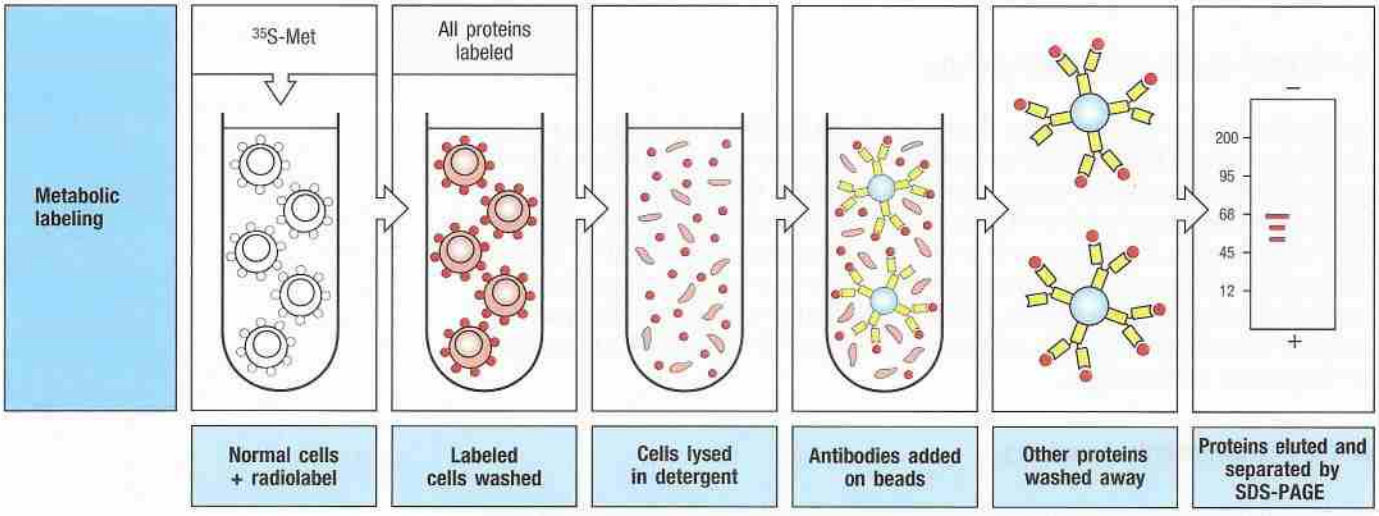

Fig. A.14 Cellular proteins reacting with an antibody can be characterized by immunoprecipitation of labeled cell lysates. All actively synthesized cellular proteins can be labeled metabolically by incubating cells with radioactive amino acids (shown here for methionine; ^{35}S-Met), or one can label just the cell-surface proteins by using radioactive iodine in a form that cannot cross the cell membrane or by a reaction with the small molecule biotin, detected by its reaction with labeled avidin (not shown). Cells are lysed with detergent, and individual, labeled, cell-associated proteins can be precipitated with a monoclonal antibody attached to beads. After unbound proteins have been washed away, the bound protein is eluted in the detergent sodium dodecyl sulfate (SDS), which dissociates it from the antibody and also coats the protein with a strong negative charge, allowing it to migrate according to its size in polyacrylamide gel electrophoresis (PAGE). The positions of the labeled proteins are determined by autoradiography using X-ray film. This technique of SDS-PAGE can be used to determine the molecular mass and subunit composition of a protein. Patterns of protein bands observed with metabolic labeling are usually more complex than those revealed by radioiodination, owing to the presence of precursor forms of the protein (right panel). The mature form of a surface protein can be identified as being the same size as that detected by surface iodination or biotinylation (not shown).

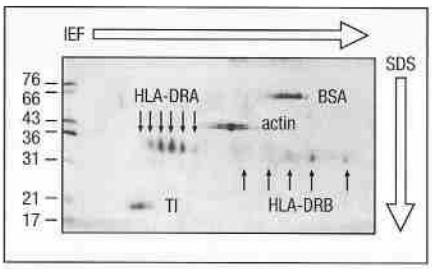

Fig. A.15 Two-dimensional gel electrophoresis of MHC class II molecules. Proteins in a human B-cell line expressing HLA-DR2 have been labeled metabolically (see Fig. A.14), precipitated with a monoclonal antibody against the human MHC class II molecule HLA-DR, and separated by isoelectric focusing (IEF) in one direction and SDS-PAGE in a second direction at right angles to the first (hence the term two-dimensional gel electrophoresis). This allows one to distinguish molecules of the same molecular mass on the basis of their charge. The separated proteins are detected by autoradiography. The MHC class II molecule is composed of two chains, α and β, labeled as HLA-DRA and HLA-DRB, respectively. Each chain is present in multiple isoforms that resolve into distinct spots upon isoelectric focusing. Three standard markers are included in the sample: 1, soybean trypsin inhibitor (TI); 2, actin; and 3, bovine serum albumin (BSA).

proteins by radioiodination under conditions that prevent iodine from crossing the plasma membrane and labeling proteins inside the cell or by a reaction that labels only cell-surface proteins with biotin, a small molecule that is detected readily by labeled avidin, a protein found in egg whites that binds biotin with very high affinity.

Once the labeled proteins have been isolated by the antibody, they can be characterized in several ways. The most common is polyacrylamide gel electrophoresis (PAGE) of the proteins after they have been dissociated from antibody in the strong ionic detergent sodium dodecyl sulfate (SDS), a technique generally abbreviated as **SDS-PAGE**. SDS binds relatively homogeneously to proteins, conferring a charge that allows the electrophoretic field to drive protein migration through the gel. The rate of migration is controlled mainly by protein size (see Fig. A.14). Proteins of differing charges can be separated using isoelectric focusing (see Section A-8). This technique can be combined with SDS-PAGE in a procedure known as **two-dimensional gel electrophoresis**, in which the immunoprecipitated protein is eluted in urea, a nonionic solubilizing agent, and run on an isoelectric focusing gel in a narrow tube of polyacrylamide. This first-dimensional isoelectric focusing gel is then placed across the top of an SDS-PAGE slab gel, which is then run vertically to separate the proteins by molecular weight (Fig. A.15). Two-dimensional gel electrophoresis is a powerful technique that allows many hundreds of proteins in a complex mixture to be distinguished from one another.

Immunoprecipitation and the related technique of immunoblotting (see Section A-15) are useful for determining the molecular mass and isoelectric point of a protein as well as its abundance, distribution, and whether, for example, it undergoes changes in molecular mass and isoelectric point as a result of processing within the cell.

Co-immunoprecipitation is an extension of the immunoprecipitation technique and is used to determine whether a given protein interacts physically with another given protein. Cell extracts containing the presumed interaction complex are first immunoprecipitated with antibody against one of the proteins. The material isolated by this means is then tested for the presence of the other protein by immunoblotting (see Section A-15) with a specific antibody against the second protein.

A-15 Immunoblotting (western blotting).

Like immunoprecipitation (see Section A-14), **immunoblotting** is used for identifying the presence of a given protein in a cell lysate, but it avoids the problem of having to label large quantities of cells with radioisotopes. Unlabeled cells are placed in detergent to solubilize all cell proteins, and the lysate is run on SDS-PAGE to separate the proteins (see Section A-14). The size-separated proteins are then transferred from the gel to a stable support such as a nitrocellulose membrane. Specific proteins are detected by treatment with antibodies able to react with SDS-solubilized proteins (mainly those that react with denatured sequences); the bound antibodies are revealed by anti-immunoglobulin

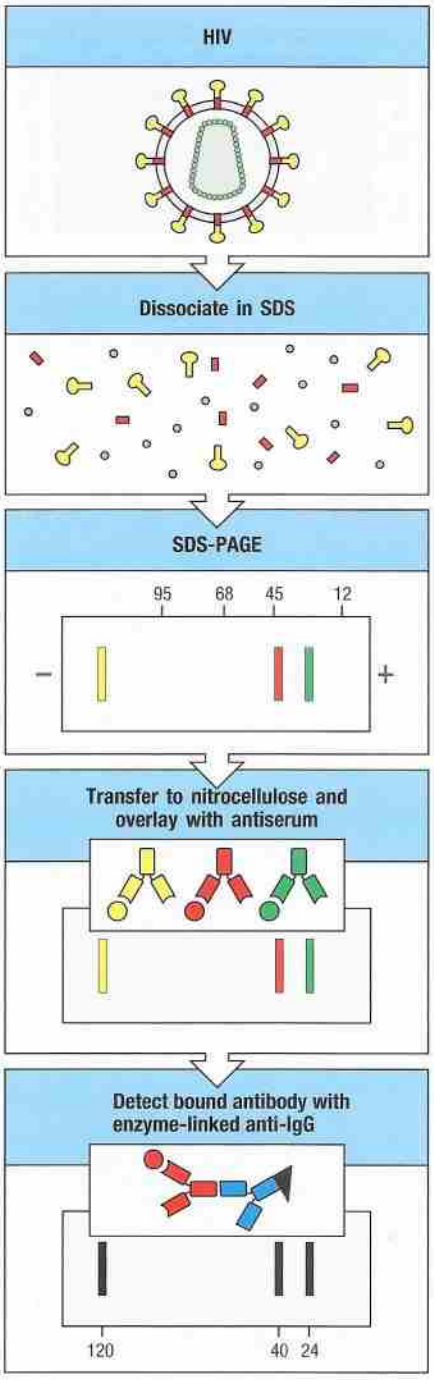

Fig. A.16 Western blotting is used to identify antibodies against the human immunodeficiency virus (HIV) in serum from infected individuals. The virus is dissociated into its constituent proteins by treatment with the detergent SDS, and its proteins are separated using SDS-PAGE. The separated proteins are transferred to a nitrocellulose sheet and reacted with the test serum. Anti-HIV antibodies in the serum bind to the various HIV proteins and are detected with enzyme-linked anti-human immunoglobulin, which deposits colored material from a colorless substrate. This general methodology will detect any combination of antibody and antigen and is used widely, although the denaturing effect of SDS means that the technique works most reliably with antibodies that recognize the antigen when it is denatured.

antibodies labeled with an enzyme. The term **western blotting** as a synonym for immunoblotting arose because the comparable technique for detecting specific DNA sequences is known as Southern blotting, after Edwin Southern, who devised it, which in turn provoked the name 'northern' for blots of size-separated RNA, and 'western' for blots of size-separated proteins. Western blots have many applications in basic research and clinical diagnosis. They are often used to test sera for the presence of antibodies against specific proteins; for example, to detect antibodies against different constituents of HIV (Fig. A.16).

A-16 Use of antibodies in the isolation and characterization of multiprotein complexes by mass spectrometry.

Many of the proteins that function in immune cells are components of multiprotein complexes. This is the case for cell-surface receptors, such as the T-cell and B-cell antigen receptors and most cytokine receptors, as well as intracellular proteins involved in signal transduction, gene expression, and cell death. Antibodies that bind to one member of such a complex can be used to identify the other members of the complex by a process of co-immunoprecipitation followed by Western blotting or **mass spectrometry**.

This technology can be used to identify protein complexes from primary immune cells that have been genetically engineered to express a small 8-amino-acid tag sequence, called Strep-tag, on the terminus of a single protein. This small peptide tag binds with extremely high affinity and specificity to a modified form of the streptavidin molecule often used to isolate biotinylated proteins. This modified streptavidin, called Strep-tactin, is tethered to an affinity resin. When cell lysates are passed over this resin, the tagged protein along with its binding partners are retained and can be eluted to process for mass spectrometry.

A mass spectrometer can provide extremely precise measurements of the masses of constituents in a preparation of molecules. To identify unknown proteins in a sample, such as that acquired by co-immunoprecipitation, the sample often is first subjected to one-dimensional SDS-PAGE or two-dimensional gel electrophoresis (see Section A-14) to separate the proteins in the complex for individual analysis. Gel slices are excised and treated with a proteolytic enzyme, such as trypsin, to digest the protein into a series of peptides that can be easily eluted from the gel. The peptide mixture is then introduced into the mass spectrometer, which ionizes the peptides, transfers them to the gas phase, and then separates them under high vacuum by subjecting them to a magnetic field. The separation is based on the mass-to-charge (m/z) ratio of each ion, and a detector collects information on the signal intensity for each ion and displays the data as a histogram (Fig. A.17). This histogram, usually referred to as a spectrum, can be compared with a database containing potential cleavage sites (for the proteolytic enzyme used) in all known protein sequences. Because of the precision of these measurements, and the information derived from multiple peptides composing the initial protein, the spectrum can often be unambiguously assigned to a unique protein in the database.

Fig. A.17 Characterization of multiprotein complexes by mass spectrometry. After immunoprecipitation of a multiprotein complex using antibodies specific for one component of the complex, the individual proteins are separated by gel electrophoresis. An individual band representing one protein is isolated and digested with a protease such as trypsin. The digested protein sample is injected into the mass spectrometer, which ionizes the peptides, transfers them to the gas phase, and then separates them on the basis of differences in their mass-to-charge (*m/z*) ratio by subjecting them under high vacuum to a magnetic field. A detector collects information on the signal intensity for each peptide ion and displays the information as a histogram. This histogram, usually referred to as a spectrum, is compared with a database containing potential cleavage sites for the proteolytic enzyme used in all known protein sequences, allowing for identification of the protein in the sample.

Modern multidimensional mass spectrometers allow peptide ions to be sequenced as well as analyzed by their mass. In these instruments, peptide ions separated in one sector are fragmented in a second sector by collision with other molecules (often an inert gas such as N_2), with the resultant fragments separated in a third section (Fig. A.18). Fragmentation occurs primarily in the peptide backbone, allowing the sequence of the peptide to be read directly from the mass spectrum of the mixture of fragments. In place of gel electrophoresis, a liquid chromatograph can be employed upstream of the mass analyzers (LC-MS/MS) to provide additional separation of peptides prior to mass separation and allow a very complex mixture of thousands of peptides to be

Fig. A.18 Determining the amino acid sequence of a peptide by multidimensional mass spectrometry (MS/MS). Multidimensional mass spectrometers consist of two mass spectrometers linked in tandem but with an interceding middle sector that fragments ions. In the first sector, the first mass spectrometer separates peptide ions, as shown in Fig. A.17. Each peptide ion from this first separation is then fragmented in the middle sector of the apparatus by collision with other molecules (often an inert gas such as N_2). Because fragmentation occurs primarily in the peptide backbone, a mixture of fragments is generated in which the fragments each differ by one amino acid residue. The resultant fragments are then separated in the second mass spectrometer, the final sector. The sequence of the peptide can be read directly from the second mass spectrum. The order of amino acid residues in the peptide can be deduced because of the exquisite precision of the measurements of each ion together with knowledge of the exact mass of each possible amino acid residue.

sequenced in a single run. It was this latter technique that played an essential role in the early studies that identified the repertoire of peptides bound to MHC molecules on the surface of antigen-presenting cells (see Chapter 6).

A-17 Isolation of peripheral blood lymphocytes by density-gradient fractionation.

The first step in studying lymphocytes is to isolate them so that their behavior can be analyzed *in vitro*. Human lymphocytes can be isolated most readily from peripheral blood by density centrifugation over a step gradient consisting of a mixture of the carbohydrate polymer Ficoll-Hypaque and the dense iodine-containing compound metrizamide. A step gradient is made by preparing a solution of Ficoll-Hypaque at a precise density (1.077 g/liter for human cells) and placing a layer of this solution at the bottom of a centrifuge tube. A sample of heparinized blood mixed with saline (heparin prevents clotting) is carefully layered on top of the Ficoll-Hypaque solution. After centrifugation for about 30 minutes, the components of the blood have separated on the basis of their densities. The upper layer contains the blood plasma and platelets, which remain in the top layer during the short centrifugation. Red blood cells and granulocytes have a higher density than the Ficoll-Hypaque solution and collect at the bottom of the tube. The population called **peripheral blood mononuclear cells (PBMCs)** collects at the interface between the blood and the Ficoll-Hypaque layers and consists mainly of lymphocytes and monocytes (Fig. A.19). Although this population is readily accessible, it is not necessarily representative of the lymphoid system, because only recirculating lymphocytes can be isolated from blood.

The 'normal' ranges in the numbers of the different types of white blood cells in blood and the normal ranges in concentrations of the various antibody classes are given in Fig. A.20.

A-18 Isolation of lymphocytes from tissues other than blood.

In experimental animals, and occasionally in humans, lymphocytes are isolated from lymphoid organs, such as spleen, thymus, bone marrow, lymph nodes, or mucosa-associated lymphoid tissue—in humans, most commonly the palatine tonsils (see Fig. 12.6). A specialized population of lymphocytes resides in surface epithelia; these cells are isolated by fractionating the epithelial layer after its detachment from the basement membrane. Finally, in situations where local immune responses are prominent, lymphocytes can be isolated from the site of the response itself. For example, in order to study the autoimmune reaction that is thought to be responsible for rheumatoid arthritis, an inflammatory response in joints, lymphocytes are isolated from the fluid aspirated from the inflamed joint space.

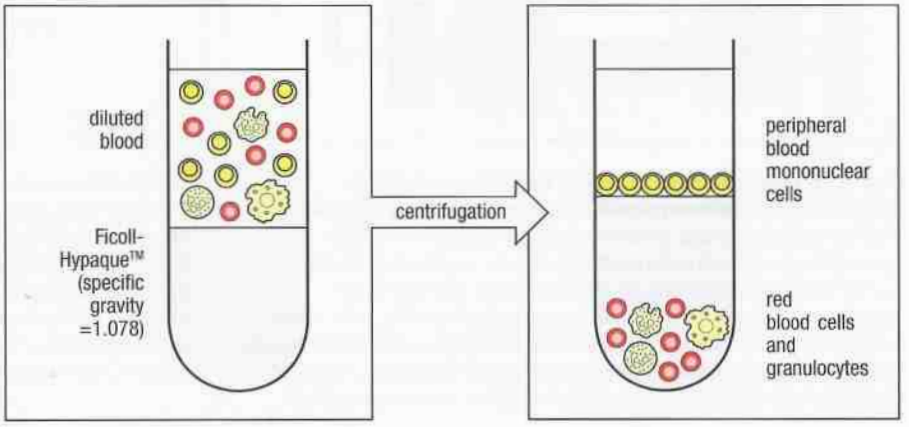

Fig. A.19 Peripheral blood mononuclear cells can be isolated from whole blood by Ficoll-Hypaque centrifugation. Diluted anticoagulated blood (left panel) is layered over Ficoll-Hypaque and centrifuged. Red blood cells and polymorphonuclear leukocytes or granulocytes are denser and travel through the Ficoll-Hypaque, while mononuclear cells consisting of lymphocytes together with some monocytes band over it and can be recovered at the interface of the two layers (right panel).

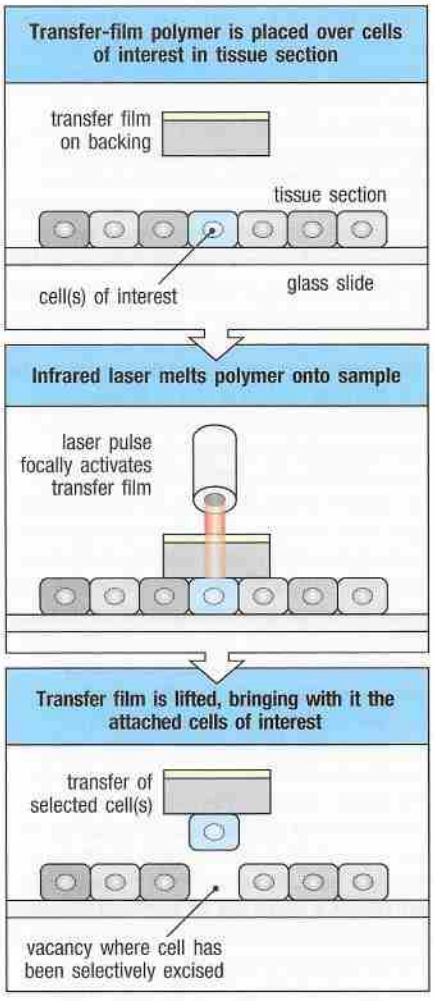
Laser-capture microdissection is a technique used to isolate specific populations of cells from an intact tissue sample or histologic specimen after visualizing the cells by light microscopy. The cells of interest can be 'captured' by placing a polymer over the sample on the microscope slide and using an infrared laser to melt the polymer onto the sample in discrete locations. Once completed, the polymer–cell composite can be lifted, and DNA, RNA, or proteins can be isolated from the dissected cells (Fig. A.21). A variant of this approach makes use of an ultraviolet (UV) laser, rather than infrared. In this case, the UV laser acts as a molecular cutting tool and can be used to cut away or even ablate the unwanted portions of the tissue, leaving intact the area of interest.



Transfer-film polymer is placed over cells of interest in tissue section

Fig. A.21 Laser-capture microdissection. Specific populations of cells from an intact tissue sample or histologic specimen can be isolated after visualizing the cells by light microscopy. A polymer called the transfer film is placed over the sample on the microscope slide, and an infrared laser is used to melt the polymer onto the sample in discrete locations. The polymer–cell composite is then lifted, and the cells of interest are isolated. DNA, RNA, or proteins can be prepared from the dissected cells.

A-19 Flow cytometry and FACS analysis.

An immensely powerful tool for defining and enumerating populations of immune cells is the flow cytometer, which detects and counts individual cells passing in a stream through a laser beam. A flow cytometer equipped to separate the identified cells is called a **fluorescence-activated cell sorter (FACS)**. These instruments are used to study the properties of cell subsets that are identified by using monoclonal antibodies against cell-surface or intracellular proteins. Individual cells within a mixed population are first labeled by treatment with specific monoclonal antibodies coupled to fluorescent dyes or by specific antibodies followed by fluorescently tagged anti-immunoglobulin antibodies. The mixture of labeled cells is then suspended in a much larger volume of saline and forced through a small nozzle, creating a fine stream of liquid composed of droplets, each containing a single cell. As each cell passes through a laser beam it scatters the laser light, and any dye molecules bound to the cell are excited and fluoresce. Sensitive photomultiplier tubes detect both the scattered light, which gives information about the size and granularity of the cell, and the fluorescence emissions, which give information about the binding of the labeled monoclonal antibodies and hence about the expression of cell-surface or intracellular proteins by each cell (Fig. A.22).

In the cell sorter, the signals passed back to the computer are used to generate an electric charge, which is passed from the nozzle through the liquid stream

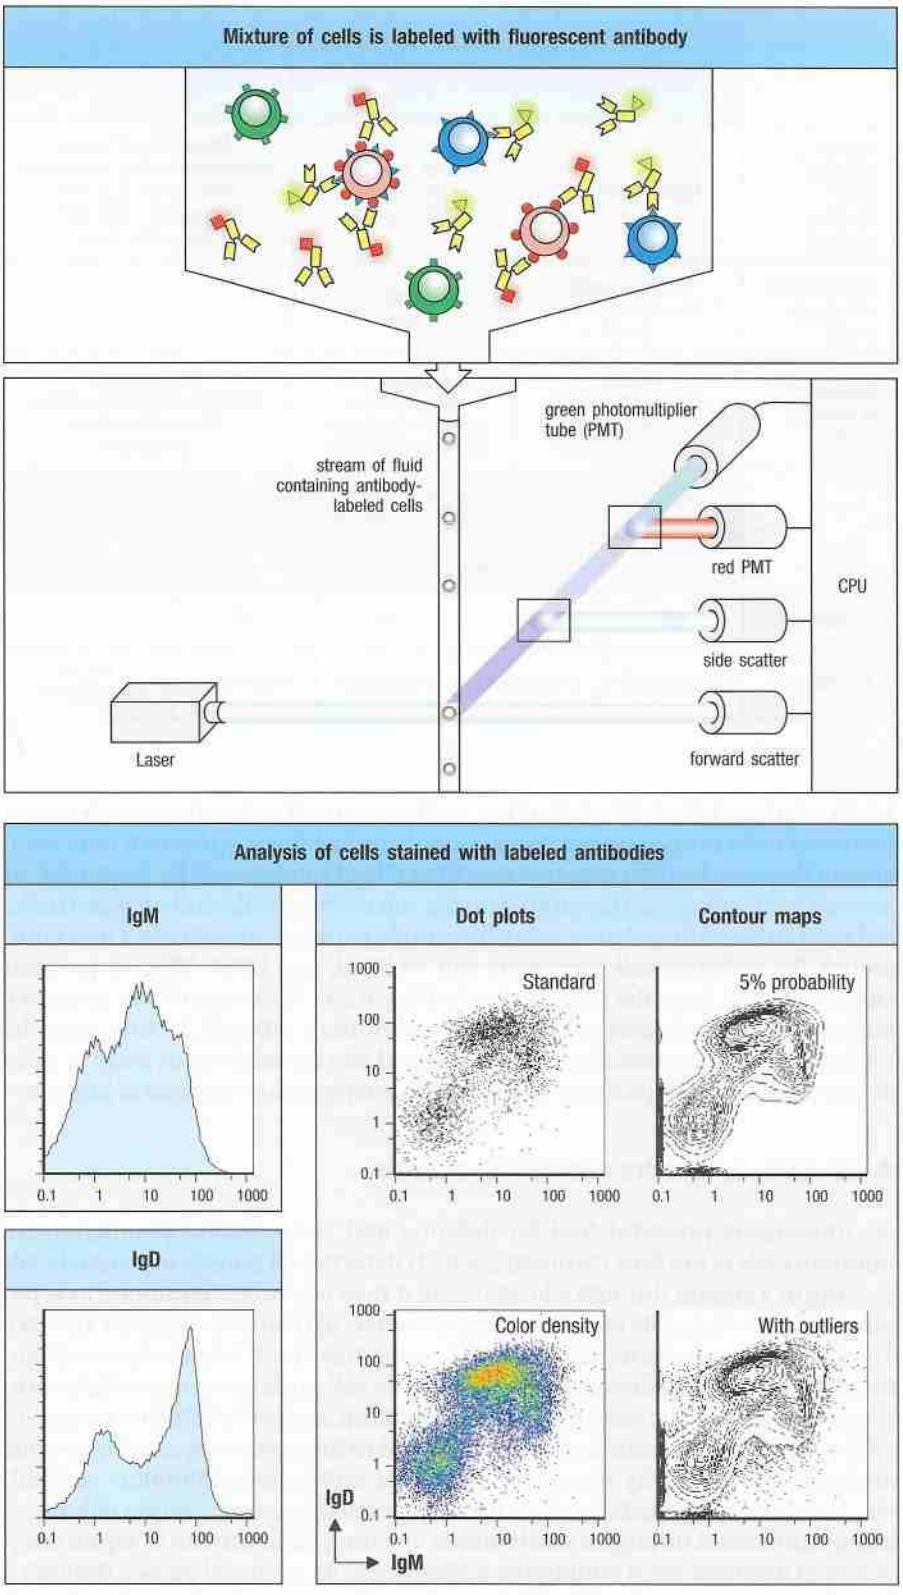

Fig. A.22 Flow cytometers allow individual cells to be identified by their cell-surface antigens and to be sorted. Cells to be analyzed by flow cytometry are first labeled with fluorescent dyes (top panel). Direct labeling uses dye-coupled antibodies specific for cell-surface antigens (as shown here), while indirect labeling uses a dye-coupled immunoglobulin to detect unlabeled cell-bound antibody. The cells are forced through a nozzle in a single-cell stream that passes through a laser beam (second panel). Photomultiplier tubes (PMTs) detect the scattering of light, which is a sign of cell size and granularity, as well as emissions from the different fluorescent dyes. This information is analyzed by computer (CPU). By examining a large number of cells, the proportion of cells with a specific set of characteristics can be determined, and levels of expression of various molecules on these cells can be measured. The lower part of the figure shows how these data can be represented, the example in this case being the expression of two surface immunoglobulins, IgM and IgD, on a sample of B cells from a mouse spleen. The two immunoglobulins have been labeled with different-colored dyes. When the expression of just one type of molecule is to be analyzed (IgM or IgD), the data are usually displayed as a histogram, as in the left-hand panels. Histograms display the distribution of cells expressing a single measured parameter (for example, size, granularity, fluorescence intensity). When two or more parameters are measured for each cell (IgM and IgD), various types of two-dimensional plots can be used to display the data, as shown in the right-hand panel. All four plots represent the same data, and in each case, the horizontal axis represents intensity of IgM fluorescence, and the vertical axis represents the intensity of IgD fluorescence. Two-color plots provide more information than histograms; they allow recognition, for example, of cells that are 'bright' for both colors, 'dull' for one and bright for the other, dull for both, negative for both, and so on. For example, the cluster of dots in the extreme lower left portions of the plots represents cells that do not express either immunoglobulin and are mostly T cells. The standard dot plot (upper left) places a single dot for each cell whose fluorescence is measured. This format works well for identifying cells that lie outside the main groups but tends to saturate in areas containing a large number of cells of the same type. A second means of presenting these data is the color dot plot (lower left), which uses color density to indicate high-density areas. A contour plot (upper right) draws 5% 'probability' contours, with contour lines drawn to indicate each successive 5% of the population; this format provides the best monochrome visualization of regions of high and low density. The lower right plot is a 5% probability contour map, which also shows outlying cells as dots.

at the precise time that the stream breaks up into droplets, each containing no more than a single cell; droplets containing a charge can then be deflected from the main stream of droplets as they pass between plates of opposite charge, so that positively charged droplets are attracted to a negatively charged plate, and vice versa. Once deflected, droplets containing cells are collected in tubes. In this way, specific subpopulations of cells, distinguished by the binding of the labeled antibody, can be purified from a mixed population of cells.

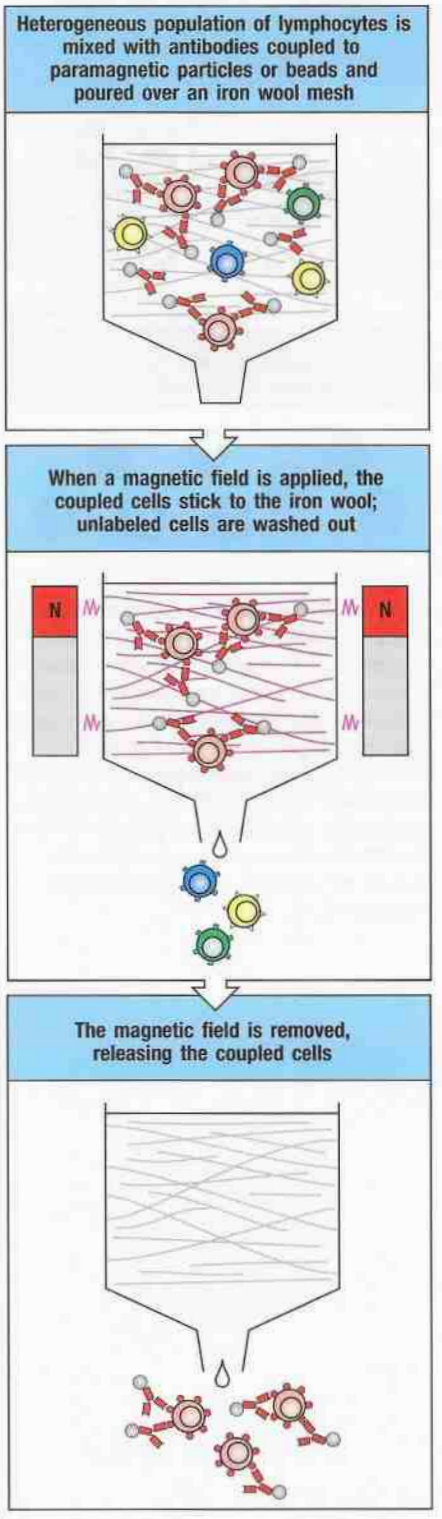
Alternatively, to deplete a population of cells, the same fluorochrome can be used to label different antibodies directed at marker proteins expressed by the various undesired cell types. The cell sorter can be used to direct labeled cells to a waste channel, retaining only the unlabeled cells.

When cells are labeled with a single fluorescent antibody, the data from a flow cytometer are usually displayed in the form of a one-dimensional histogram of fluorescence intensity versus cell numbers. If two or more antibodies are used, each coupled to a different fluorescent dye, then the data are usually displayed in the form of a two-dimensional scatter diagram or as a contour diagram, where the fluorescence of one dye-labeled antibody is plotted against that of a second, with the result that a population of cells labeled with one antibody can be further subdivided by its labeling with the second antibody (see Fig. A.22). By examining large numbers of cells, flow cytometry can give quantitative data on the percentage of cells bearing different proteins, such as surface immunoglobulin, which characterizes B cells; the T-cell receptor–associated molecules known as CD3; and the CD4 and CD8 co-receptor proteins that distinguish the major T-cell subsets. Likewise, FACS analysis has been instrumental in defining stages in the early development of B and T cells. This technology also played a vital role in the early identification of AIDS as a disease in which T cells bearing CD4 are depleted selectively (see Chapter 13). Advances in FACS technology permit progressively more antibodies labeled with distinct fluorescent dyes to be used at the same time. For experiments aimed at cell analysis, rather than cell sorting, machines with four lasers that can simultaneously measure 18 different fluorescent dyes are currently available. However, FACS analysis is constrained by the spectral properties of the fluorescent dyes used for coupling to antibodies, and this technology may have reached its limit.

An alternative to FACS is a technology based on detecting heavy-metal atoms that are coupled to antibodies. Cell populations labeled with heavy metal–coupled antibodies are analyzed on a machine called a CyTOF, which combines liquid fluidics with a mass spectrometer. As each cell is analyzed, the quantity of each heavy metal associated with that cell, and thus the abundance of the target of each antibody, is measured. In total, this technology is estimated to have the capability to measure 100 distinct heavy metals, greatly expanding the range of analysis that is currently possible by FACS. However, with this technique, the cells are destroyed by the ionization process required for the mass spectrometry analysis, so the CyTOF cannot function as a cell sorter.

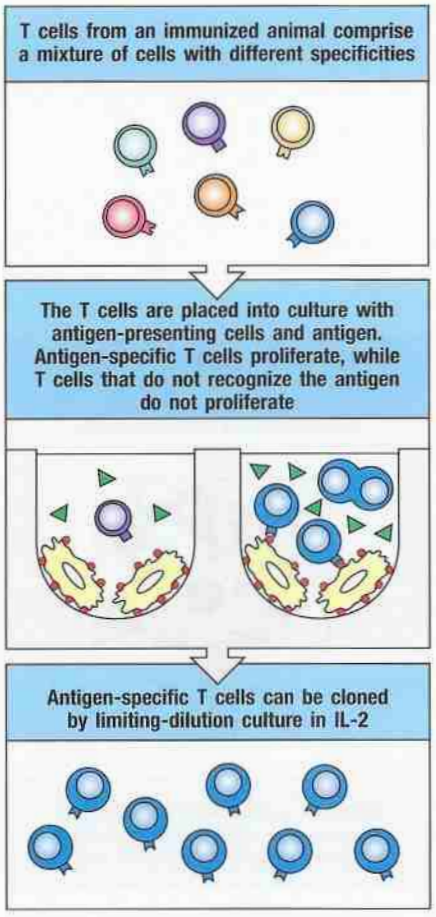
A-20 Lymphocyte isolation using antibody-coated magnetic beads.

Although FACS is superb for isolating small numbers of cells in pure form, mechanical means of separating cells are preferable when large numbers of lymphocytes must be prepared quickly. A powerful and efficient way of isolating lymphocyte populations is to couple paramagnetic beads to monoclonal antibodies that recognize distinguishing cell-surface molecules. These antibody-coated beads are mixed with the cells to be separated and are run through a column containing material that attracts the paramagnetic beads when the column is placed in a strong magnetic field. Cells binding the magnetically labeled antibodies are retained; cells lacking the appropriate surface molecule can be washed away (Fig. A.23). The retained cells are recovered by



Heterogeneous population of lymphocytes is mixed with antibodies coupled to paramagnetic particles or beads and poured over an iron wool mesh
When a magnetic field is applied, the coupled cells stick to the iron wool; unlabeled cells are washed out
N
N
The magnetic field is removed, releasing the coupled cells

Fig. A.23 Lymphocyte subpopulations can be separated physically by using antibodies coupled to paramagnetic particles or beads. A mouse monoclonal antibody specific for a particular cell-surface molecule is coupled to paramagnetic particles or beads. It is mixed with a heterogeneous population of lymphocytes and poured over an iron wool mesh in a column. A magnetic field is applied so that the antibody-bound cells stick to the iron wool while cells that have not bound antibody are washed out; these cells are said to be negatively selected for lack of the molecule in question. The bound cells are released by removing the magnetic field; they are said to be positively selected for presence of the antigen recognized by the antibody.



T cells from an immunized animal comprise a mixture of cells with different specificities
The T cells are placed into culture with antigen-presenting cells and antigen. Antigen-specific T cells proliferate, while T cells that do not recognize the antigen do not proliferate
Antigen-specific T cells can be cloned by limiting-dilution culture in IL-2

Fig. A.24 Production of cloned T-cell lines. T cells from an immunized donor, comprising a mixture of cells with different specificities, are activated with antigen and antigen-presenting cells. Single responding cells are cultured in the T-cell growth factor IL-2, which selectively stimulates the responding cells to proliferate. From these single cells, cloned lines specific for antigen are identified and can be propagated by culture with antigen, antigen-presenting cells, and IL-2.

removing the column from the magnetic field. In this case, the bound cells are positively selected for expression of the particular cell-surface molecule, while the unbound cells are negatively selected for its absence.

A-21 Isolation of homogeneous T-cell lines.

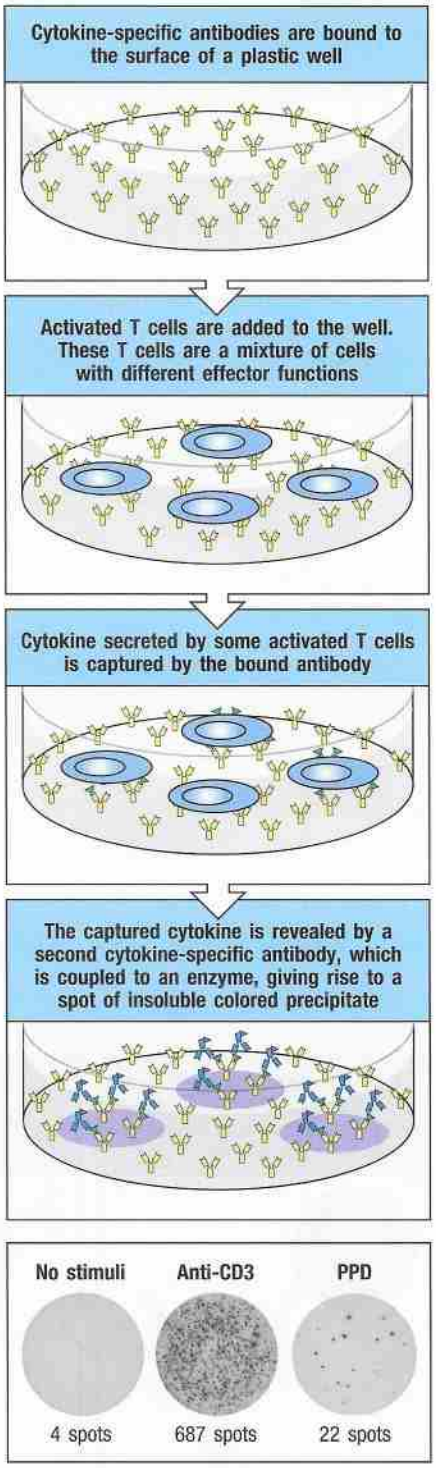
The analysis of specificity and effector function of T cells depends heavily on the study of monoclonal populations of T lymphocytes. These can be obtained in four distinct ways—T-cell hybrids, cloned T-cell lines, T-cell tumors, and limiting-dilution culture. By analogy with B-cell hybridomas (see Section A-8), normal T cells proliferating in response to specific antigen can be fused to malignant T-cell lymphoma lines to generate **T-cell hybrids**. The hybrids express the receptor of the normal T cell but proliferate indefinitely owing to the cancerous state of the lymphoma parent. T-cell hybrids can be cloned to yield a population of cells all having the same T-cell receptor. When stimulated by their specific antigen, these cells release cytokines such as the T-cell growth factor interleukin-2 (IL-2), and the production of cytokines is used as an assay to assess the antigen specificity of the T-cell hybrid.

T-cell hybrids are excellent tools for the analysis of T-cell specificity because they grow readily in suspension culture. However, they cannot be used to analyze the regulation of specific T-cell proliferation in response to antigen because they are continually dividing. T-cell hybrids also cannot be transferred into an animal to test for function *in vivo* because they would give rise to tumors. Functional analysis of T-cell hybrids is also confounded by the fact that the malignant partner cell affects their behavior in functional assays. Therefore, the regulation of T-cell growth and the effector functions of T cells must be studied using **T-cell clones**. These are clonal cell lines of a single T-cell type and antigen specificity, which are derived from cultures of heterogeneous T cells, called **T-cell lines**, whose growth is dependent on periodic restimulation with specific antigen and, frequently, on the addition of T-cell growth factors (Fig. A.24). T-cell clones also require periodic restimulation with antigen and are more tedious to grow than T-cell hybrids, but because their growth depends on specific antigen recognition, they maintain antigen specificity, which is often lost in T-cell hybrids. Cloned T-cell lines can be used for studies of effector function both *in vitro* and *in vivo*. In addition, the proliferation of T cells, a critical aspect of clonal selection, can be characterized only in cloned T-cell lines, where such growth is dependent on antigen recognition. Thus, both types of monoclonal T-cell lines, T-cell hybrids and antigen-dependent T-cell clones, have valuable applications in experimental studies.

Studies of human T cells have relied largely on T-cell clones because a suitable fusion partner for making T-cell hybrids has not been identified. However, a human T-cell lymphoma line, called Jurkat, has been characterized extensively because it secretes IL-2 when its antigen receptor is cross-linked with anti-receptor monoclonal antibodies. This simple assay system has yielded much information about signal transduction in T cells. One of the Jurkat cell line's most interesting features, shared with T-cell hybrids, is that it stops growing when its antigen receptor is cross-linked. This has allowed mutants lacking the receptor or having defects in signal transduction pathways to be selected simply by culturing the cells with anti-receptor antibody and selecting those that continue to grow. Thus, T-cell tumors, T-cell hybrids, and cloned T-cell lines all have valuable applications in experimental immunology.

A-22 ELISPOT assay.

A modification of the ELISA antigen-capture assay (see Section A-4), called the **ELISPOT assay**, is a powerful tool for measuring the frequency of T-cell responses and also provides information about the cytokines produced.



Cytokine-specific antibodies are bound to the surface of a plastic well
Activated T cells are added to the well. These T cells are a mixture of cells with different effector functions
Cytokine secreted by some activated T cells is captured by the bound antibody
The captured cytokine is revealed by a second cytokine-specific antibody, which is coupled to an enzyme, giving rise to a spot of insoluble colored precipitate
No stimuli
Anti-CD3
PPD
4 spots
687 spots
22 spots

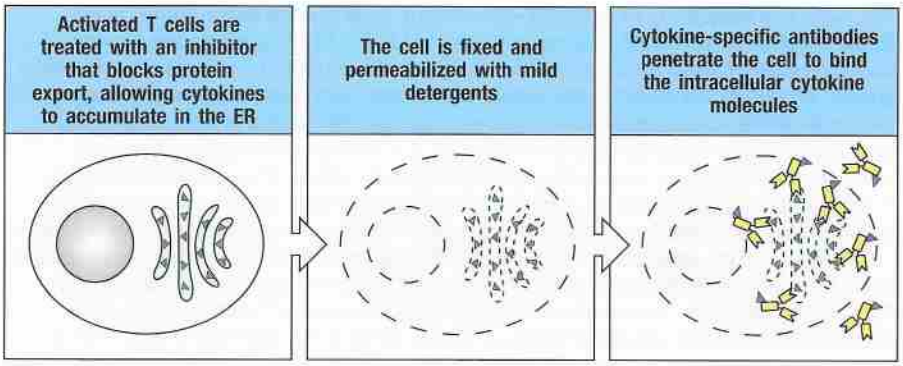
Fig. A.25 The frequency of cytokine-secreting T cells can be determined by the ELISPOT assay. The ELISPOT assay is a variant of ELISA in which antibodies bound to a plastic surface are used to capture cytokines secreted by individual T cells. Usually, cytokine-specific antibodies are bound to the surface of a plastic tissue-culture well, and the unbound antibodies are removed (top panel). Activated T cells are then added to the well and settle onto the antibody-coated surface (second panel). If a T cell is secreting the appropriate cytokine, this will then be captured by the antibody molecules on the plate surrounding the T cell (third panel). After a period of time the T cells are removed, and the presence of the specific cytokine is detected using an enzyme-labeled second antibody specific for the same cytokine. Where this antibody binds, a colored reaction product can be formed (fourth panel). Each T cell that originally secreted the cytokine gives rise to a single spot of color, hence the name of the assay. The results of such an ELISPOT assay for T cells secreting IFN-γ in response to different stimuli are shown in the last panel. In this example, T cells from an individual exposed to *Mycobacterium tuberculosis* were left unstimulated (left), stimulated with anti-CD3 antibody as a positive control (middle), or stimulated with purified protein derivative (PPD) isolated from *Mycobacterium tuberculosis* bacteria. As can be seen, there are more spots in the PPD-stimulated condition than in the unstimulated condition, a clear indication that the individual's T cells were previously exposed to *Mycobacterium tuberculosis* antigens.

Populations of T cells are stimulated with the antigen of interest and are then allowed to settle onto a plastic plate coated with antibodies against the cytokine that is to be assayed (Fig. A.25). If an activated T cell is secreting that cytokine, the cytokine is captured by the antibody on the plastic plate. After a period of time the cells are removed, and a second antibody against the cytokine is added to the plate to reveal a circle ('spot') of bound cytokine surrounding the position of each activated T cell; it is these circles that give the ELISPOT assay its name. By counting each spot and knowing the number of T cells originally added to the plate, one can easily calculate the frequency of T cells secreting that particular cytokine. ELISPOT can also be used to detect specific antibody secretion by B cells, in this case by using antigen-coated surfaces to trap specific antibody and labeled anti-immunoglobulin to detect the bound antibody.

A-23 Identification of functional subsets of T cells based on cytokine production or transcription factor expression.

One problem with the detection of cytokine production on a single-cell level is that the cytokines are secreted by the T cells into the surrounding medium, and any association with the originating cell is lost. Three methods have been devised that allow the cytokine profile produced by individual cells to be determined. The first, that of **intracellular cytokine staining** (Fig. A.26), relies on the use of metabolic poisons that inhibit protein export from the cell. The cytokine thus accumulates within the endoplasmic reticulum and vesicular network of the cell. If the cells are subsequently fixed and rendered permeable by the use of mild detergents, antibodies can gain access to these intracellular compartments and detect the cytokine. The T cells can be stained for other markers simultaneously, and thus the frequency of IL-10–producing $CD25^+$ CD4 T cells, for example, can be easily obtained.

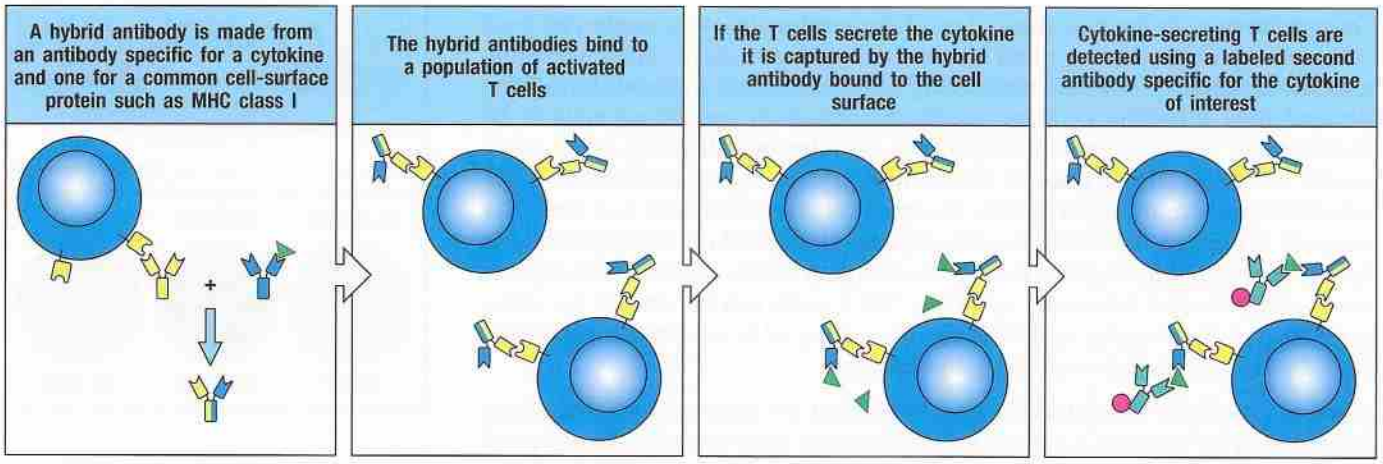
A second method, which has the advantage that the cells being analyzed are not killed in the process, is called cytokine capture. This technique uses hybrid antibodies, in which the two separate heavy- and light-chain pairs from different antibodies are combined to give a mixed antibody molecule in which the two antigen-binding sites recognize different ligands (Fig. A.27). In the bispecific antibodies used to detect cytokine production, one of the antigen-binding sites is specific for a T-cell surface marker, while the other is specific for the cytokine in question. The bispecific antibody binds to the T cells through the binding site for the cell-surface marker, leaving the cytokine-binding site free. If that T cell is secreting the particular cytokine, the cytokine is captured by the bound antibody before it diffuses away from the surface of the cell. It can then be detected by adding to the cells a fluorochrome-labeled second antibody specific for the cytokine.



Activated T cells are treated with an inhibitor that blocks protein export, allowing cytokines to accumulate in the ER
The cell is fixed and permeabilized with mild detergents
Cytokine-specific antibodies penetrate the cell to bind the intracellular cytokine molecules

Fig. A.26 Cytokine-secreting cells can be identified by intracellular cytokine staining. Fluorochrome-labeled antibodies can be used to detect the cytokines secreted by activated T cells after the cytokine molecules have been allowed to accumulate inside the cell. The accumulation of cytokine molecules to a high enough concentration for efficient detection is achieved by treating the activated T cells with inhibitors of protein export. In such treated cells, proteins destined to be secreted are instead retained within the endoplasmic reticulum (ER; left panel). These treated cells are then fixed, to cross-link the proteins inside the cell and in the cell membranes, so that they are not lost when the cell is permeabilized by dissolving the cell membrane in a mild detergent (center panel). Fluorochrome-labeled antibodies can now enter the permeabilized cell and bind to the cytokines inside the cell (right panel). Cells labeled in this way can also be labeled with antibodies that bind to cell-surface proteins to determine which subsets of T cells are secreting particular cytokines.

A third method for identifying which T cells in a population produce a particular cytokine utilizes cytokine gene reporter mice. In these lines of mice, a cDNA clone encoding a readily detectable protein (the 'reporter' protein) is inserted into the 3′ untranslated region of the targeted cytokine gene downstream of a sequence known as an internal ribosome entry site (IRES). The IRES sequence allows translation of the reporter protein from the same mRNA as that encoding the cytokine; thus, the reporter protein is produced



A hybrid antibody is made from an antibody specific for a cytokine and one for a common cell-surface protein such as MHC class I
The hybrid antibodies bind to a population of activated T cells
If the T cells secrete the cytokine it is captured by the hybrid antibody bound to the cell surface
Cytokine-secreting T cells are detected using a labeled second antibody specific for the cytokine of interest

Fig. A.27 Hybrid antibodies containing cell-specific and cytokine-specific binding sites can be used to assay cytokine secretion by living cells and to purify cells secreting particular cytokines. Hybrid antibodies can be made by mixing together heavy- and light-chain pairs from antibodies of different specificities; for example, an antibody against an MHC class I molecule and an antibody specific for a cytokine such as IL-4 (first panel). The hybrid antibodies are then added to a population of activated T cells and bind to each cell via the MHC class I binding arm (second panel). If some of the cells in the population are secreting the appropriate cytokine, IL-4, this is captured by the cytokine-specific arm of the hybrid antibody (third panel). The presence of the cytokine can then be revealed; for example, by using a fluorochrome-labeled second antibody specific for the same cytokine but binding to a different site from the one used by the hybrid antibody (last panel). The labeled cells are analyzed by flow cytometry or are isolated using a fluorescence-activated cell sorter (FACS). Alternatively, the second cytokine-specific antibody can be coupled to magnetic beads and the cytokine-producing cells isolated magnetically.

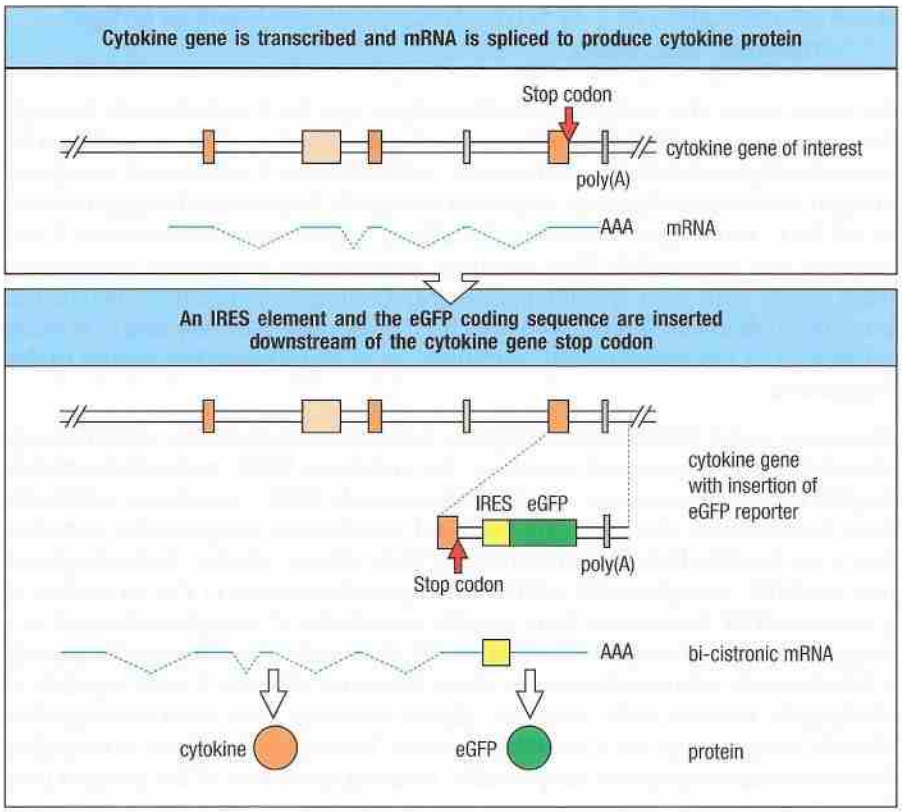


Fig. A.28 Cytokine-expressing cells can be tracked *in vivo* using cytokine gene knock-in reporter mice. To identify cells expressing a specific cytokine in intact animals, the locus encoding the cytokine is modified by homologous recombination (see Fig. A.45 and Section A-36). An internal ribosome entry site (IRES) and the gene for a fluorescent protein such as eGFP are inserted 3′ of the last exon of the cytokine gene, downstream of the cytokine protein stop codon and upstream of the mRNA transcription termination and polyadenylation signal [the poly(A) site]. The IRES element allows the ribosome to initiate translation of a second protein-coding sequence at an internal site on the mRNA. When the modified locus is transcribed and spliced to form the mature mRNA, both the intact cytokine protein and the fluorescent reporter protein (for example, eGFP) are produced from the same transcript. This allows the identification and characterization of cytokine-expressing cells, such as by flow cytometry, on the basis of the detection of eGFP.

only when the cytokine mRNA is expressed (Fig. A.28). Common reporter proteins for this application are fluorescent proteins, such as green fluorescent protein (GFP). In fact, the GFP commonly used for this purpose contains a point mutation that greatly improves its spectral properties for experimental purposes. This version of GFP is commonly referred to as 'enhanced GFP,' or 'eGFP' for short. eGFP can be detected by FACS or by fluorescent microscopy using the settings designed to detect the commonly used fluorescent dye FITC. Because of the broad utility of these fluorescent proteins, a host of GFP derivatives has been developed by genetic engineering of the original GFP protein. Each derivative has distinct fluorescent properties and therefore can be uniquely identified, allowing these proteins to be used in combination with each other to provide information about multiple cytokines at the same time (Fig. A.29).

Several of these techniques for measuring cytokine expression by T-cell subsets have been adapted to examine the transcription factors expressed by T cells and other lymphocytes, providing an alternative method for identifying functional lymphocyte subsets. In one approach, antibodies specific for lineage-defining transcription factors are used to label permeabilized cells. As was described earlier for the intracellular cytokine staining assay, the cells can then be examined by flow cytometry or immunofluorescence microscopy. In another approach, lines of reporter mice have been generated in which the gene locus encoding a transcription factor is modified to express a fluorescent protein, such as eGFP. For both of these approaches, the advantage of using transcription factors to identify lymphocyte subsets is that there is no need to stimulate the cells prior to antibody staining or to assess reporter protein expression, as lineage-defining transcription factors are constitutively expressed by the cells. Therefore, this latter approach is more widely used for the identification of T-cell and other lymphocyte subsets in intact tissues by microscopy.

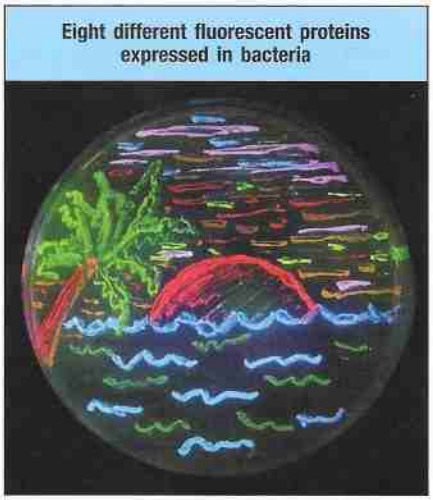

Fig. A.29 Fluorescent proteins are available in a rainbow of colors. Derivatives of GFP and a red-fluorescent coral protein can generate eight different fluorescent colors. A beach scene is drawn with bacterial strains expressing each fluorescent protein.

A-24 Identification of T or B lymphocytes on the basis of antigen receptor specificity.

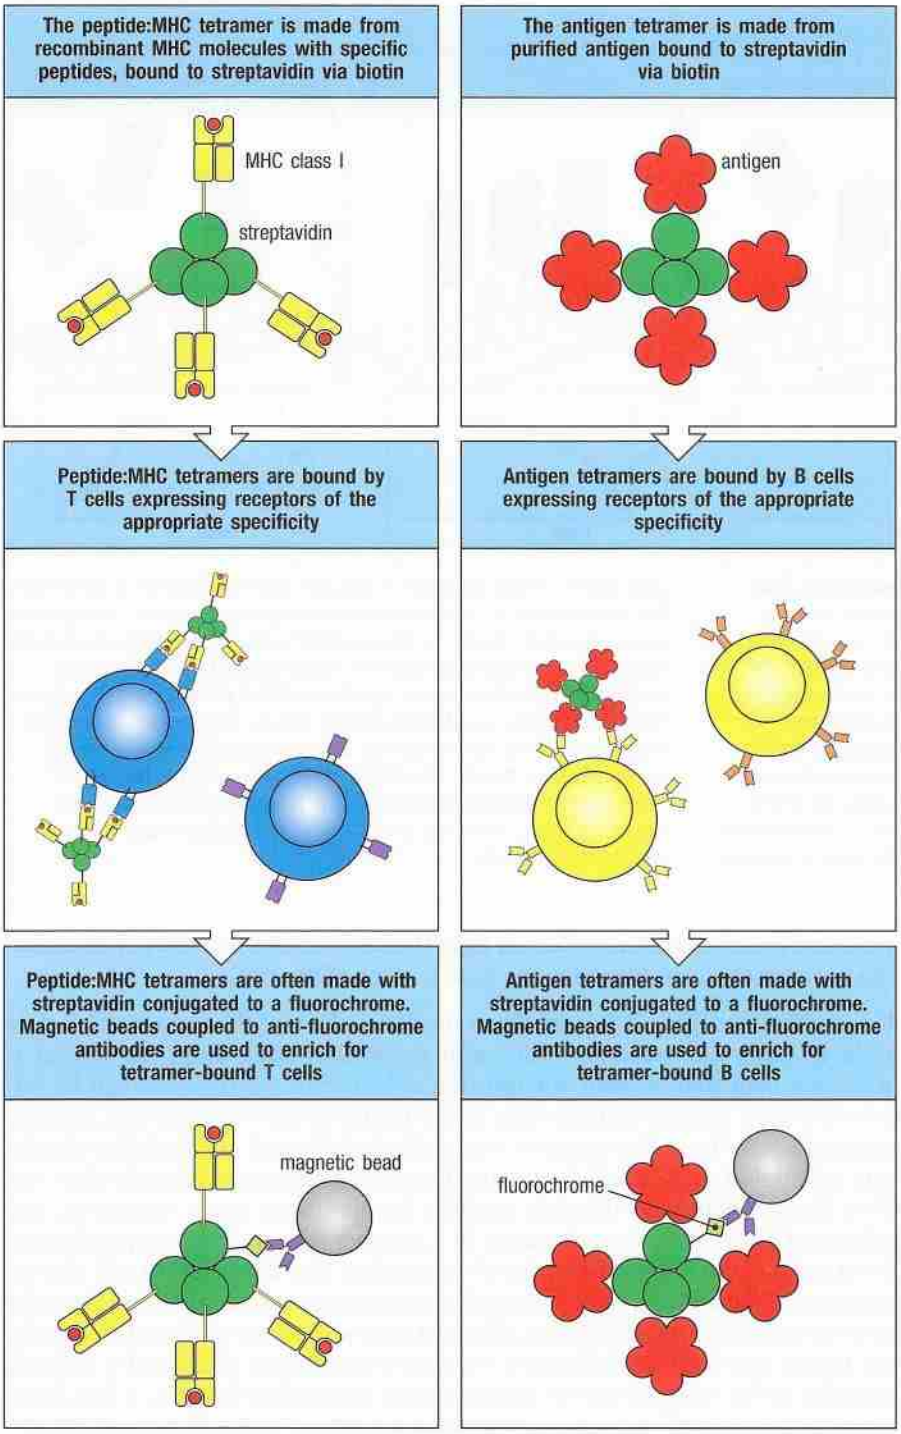
For many years, the ability to identify antigen-specific T cells directly through their receptor specificity eluded immunologists. Foreign antigen could not be used directly to identify T cells because, unlike B cells, T cells do not recognize antigen alone but rather the complexes of peptide fragments of antigen bound to self MHC molecules. Moreover, the affinity of interaction between the T-cell receptor and the peptide:MHC complex is in practice so low that attempts to label T cells with their specific peptide:MHC complexes routinely failed. The breakthrough in labeling antigen-specific T cells came with the idea of making multimers of the peptide:MHC complex, so as to increase the avidity of the interaction.

Peptides can be biotinylated using the bacterial enzyme BirA, which recognizes a specific amino acid sequence. Recombinant MHC molecules containing this target sequence are used to make peptide:MHC complexes, which are then biotinylated. Avidin, or its bacterial counterpart streptavidin, contains four sites that bind biotin with extremely high affinity. Mixing the biotinylated peptide:MHC complex with avidin or streptavidin results in the formation of a **peptide:MHC tetramer**—four specific peptide:MHC complexes bound to a single molecule of streptavidin (Fig. A.30). Routinely, the streptavidin moiety is labeled with a fluorochrome to allow detection of those T cells capable of binding the peptide:MHC tetramer. Similar methods have been developed to identify antigen-specific B cells. In this case, biotinylated antigen is bound to fluorochrome-conjugated streptavidin, creating tetramers of the antigen (see Fig. A.30).

Peptide:MHC tetramers have been used to identify populations of antigen-specific T cells in, for example, patients with acute Epstein–Barr virus infections (infectious mononucleosis), showing that up to 80% of the peripheral T cells in infected individuals can be specific for a single peptide:MHC complex. They have also been used to follow responses over timescales of years in individuals with HIV or cytomegalovirus infections. These reagents have also been important in identifying the cells responding, for example, to nonclassical MHC class I molecules such as HLA-E or HLA-G, in both cases showing that these nonclassical molecules are recognized by subsets of NK receptors. Studies identifying antigen-specific B cells have been instrumental in identifying autoreactive B cells in autoimmune individuals and in characterizing B-cell responses to vaccination. In many cases, particularly in studies of human memory T and B cells, the frequency of antigen-specific cells is very low (<1% of total peripheral blood lymphocytes). In these cases, cells are first incubated with the fluorochrome-conjugated peptide:MHC or antigen tetramers, followed by the addition of magnetic beads that bind to the fluorochrome. The antigen-specific T or B cell populations can then be enriched by passing the cells over a magnet. This enrichment step makes further characterization and/or sorting of the antigen-specific cells more reliable and efficient and is frequently used to sort cells for molecular analyses of their T-cell or B-cell receptor repertoires or their transcriptomes.

A-25 Biosensor assays for measuring the rates of association and dissociation of antigen receptors for their ligands.

Two important questions are always asked of any receptor–ligand interaction: What is the strength of binding, or affinity, of the interaction, and what are the rates of association and dissociation? These parameters are generally assessed using purified preparations of proteins. For receptors that are integral membrane proteins in their native state, soluble forms of the proteins are prepared, usually by truncating the proteins to eliminate their membrane-spanning



The peptide:MHC tetramer is made from recombinant MHC molecules with specific peptides, bound to streptavidin via biotin

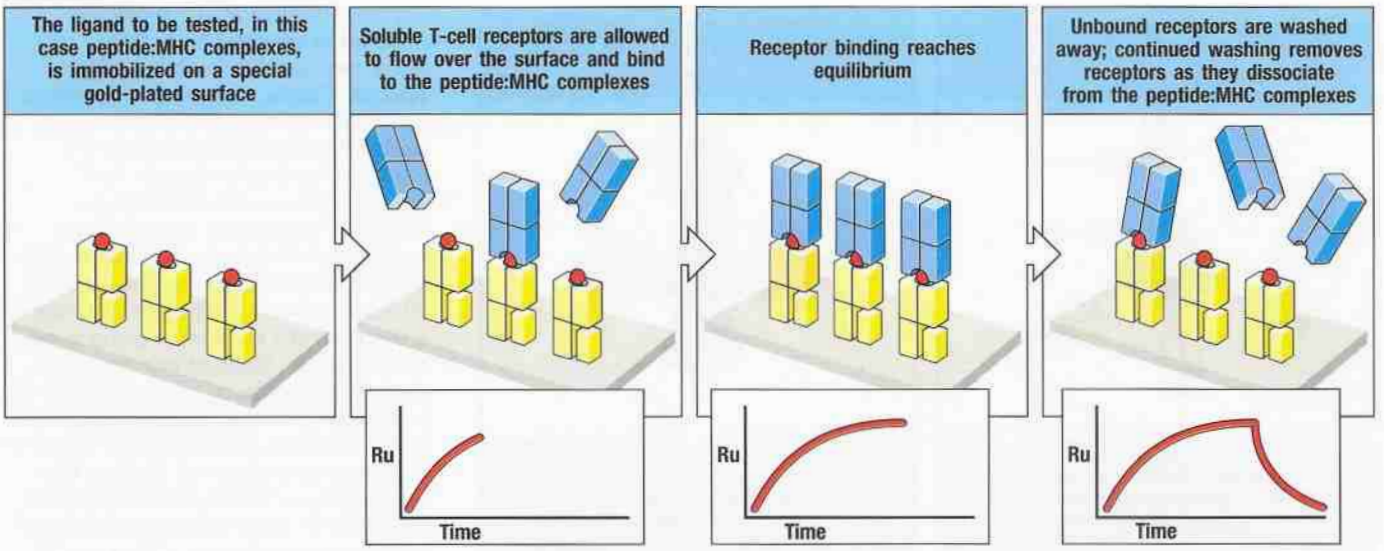
fluorochrome

Fig. A.30 Peptide:MHC complexes coupled to streptavidin to form tetramers are able to stain antigen-specific T cells. A peptide:MHC tetramer is formed from recombinant refolded peptide:MHC complexes containing a single defined peptide epitope. MHC molecules that contain biotin can be chemically synthesized, but usually the recombinant MHC heavy chain is linked to a bacterial biotinylation sequence, a target for the *Escherichia coli* enzyme BirA, which is used to add a single biotin group to the MHC molecule. Streptavidin is a tetramer, each subunit having a single binding site for biotin; hence the streptavidin:peptide:MHC complex creates a tetramer of peptide:MHC complexes (top left panel). Although the affinity between the T-cell receptor and its peptide:MHC ligand is too low for a single complex to bind stably to a T cell, the tetramer makes a more avid interaction with multiple peptide:MHC complexes binding simultaneously and is able to bind to T cells whose receptors are specific for the particular peptide:MHC complex (middle left panel). Routinely, the streptavidin molecules are coupled to a fluorochrome, so that the binding to T cells can be monitored by flow cytometry. Additionally, anti-fluorochrome antibodies coupled to magnetic beads can be used to enrich for tetramer-binding T cells (bottom left panel), as shown in Figure A.23. A similar strategy is used to generate antigen tetramers by mixing biotinylated antigen together with streptavidin (top right panel). Antigen tetramers will be bound by B cells expressing receptors of the appropriate specificity (middle right panel). When antigen tetramers are made with fluorochrome-conjugated streptavidin, antigen-specific B cells can be monitored by flow cytometry or enriched after incubation with anti-fluorochrome antibodies coupled to magnetic beads (bottom right panel).

domains. With these purified proteins, binding rates can be measured by following the binding of ligands to receptors immobilized on gold-plated glass slides using a phenomenon known as **surface plasmon resonance (SPR)** to detect the binding (Fig. A.31). A full explanation of surface plasmon resonance is beyond the scope of this textbook, as it is based on advanced physical and quantum mechanical principles. In brief, it relies on the total internal reflection of a beam of light from the surface of a gold-coated glass slide. As the light is reflected, some of its energy excites electrons in the gold coating, and these excited electrons are affected by the electric field of any molecules binding to the surface of the gold coating. The more molecules that bind to the surface, the greater is the effect on the excited electrons, and this in turn affects the



The ligand to be tested, in this case peptide:MHC complexes, is immobilized on a special gold-plated surface
Soluble T-cell receptors are allowed to flow over the surface and bind to the peptide:MHC complexes
Receptor binding reaches equilibrium
Unbound receptors are washed away; continued washing removes receptors as they dissociate from the peptide:MHC complexes
Ru
Time
Ru
Time
Ru
Time

Fig. A.31 Measurement of receptor–ligand interactions can be made in real time using a biosensor. Biosensors are able to measure the binding of molecules on the surface of gold-plated glass chips through the indirect effects of the binding on the total internal reflection of a beam of polarized light at the surface of the chip. Changes in the angle and intensity of the reflected beam are measured in 'resonance units' (Ru) and plotted against time in what is termed a 'sensorgram.' Depending on the exact nature of the receptor–ligand pair to be analyzed, either the receptor or the ligand can be immobilized on the surface of the chip. In the example shown, peptide:MHC complexes are immobilized on such a surface (first panel). T-cell receptors in solution are now allowed to flow over the surface and to bind to the immobilized peptide:MHC complexes (second panel). As the T-cell receptors bind, the sensorgram (insets) reflects the increasing amount of protein bound. As the binding reaches either saturation or equilibrium (third panel), the sensorgram shows a plateau, as no more protein binds. At this point, unbound receptors can be washed away. With continued washing, bound receptors now start to dissociate and are removed in the flow of the washing solution (last panel). The sensorgram now shows a declining curve, reflecting the rate at which receptor and ligand dissociation occurs.

reflected light beam. The reflected light thus becomes a sensitive measure of the number of atoms bound to the gold surface of the slide.

If a purified receptor is immobilized on the surface of the gold-coated glass slide to make a biosensor 'chip,' and a solution containing the ligand is streamed over that surface, the binding of ligand to the receptor can be followed until it reaches equilibrium. If the ligand is then washed out, dissociation of ligand from the receptor can easily be followed and the dissociation rate calculated. A new solution of the ligand at a different concentration can then be streamed over the chip and the binding once again measured. The affinity of binding can be calculated in a number of ways in this type of assay. Most simply, the ratio of the rates of association and dissociation will give an estimate of the affinity, but more accurate estimates can be obtained from the measurements of the binding at different concentrations of ligand. Similarly, the ligand can be immobilized on the gold-coated glass slide, and a solution containing the receptor can be streamed over the surface (see Fig. A.31). From measurements of binding at equilibrium, a Scatchard plot will give a measurement of the affinity of the receptor–ligand interaction.

A-26 Assays of lymphocyte proliferation.

To function in adaptive immunity, rare antigen-specific lymphocytes must proliferate extensively before they differentiate into functional effector cells in order to generate sufficient numbers of effector cells of a particular specificity. Thus, the analysis of induced lymphocyte proliferation is a central issue in their study. It is difficult, however, to detect the proliferation of normal lymphocytes in response to specific antigen because only a minute proportion of cells will be stimulated to divide. Great impetus was given to the field of lymphocyte culture by the finding that certain substances induce

many or all lymphocytes of a given type to proliferate. These substances are referred to collectively as **polyclonal mitogens** because they induce mitosis in lymphocytes of many different specificities or clonal origins. T and B lymphocytes are stimulated by different polyclonal mitogens (Fig. A.32). Polyclonal mitogens seem to trigger essentially the same growth-response mechanisms as antigen. Lymphocytes normally exist as resting cells in the G_0 phase of the cell cycle. When stimulated with polyclonal mitogens, they rapidly enter the G_1 phase and progress through the cell cycle. In most studies, lymphocyte proliferation is most simply measured by the incorporation of ^{3}H-thymidine into DNA. This assay is used clinically for assessing the ability of lymphocytes from patients with suspected immunodeficiencies to proliferate in response to a nonspecific stimulus.

An alternative to the use of a radioisotope to measure lymphocyte proliferation is to use a fluorescent assay that can be performed by FACS. For this assay, the lymphocytes are incubated with a fluorescent dye such as carboxyfluorescein succinimidyl ester (CFSE). This dye enters the cell and, once in the cytosol, becomes covalently coupled to lysine residues on cellular proteins. Each time the cell divides, the amount of CFSE is cut in half, as each daughter cell inherits one-half of the CFSE-labeled proteins. When a population of dividing cells is analyzed by FACS, peaks of CFSE fluorescence can be detected, each of which represents cells that have undergone a fixed number of divisions (Fig. A.33). This assay is capable of detecting up to 7–8 cell divisions, after which CFSE fluorescence can no longer be measured.

Once lymphocyte culture had been optimized using the proliferative response to polyclonal mitogens as an assay, it became possible to detect antigen-specific T-cell proliferation in culture by measuring ^{3}H-thymidine uptake in response to an antigen to which the T-cell donor had previously been immunized (Fig. A.34). This is the assay most commonly used for assessing T-cell responses after immunization, but it reveals little about the functional capabilities of the responding T cells. These must be ascertained by functional assays, as outlined in Sections A-28 and A-29.

Mitogen	Responding cells
Phytohemagglutinin (PHA) (red kidney bean)	T cells
Concanavalin (ConA) (jack bean)	T cells
Pokeweed mitogen (PWM) (pokeweed)	T and B cells
Lipopolysaccharide (LPS) (*Escherichia coli*)	B cells (mouse)

Fig. A.32 Polyclonal mitogens, many of plant origin, stimulate lymphocyte proliferation in tissue culture. Many of these mitogens are used to test the ability of lymphocytes in human peripheral blood to proliferate.

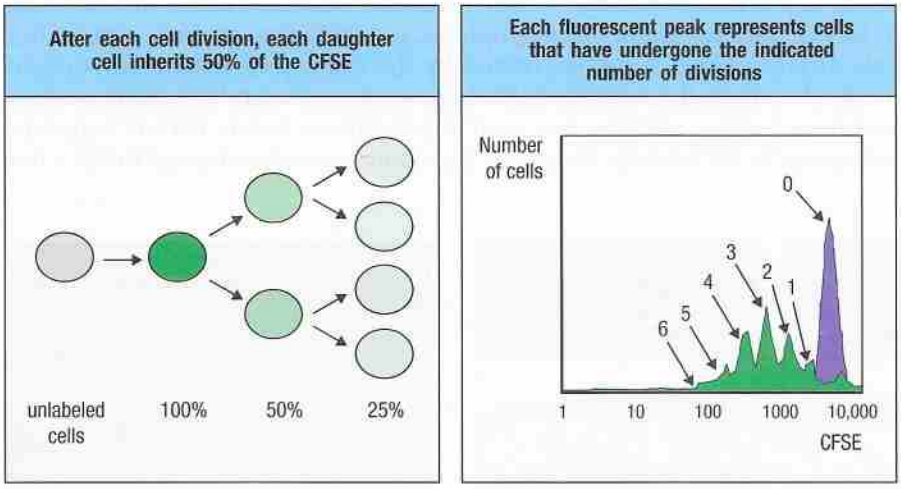


Fig. A.33 A flow cytometric assay based on CFSE dilution to measure cell proliferation. Cells are first incubated with a fluorescent dye such as carboxyfluorescein succinimidyl ester (CFSE). This dye enters the cell and, once in the cytosol, becomes covalently coupled to lysine residues on cellular proteins. Each time the cell divides, the amount of CFSE is diluted by one-half, as each daughter cell inherits one-half of the CFSE-labeled proteins. Cell division can then be analyzed by flow cytometry, where a histogram of CFSE fluorescence displays a series of peaks, each of which represents cells that have undergone a fixed number of divisions. Under optimal conditions, this assay is capable of detecting up to 7–8 cell divisions, after which CFSE fluorescence can no longer be measured.

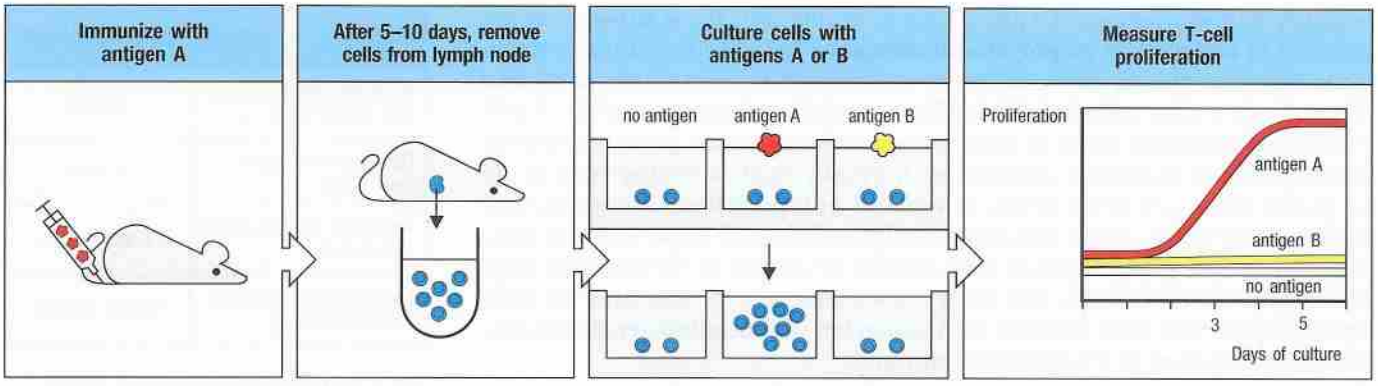

Fig. A.34 Antigen-specific T-cell proliferation is used frequently as an assay for T-cell responses. T cells from mice or humans that have been immunized with an antigen (antigen A) proliferate when they are exposed to antigen A and antigen-presenting cells but not when cultured with unrelated antigens to which the hosts have not been immunized (antigen B). Proliferation can be measured by incorporation of ^{3}H-thymidine into the DNA of actively dividing cells. Antigen-specific proliferation is a hallmark of specific CD4 T-cell immunity.

A-27 Measurements of apoptosis.

Apoptotic cells can be detected by a procedure known as **TUNEL (TdT-dependent dUTP-biotin nick-end labeling) staining**. In this technique, the 3′ ends of the DNA fragments generated in apoptotic cells are labeled with biotin-coupled uridine by using the enzyme terminal deoxynucleotidyl transferase (TdT). The biotin label is then detected with enzyme-tagged streptavidin, which binds to biotin. When the colorless substrate of the enzyme is added to a tissue section or cell culture, it produces a colored precipitate only in cells that have undergone apoptosis (Fig. A.35).

Additional methods are often used to detect apoptosis of cells in experimental animals. One simple method is to incubate cells with a fluorescently labeled preparation of the protein **annexin V**. This protein has a high affinity for a specific membrane phospholipid, phosphatidylserine (PS). In healthy cells, PS is found exclusively on the inner leaflet of the plasma membrane and is therefore inaccessible to extracellular incubation with annexin V. When cells are undergoing apoptosis, the PS is transported to the outer cell surface, where it can be bound by the fluorescently labeled annexin V, which is then detected by FACS (Fig. A.36). Annexin V staining is often combined with a viability dye such as propidium iodide (PI) or 7-amino-actinomycin D (7-AAD). These two dyes fluoresce when bound to DNA but

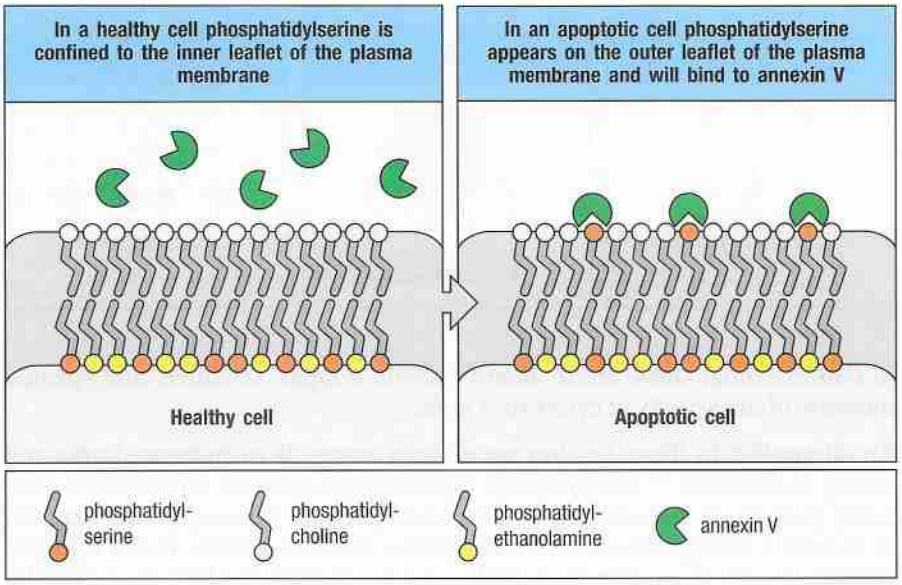
DNA

Fig. A.35 In the TUNEL assay, fragmented DNA is labeled by terminal deoxynucleotidyl transferase (TdT) to reveal apoptotic cells. When cells undergo programmed cell death, or apoptosis, their DNA becomes fragmented (first panel). The enzyme TdT is able to add nucleotides to the ends of DNA fragments; most commonly in this assay, biotin-labeled nucleotides (usually dUTP) are added (second panel). The biotinylated DNA can be detected by using streptavidin, which binds to biotin, coupled to enzymes that convert a colorless substrate into a colored insoluble product (third panel). Cells stained in this way can be detected by light microscopy, as shown in the photograph of apoptotic cells (stained red) in the thymic cortex.



In a healthy cell phosphatidylserine is confined to the inner leaflet of the plasma membrane
In an apoptotic cell phosphatidylserine appears on the outer leaflet of the plasma membrane and will bind to annexin V
Healthy cell
Apoptotic cell
phosphatidyl-serine

phosphatidyl-ethanolamine
annexin V

Fig. A.36 Detection of apoptotic cells with annexin V. In healthy cells, the membrane phospholipid phosphatidylserine is oriented with its polar headgroup facing the cytosolic face of the plasma membrane. When cells undergo apoptosis, the enzyme responsible for maintaining phosphatidylserine polarity, called flippase, is no longer active. As a result, phosphatidylserine becomes randomly oriented, with many molecules exposing their polar head groups on the extracellular face of the plasma membrane. The protein annexin V binds tightly to the exposed phosphatidylserine and, if fluorescently labeled, can be used to detect apoptotic cells by FACS.

are unable to enter viable or apoptotic cells prior to their loss of membrane integrity. Therefore, when combined with annexin V, cells in the early stages of apoptosis can be identified as annexin V–positive but PI/7-AAD–negative, whereas cells in the late stages of apoptosis are both annexin V–positive and PI/7-AAD–positive.

An additional assay that provides a sensitive means of detecting apoptotic cells by FACS analysis is based on the detection of activated caspase 3, a cysteine protease that functions in the execution phase of the apoptotic cell-death program. Caspase 3 is initially synthesized by cells in an inactive precursor form called a pro-caspase. When cells are undergoing apoptosis, pro-caspase 3 is cleaved into two subunits that dimerize to form the active enzyme. Antibodies have been generated that detect the active form of caspase 3, but not pro-caspase 3, and fluorescently coupled versions of these antibodies can be used to detect apoptotic cells that have been fixed and permeabilized (Fig A.37).

A-28 Assays for cytotoxic T cells.

Activated CD8 T cells generally kill any cells that display the specific peptide:MHC class I complex they recognize. Thus, CD8 T-cell function can be determined using the simplest and most rapid T-cell bioassay—the killing of a target cell by a cytotoxic T cell. This is usually detected in a ^{51}Cr-release assay. Live cells will take up, but do not spontaneously release, radioactively labeled sodium chromate, $Na_2{}^{51}CrO_4$. When these labeled cells are killed, the radioactive chromate is released, and its presence in the supernatant of mixtures of target cells and cytotoxic T cells can be measured (Fig. A.38). In a similar assay, proliferating target cells such as tumor cells can be labeled with ^3H-thymidine, which is incorporated into the replicating DNA. On attack by a cytotoxic T cell, the DNA of the target cells is rapidly fragmented and retained in the filtrate, while large, unfragmented DNA is collected on a filter, and one can measure either the release of these fragments or the retention of ^3H-thymidine

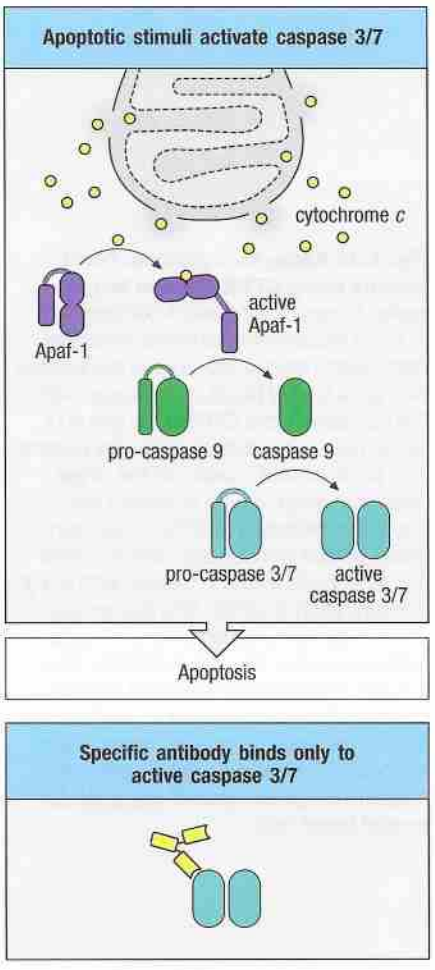

Fig. A.37 Detection of apoptotic cells by intracellular staining for active caspases. An early event in the apoptotic process is the release of cytochrome *c* from mitochondria. Cytochrome *c* binds to Apaf-1, leading to the cleavage of pro-caspase 9 into active caspase 9. Caspase 9 then cleaves pro-caspase 3 and pro-caspase 7 to yield their active forms, 'executioner' caspases that promote cell death. Antibodies that recognize the active caspase 3 or caspase 7, but not the pro-caspase forms of these enzymes, will detect permeabilized cells undergoing apoptosis.

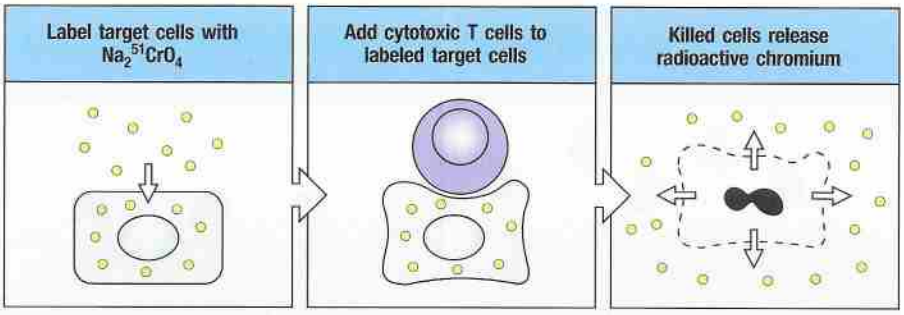

Label target cells with $Na_2{}^{51}CrO_4$
Add cytotoxic T cells to labeled target cells
Killed cells release radioactive chromium

Fig. A.38 Cytotoxic T-cell activity is often assessed by chromium release from labeled target cells. Target cells are labeled with radioactive chromium as $Na_2{}^{51}CrO_4$, washed to remove excess radioactivity, and exposed to cytotoxic T cells. Cell destruction is measured by the release of radioactive chromium into the medium, detectable within 4 hours of mixing target cells with T cells.

in chromosomal DNA. These assays provide a rapid, sensitive, and specific measure of the activity of cytotoxic T cells.

An alternative to these *in vitro* cytotoxicity assays is to measure target-cell killing by cytotoxic T cells in intact experimental animals. This assay is generally performed with mice that have been infected with a pathogen known to induce a strong cytotoxic T-cell response, such as a virus. Target cells are incubated with the antigenic peptide, which will bind to MHC class I on the target-cell surface. These cells are then incubated with a low concentration of the fluorescent dye CFSE (see Section A-26). A control population of cells that is not given the antigenic peptide is incubated with a high concentration of CFSE, allowing these cells to be distinguished from the antigen-bearing target cells. The two cell populations are mixed 1:1 and injected into the experimental animals. Four hours later, spleen cells are recovered from the animals and analyzed by FACS, allowing the specific target-cell lysis to be calculated from the ratio of the two CFSE-labeled cell populations (Fig. A.39).

A-29 Assays for CD4 T cells.

CD4 T-cell functions usually involve the activation rather than the killing of cells bearing specific antigen. The activating effects of CD4 T cells on B cells or macrophages are mediated in large part by cytokines, which are released by

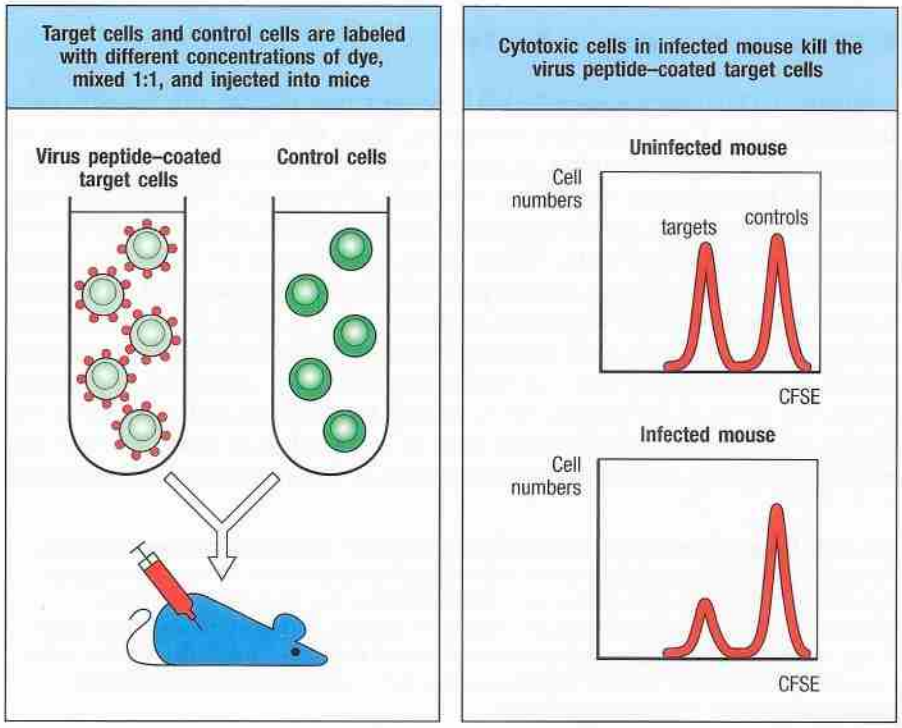

Fig. A.39 Assay for cytotoxic T-cell activity using CFSE-labeled target cells. To detect cytotoxic T-cell activity in intact experimental animals, mice that have been infected with a virus are injected with a mixture of target cells labeled with the fluorescent dye CFSE. One group of target cells is incubated with a viral peptide that binds to MHC class I on the target cells; this group of cells is labeled with a low concentration of CFSE. A second group of cells is incubated with a control (nonviral) peptide and is labeled with a high concentration of CFSE. The two groups of cells are mixed together in a 1:1 ratio and injected into the infected mice. After 4 hours, the mice are sacrificed and the target cells are recovered and analyzed by flow cytometry. Examination of the ratio of the two target-cell populations provides a measure of specific lysis of viral peptide–coated target cells.

the T cell when it recognizes antigen. Thus, CD4 T-cell function is usually studied by measuring the type and amount of cytokine released. Because different effector T cells release different amounts and types of cytokines, one can learn about the effector potential of a T cell by measuring the proteins it produces.

Cytokines can be detected by their activity in biological assays of cell growth, where the cytokines serve either as growth factors or as growth inhibitors. A more specific assay is a modification of ELISA known as a capture or sandwich ELISA (see Section A-4). In this assay, the cytokine is characterized by its ability to act as a bridge between two monoclonal antibodies reacting with different epitopes on the cytokine molecule. Cytokine-secreting cells can also be detected by ELISPOT (see Section A-22).

Sandwich ELISA and ELISPOT avoid a major problem of cytokine bioassays; namely, the ability of different cytokines to stimulate the same response in a bioassay. Bioassays must always be confirmed by inhibition of the response with neutralizing monoclonal antibodies specific for the cytokine. Another way of identifying cells actively producing a given cytokine is to stain them with a fluorescently tagged anti-cytokine monoclonal antibody, and then identify and count them by FACS (see Section A-23).

A quite different approach to detecting cytokine production is to determine the presence and amount of the relevant cytokine mRNA in stimulated T cells. This can be done for single cells by *in situ* hybridization and for cell populations by the **reverse transcriptase–polymerase chain reaction (RT-PCR)**. Reverse transcriptase is an enzyme used by certain RNA viruses, such as HIV, to convert an RNA genome into a DNA copy, or complementary DNA (cDNA). In RT-PCR, mRNA is isolated from cells, and cDNA copies are made *in vitro* using reverse transcriptase. The desired cDNA is then selectively amplified by PCR by using sequence-specific primers. When the products of the reaction are subjected to electrophoresis on an agarose gel, the amplified DNA can be visualized as a band of a specific size. The amount of amplified cDNA sequence will be proportional to its representation in the mRNA; stimulated T cells actively producing a particular cytokine will produce large amounts of that particular mRNA and will thus give correspondingly large amounts of the selected cDNA on RT-PCR. The level of cytokine mRNA in the original tissue is usually determined by comparison with the outcome of RT-PCR on the mRNA produced by a so-called housekeeping gene expressed by all cells.

A-30 Transfer of protective immunity.

Protective immunity to a pathogen may involve humoral immunity, cell-mediated immunity, or both. For studies in experimental animals such as inbred mice, the nature of protective immunity can be determined by transferring serum or lymphoid cells from an immunized donor animal to an unimmunized syngeneic recipient (that is, a genetically identical animal of the same inbred strain). If protection against infection can be conferred by the transfer of serum, the immunity is provided by circulating antibodies and is called **humoral immunity**. Transfer of immunity by antiserum or purified antibodies provides immediate protection against many pathogens and against toxins such as those of tetanus and snake venom (Fig. A.40). However, although protection is immediate, it is temporary, lasting only so long as the transferred antibodies remain active in the recipient's body. This type of transfer is therefore called **passive immunization**, to distinguish it from **active immunization** with antigen, which can provide lasting immunity. A disadvantage of passive immunization is that the recipient may become immunized to the antiserum used to transfer immunity. Horse or sheep sera are the usual sources of anti-snake venoms used in humans, and repeated administration can lead either to serum sickness or if the recipient becomes allergic to the foreign serum, to anaphylaxis (see Section 14-1).

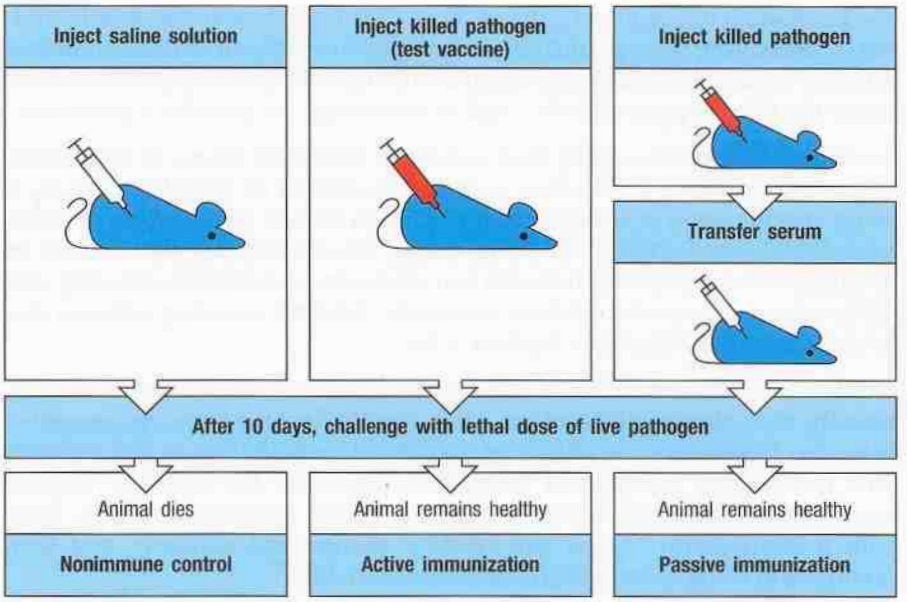

Fig. A.40 *In vivo* assay for the presence of protective immunity after vaccination in animals. Mice are injected with the test vaccine, such as a heat-killed pathogen, or a control such as saline solution. Different groups are then challenged with lethal or pathogenic doses of the test pathogen or with an unrelated pathogen as a specificity control (not shown). Unimmunized animals die or become severely infected (left panel). Successful vaccination is seen as specific protection of immunized mice against infection with the test pathogen. This is called active immunity, and the process is called active immunization (middle panel). If this immune protection can be transferred to a normal syngeneic recipient with serum from an immune donor, then immunity is mediated by antibodies; such immunity is called humoral immunity and the process is called passive immunization (right panel). If immunity can be transferred only by infusing lymphoid cells from the immune donor into a normal syngeneic recipient, then the immunity is called cell-mediated immunity and the transfer process is called adoptive transfer or adoptive immunization (not shown). Passive immunity is short-lived, because antibody is eventually catabolized, but adoptively transferred immunity is mediated by immune cells, which can survive and provide longer-lasting immunity.

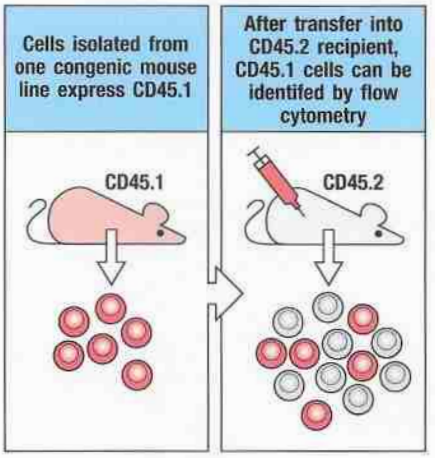
Protection against many diseases cannot be transferred with serum but can be transferred by lymphoid cells from immunized donors. The transfer of lymphoid cells from an immune donor to a normal syngeneic recipient is called **adoptive transfer**, or **adoptive immunization**, and the immunity transferred is called **adoptive immunity**. Immunity that can be transferred only with lymphoid cells is called **cell-mediated immunity**. Such cell transfers must be between genetically identical donors and recipients, such as members of the same inbred strain of mouse, so that the donor lymphocytes are not rejected by the recipient and do not attack the recipient's tissues. Adoptive transfer of immunity is used clinically in humans in experimental approaches to cancer therapy or as an adjunct to bone marrow transplantation; in these cases, the patient's own T cells, or the T cells of the bone marrow donor, are given.

A-31 Adoptive transfer of lymphocytes.

Ionizing radiation from X-ray or gamma-ray sources kills lymphoid and other immune cells at doses that spare the other tissues of the body. This makes it possible to eliminate immune function in a recipient animal before attempting to restore immune function by adoptive transfer and allows the effect of the adoptively transferred cells to be studied in the absence of other lymphoid cells. James Gowans originally used this technique to prove the role of the lymphocyte in immune responses. He showed that all active immune responses could be transferred to irradiated recipients by small lymphocytes from immunized donors.



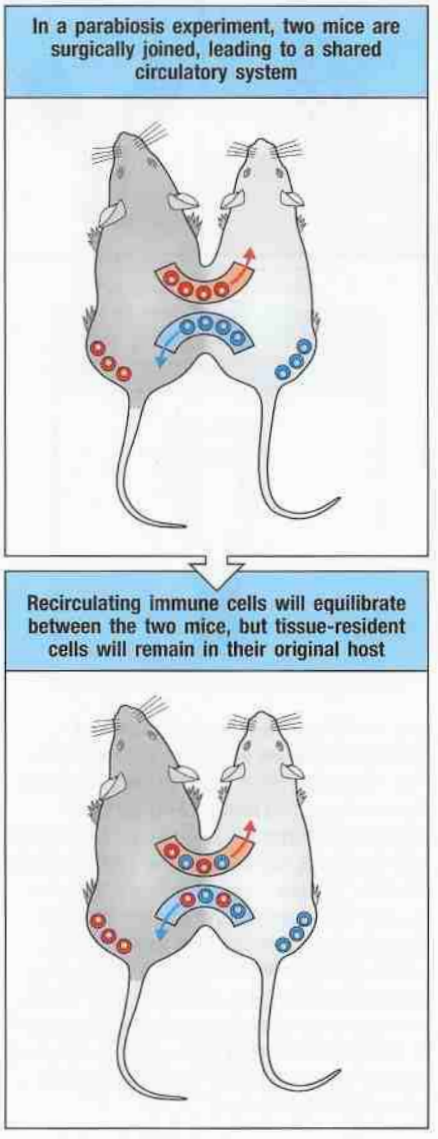
Cells isolated from one congenic mouse line express CD45.1
After transfer into CD45.2 recipient, CD45.1 cells can be identifed by flow cytometry
CD45.1
CD45.2

Fig. A.41 Adoptive transfer of congenically marked cells. Hematopoietic cells can be transferred between genetically identical (or nearly identical) mice. The transferred cells, usually a minority population in the recipient, are identified on the basis of expression of an allelic variant of an abundant cell-surface receptor. One common receptor used for this purpose is CD45, which has two alleles that can be distinguished by allele-specific antibodies. When cells from a CD45.1$^+$ mouse are transferred into mice of the identical strain (save for their expression of CD45.2), the donor-cell population can easily be identified by antibody staining followed by flow cytometry or immunofluorescence microscopy.

One common use of adoptive transfer assays takes advantage of the availability of T-cell receptor or B-cell receptor transgenic mice (see Section A-35). In this case, the adoptively transferred lymphocytes are a homogeneous population with a fixed antigen specificity. These cells can be transferred into unmanipulated recipient animals of the same inbred strain without the need to deplete the host immune system, and their ability to respond to immunization or challenge by infection can be monitored. One advantage of this experimental strategy is that relatively small numbers of antigen-specific T cells or B cells can be transferred; after dilution by the recipient's lymphocyte population, the responses of these cells can be examined in the environment of a normal immune response carried out by the host's immune system. Commonly, the transferred cells are 'marked' with an allelic variant of an abundant cell-surface receptor, such as CD45 (Fig. A.41). When the donor lymphocytes express one allelic variant of CD45 and the recipient cells express a different variant, the transferred cells can easily be distinguished from the host cells by staining with an antibody that binds to one variant of CD45 but not the other. When two strains of mice are genetically identical with the exception of a single gene, they are said to be **congenic**. In the example above, the donor strain and the recipient strain are referred to as 'CD45 congenics'; it should be noted, however, that in the case where one strain is a T-cell receptor or B-cell receptor transgenic line, this terminology is not completely accurate, as the presence of the transgenic DNA as a genetic difference is conveniently ignored. Such adoptive transfer studies are a cornerstone in the study of the intact immune system. They have provided a rapid and convenient means of determining the effects of many gene deficiencies, such as those in cell-surface receptors, transcription factors, cytokines, and cell-survival or cell-death genes, on the ability of T cells or B cells to mount protective immune responses.

A-32 Assessment of lymphocyte tissue residency by parabiosis.

While many immune cells in the body are found circulating between the blood and the secondary lymphoid organs, some subsets home to tissue sites and persist in these locations as long-term tissue-resident cells. Mucosal surfaces, such as the skin, lung, and gastrointestinal tract, are particularly rich in tissue-resident immune cells. Often, as in studies of memory T-cell populations generated in response to infection, it is difficult to distinguish circulating T cells from tissue-resident T cells on the basis of flow cytometry analysis of surface markers. One approach to resolving the tissue-resident from the recirculating populations utilizes an experimental technique known as **parabiosis**. In this technique, two mice generally differing in the expression of a congenic marker are joined at the flanks by suturing skin from the two mice together (Fig. A.42). Approximately 2 weeks after this surgery, new vasculature is formed in the



In a parabiosis experiment, two mice are surgically joined, leading to a shared circulatory system
Recirculating immune cells will equilibrate between the two mice, but tissue-resident cells will remain in their original host

Fig. A.42 Parabiotic mice are used to assess recirculating versus tissue-resident hematopoietic cell populations. When two mice are surgically joined by the skin of their flanks, the vascular systems of the mice also join together. By 2–3 weeks after surgery, recirculating immune-cell populations equilibrate between the two animals, and the hematopoietic-cell populations in the blood become a mixture of the two types. If the mice carry congenic markers, the cells of each donor can be distinguished (shown as red versus blue cells). However, tissue-resident populations, such as tissue-resident memory T cells, do not equilibrate between the two conjoined mice and remain in the tissue of their origin.

skin, and the mice develop a joined circulatory system. Circulating cells in the blood will be a mixture of cells derived from the two mice. However, cells that reside in the tissues without recirculating in the blood will remain in their original host.

A-33 Hematopoietic stem-cell transfers.

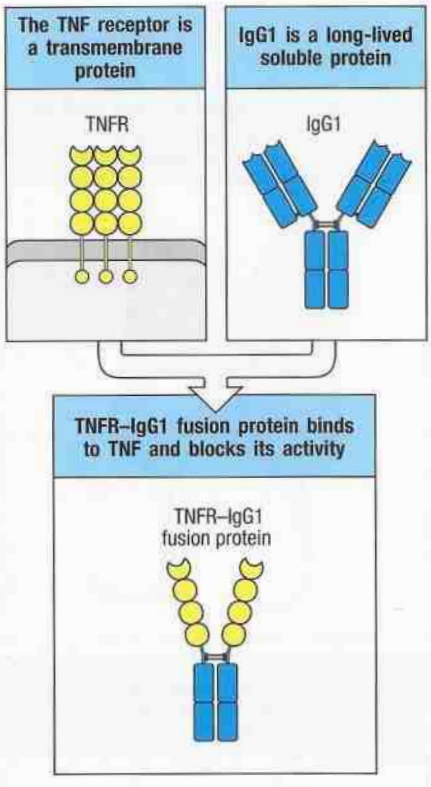
All cells of hematopoietic origin can be eliminated by treatment with high doses of gamma radiation or X-rays, allowing replacement of the entire hematopoietic system, including lymphocytes, by transfusion of donor bone marrow or purified hematopoietic stem cells from another animal. The resulting animals are called **radiation bone marrow chimeras**, from the Greek word *chimera*, a mythical animal that had the head of a lion, the tail of a serpent, and the body of a goat. This technique is used experimentally to examine the development of immune-cell lineages, as opposed to their effector functions, and has been particularly important in studying T-cell development. Essentially the same technique is used in humans to replace the hematopoietic system when it fails, as in aplastic anemia or after nuclear accidents, or to eradicate the bone marrow and replace it with normal marrow in the treatment of certain cancers. In humans, bone marrow is the main source of hematopoietic stem cells, but they are increasingly being obtained from peripheral blood after the donor has been treated with hematopoietic growth factors, such as GM-CSF, or from umbilical cord blood, which is rich in such stem cells (see Chapter 15).

A-34 *In vivo* administration of antibodies.

Antibodies administered to intact experimental animals or to humans provide a potent means of manipulating the immune system. Depending on the target molecule recognized by the antibody, and the intrinsic properties of each antibody, *in vivo* antibody administration can either inhibit the function of the target molecule or, in some cases, lead to the elimination of a cell population that expresses the target molecule.

In animal models, antibodies targeting an individual cytokine have been used to inhibit that cytokine's function during an otherwise intact immune response. Experiments of this type provided some of the first evidence that the cytokine IL-12 provides an important signal in polarizing $CD4^+$ T cells into the T_H1 lineage after infection with an intracellular protozoan. This approach has also been used with great success in humans. One of the most common treatments for the inflammatory autoimmune disease rheumatoid arthritis (see Chapter 16) is the administration of an antibody that binds to the cytokine TNF-α; in this case, the inhibition of TNF-α activity provides patients with relief from the symptoms of joint inflammation. The great utility of this antibody therapy has led to the development of related strategies for inhibiting cytokine actions *in vivo*. One successful approach has been to create a hybrid protein that has the ligand-binding domain of the cytokine's receptor fused to the constant-region domains (Fc) of an antibody heavy chain (Fig. A.43). This Fc-fusion protein acquires the stability and long half-life of an antibody but has the binding properties of the cytokine receptor. When given *in vivo*, the Fc-fusion protein binds to the cytokine, thereby interfering with the cytokine's ability to stimulate its receptor on immune cells. As an example, the Fc-fusion protein containing the TNF-receptor ligand-binding domain has also been used as an effective treatment for patients with rheumatoid arthritis.

Antibody administration can also be used to augment the immune response by interfering with T-cell surface receptors, such as CTLA-4 or PD-1. When engaged by their ligands, these receptors normally function to down-regulate the immune response. From experiments in mice, antibodies that bind to and inhibit these receptors have been found to enhance immune responses to



The TNF receptor is a transmembrane protein
TNFR
IgG1 is a long-lived soluble protein
IgG1
TNFR–IgG1 fusion protein binds to TNF and blocks its activity
TNFR–IgG1 fusion protein

Fig. A.43 *In vivo* administration of antibodies is an effective therapeutic. The cytokine TNF-α contributes to chronic inflammation in a range of conditions, including rheumatoid arthritis, by binding to and triggering signaling of the TNF receptor (TNFR). To treat these conditions, a fusion protein consisting of the constant-region domains of human IgG1 is fused to the extracellular portion of the TNFR, creating a therapeutic known as etanercept. When administered to patients, this fusion protein is effective at binding TNF-α and preventing it from triggering TNFR signaling, thereby reducing inflammation.

tumors, leading in some cases to tumor eradication. Currently, these strategies are being tested in humans for a variety of tumor types, and the initial results have shown great promise.

In vivo administration of antibodies can also be used to deplete specific cell populations. The efficiency with which a given antibody functions for *in vivo* depletion is quite variable, as the mechanism relies on a process known as **antibody-dependent cell-mediated cytotoxicity (ADCC)** (see Section 10-23 and Fig. 10.42). When a cell is coated with antibodies, it becomes a target of natural killer (NK) cells that express the Fc receptor known as CD16, or FcγRIII. The cross-linking of FcγRIII induces the NK cell to kill the antibody-coated target cell. While FcγRIII is a receptor for IgG, it does not bind with equal affinity to all IgG subtypes; thus the efficiency of ADCC after administration of a given antibody is determined by its ability to cross-link FcγRIII and induce NK-cell killing. Common uses for this technique include the depletion of $CD4^+$ T cells with an antibody to CD4 or the depletion of $CD8^+$ T cells with an antibody to CD8. In human patients undergoing organ transplantation, T cells are transiently depleted by administering an antibody to the CD3 component of the T-cell receptor complex. This produces a severe, but temporary, state of immunosuppression during the early post-transplantation stages. As with all *in vivo* antibody-depletion regimens, the depleted cell population gradually returns as cells of that subset are replenished by ongoing lymphocyte development.

A-35 Transgenic mice.

The function of genes has traditionally been studied by observing the effects of spontaneous mutations in whole organisms and, more recently, by analyzing the effects of targeted mutations in cultured cells. The advent of gene cloning and *in vitro* mutagenesis now makes it possible to produce specific mutations in whole animals. Mice with extra copies or altered copies of a gene in their genome can be generated by **transgenesis**, which is now a well-established procedure. To produce **transgenic mice**, a cloned gene is introduced into the mouse genome by microinjection into the male pronucleus of a fertilized egg, which is then implanted into the uterus of a pseudopregnant female mouse. In some of the eggs, the injected DNA becomes integrated randomly into the genome, giving rise to a mouse that has an extra genetic element of known structure, the transgene (Fig. A.44).

This technique allows one to study the impact of a newly discovered gene on development, to identify the regulatory regions of a gene required for its normal tissue-specific expression, to determine the effects of its overexpression or its expression in inappropriate tissues, and to find out the impact of mutations on gene function. Transgenic mice have been particularly useful in studying the role of T-cell and B-cell receptors in lymphocyte development, as described in Chapter 8, and in providing a source of primary T and B lymphocytes of known antigen specificity for adoptive transfer studies (see Section A-31). This utility is largely due to the fact that expression of the transgene-encoded T-cell and B-cell receptors preempts the rearrangement and expression of the endogenous antigen receptor genes during T-cell and B-cell development, respectively, thereby generating homogeneous populations of cells bearing a unique antigen receptor of known specificity.

Fig. A.44 The function and expression of genes can be studied in vivo by using transgenic mice. DNA encoding a protein of interest, here the mouse MHC class II protein Eα, is purified and microinjected into the male pronuclei of fertilized eggs. The eggs are then implanted into pseudopregnant female mice. The resulting offspring are screened for the presence of the transgene in their cells, and positive mice are used as founders that transmit the transgene to their offspring, establishing a line of transgenic mice that carry one or more extra genes. The function of the Eα gene used here is tested by breeding the transgene into C57BL/6 mice that carry an inactivating mutation in their endogenous Eα gene.

A-36 Gene knockout by targeted disruption.

In many cases, the functions of a particular gene can be fully understood only if a mutant animal that does not express the gene can be obtained. Whereas genes used to be discovered through the identification of mutant phenotypes, it is now far more common to discover and isolate the normal gene and then determine its function by replacing it *in vivo* with a defective copy. This procedure is known as **gene knockout**, and it has been made possible by two developments: a powerful strategy to select for targeted mutation by homologous recombination, and the development of continually growing lines of **embryonic stem cells (ES cells)**. These are embryonic cells that, on implantation into a blastocyst, can give rise to all cell lineages in a chimeric mouse.

The technique of **gene targeting** takes advantage of the phenomenon known as **homologous recombination** (Fig. A.45). Cloned copies of the target gene are altered to make them nonfunctional and are then introduced into the ES cell, where they recombine with the homologous gene in the cell's genome, replacing the normal gene with a nonfunctional copy. Homologous recombination is a rare event in mammalian cells, and thus a powerful selection strategy is required to detect those cells in which it has occurred. Most commonly, the introduced gene construct has its sequence disrupted by an inserted antibiotic-resistance gene such as that for neomycin resistance (*neo*^{r}). If this construct undergoes homologous recombination with the endogenous copy of the gene, the endogenous gene is disrupted but the antibiotic-resistance gene remains functional, allowing cells that have incorporated the gene to be selected in culture for resistance to the neomycin-like drug G418. However, antibiotic resistance on its own shows only that the cells have taken up and integrated the neomycin-resistance gene. To be able to select for those cells

Homologous recombination replaces wild-type β2-microglobulin gene with interrupted copy
Cell is killed by G418 (a neomycin analog)
Cell is killed by ganciclovir
Cell expresses neomycin resistance but not HSV-tk, so is not killed by either G418 or ganciclovir

Fig. A.45 The deletion of specific genes can be accomplished by homologous recombination. When pieces of DNA are introduced into cells, they can integrate into cellular DNA in two different ways. If they randomly insert into sites of DNA breaks, the whole piece is usually integrated, often in several copies. However, extrachromosomal DNA can also undergo homologous recombination with the cellular copy of the gene, in which case only the central, homologous region is incorporated into cellular DNA. Inserting a selectable marker gene such as resistance to neomycin (*neo*^{r}) into the coding region of a gene does not prevent homologous recombination, and it achieves two goals. First, any cell that has integrated the injected DNA is protected from the neomycin-like antibiotic G418. Second, when the gene recombines with homologous cellular DNA, *neo*^{r} disrupts the coding sequence of the modified cellular gene. Homologous recombinants can be discriminated from random insertions if the gene encoding herpes simplex virus thymidine kinase (*HSV-tk*) is placed at one or both ends of the DNA construct, which is often known as a 'targeting construct' because it targets the cellular gene. In random DNA integrations, *HSV-tk* is retained. *HSV-tk* renders the cell sensitive to the antiviral agent ganciclovir. However, as *HSV-tk* is not homologous to the target DNA, it is lost from homologous recombinants. Thus, cells that have undergone homologous recombination are uniquely resistant to both G418 and ganciclovir and survive in a mixture of the two antibiotics. The presence of the disrupted gene has to be confirmed by Southern blotting or by PCR using primers in *neo*^{r} and in cellular DNA lying outside the region used in the targeting construct. By using two different resistance genes, one can disrupt the two cellular copies of a gene, making a deletion mutant (not shown).

Some offspring contain tissues (including germ cells) that derive from the injected cells
Breed chimeric mice to generate homozygous β_2-microglobulin–deficient strain

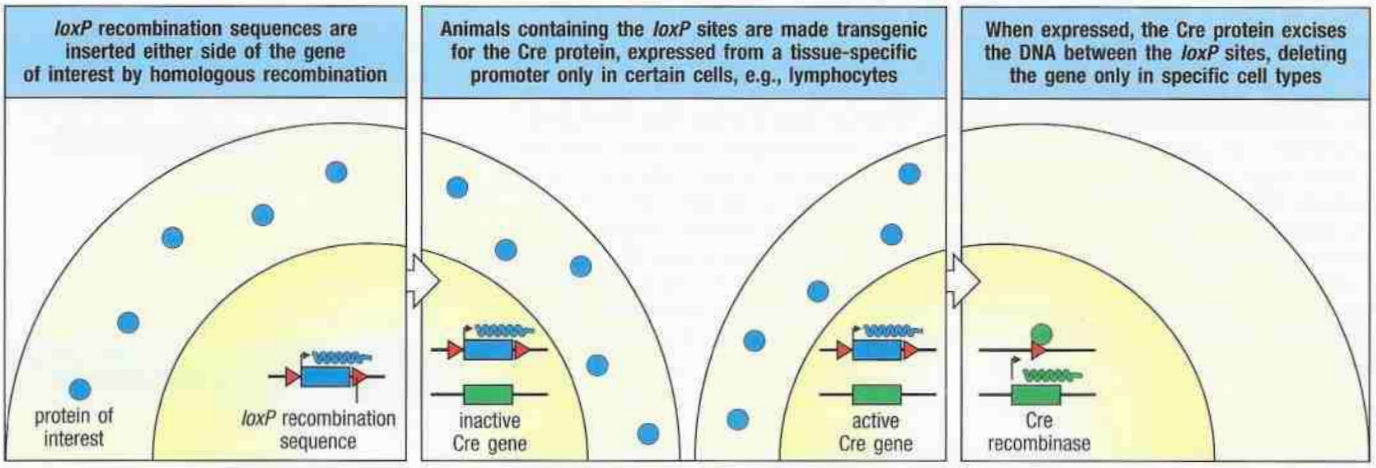
Fig. A.46 Gene knockout in embryonic stem cells enables mutant mice to be produced. Specific genes can be inactivated by homologous recombination in cultures of embryonic stem cells (ES cells). Homologous recombination is performed as described in Fig. A.45. In this example, the gene encoding β_2-microglobulin in ES cells is disrupted by homologous recombination with a targeting construct. Only a single copy of the gene needs to be disrupted. ES cells in which homologous recombination has taken place are injected into mouse blastocysts. If the mutant ES cells give rise to germ cells in the resulting chimeric mice (striped in the figure), the mutant gene can be transferred to their offspring. By breeding the mutant gene to homozygosity, offspring can be tested to determine if a mutant phenotype is generated. In this case, the homozygous mutant mice lack MHC class I molecules on their cells, because MHC class I molecules have to pair with β_2-microglobulin for surface expression. The β_2-microglobulin–deficient mice can then be bred with mice transgenic for subtler mutants of the deleted gene, allowing the effect of such mutants to be tested *in vivo*.

in which homologous recombination has occurred, the ends of the construct usually carry the thymidine kinase gene from the herpes simplex virus (*HSV-tk*). Cells that incorporate DNA randomly usually retain the entire DNA construct including *HSV-tk*, whereas homologous recombination between the construct and cellular DNA, the desired result, involves the exchange of homologous DNA sequences so that the nonhomologous *HSV-tk* genes at the ends of the construct are eliminated. Cells carrying *HSV-tk* are killed by the antiviral drug ganciclovir, and so cells with homologous recombinations have the unique feature of being resistant to both neomycin and ganciclovir, allowing them to be selected efficiently when these drugs are added to the cultures (see Fig. A.45).

To knock out a gene *in vivo*, it is necessary only to disrupt one copy of the cellular gene in an ES cell. These ES cells are then injected into a blastocyst, which is reimplanted into the uterus. The cells carrying the disrupted gene become incorporated into the developing embryo and contribute to all tissues of the resulting chimeric offspring, including those of the germline. The mutated gene can therefore be transmitted to some of the offspring of the original chimera, and further breeding to homozygosity of the mutant gene produces mice that completely lack the expression of that particular gene product (Fig. A.46). The effects of the absence of the gene's function can then be studied. In addition, the parts of the gene that are essential for its function can be identified by determining whether function can be restored by introducing different mutated copies of the gene back into the genome by transgenesis. The manipulation of the mouse genome by gene knockout and transgenesis has revolutionized our understanding of the role of individual genes in lymphocyte development and function.

Because the most commonly used ES cells are derived from a poorly characterized strain of mice known as strain 129, the analysis of the function of a gene knockout often requires extensive back-crossing to another strain. One can track the presence of the mutant copy of the gene by the presence of the gene *neo*^{r}. After sufficient back-crossing, the mice are intercrossed to produce mutants on a stable genetic background.

A problem with gene knockouts arises when the function of the gene is essential for the survival of the animal; in such cases the gene is termed a **recessive lethal gene**, and homozygous animals cannot be produced. To study the function of such a gene, tissue-specific or developmentally regulated gene deletion can be employed. This strategy makes use of the DNA sequences and enzymes used by bacteriophage P1 to excise itself from a host cell's genome. Integrated bacteriophage P1 DNA is flanked by recombination signal sequences called *loxP* sites. A recombinase, Cre, recognizes these sites, cuts the DNA, and joins the two ends, thus excising the intervening DNA in the form of a circle. This mechanism can be adapted to allow the deletion of specific genes in a transgenic animal only in certain tissues or at certain times in development. First, *loxP* sites flanking a gene, or perhaps flanking just a single exon, are introduced



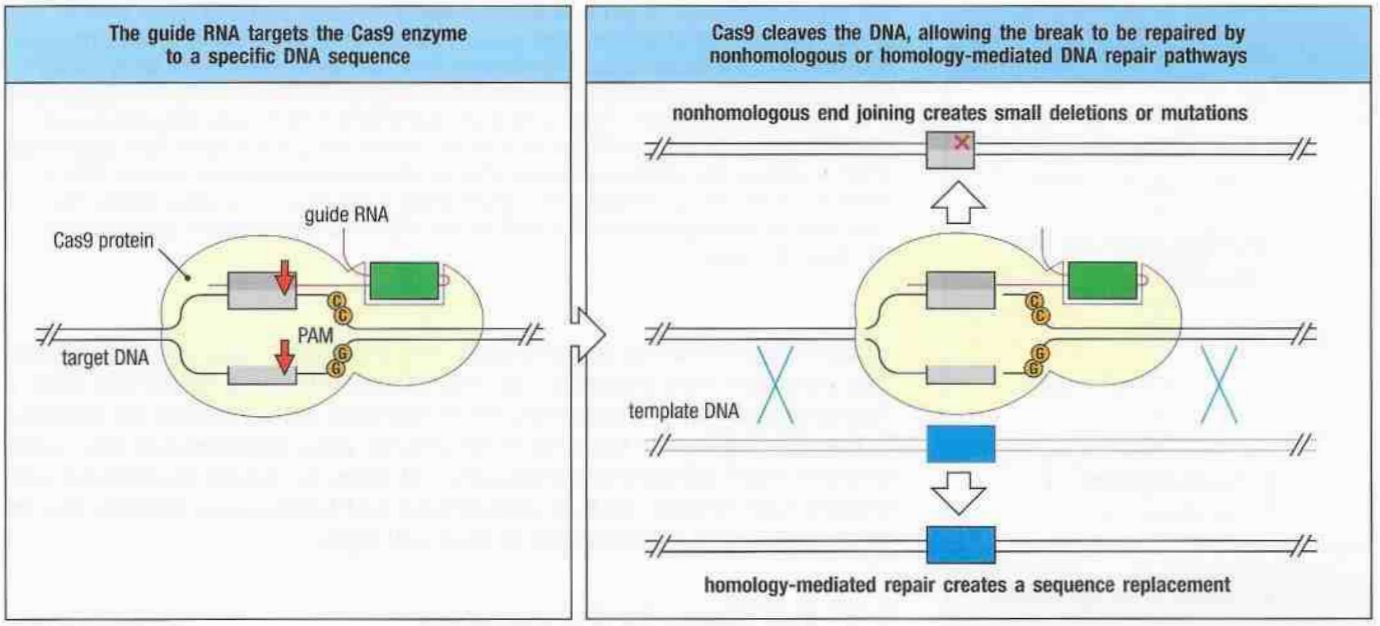
loxP recombination sequences are inserted either side of the gene of interest by homologous recombination
Animals containing the *loxP* sites are made transgenic for the Cre protein, expressed from a tissue-specific promoter only in certain cells, e.g., lymphocytes
When expressed, the Cre protein excises the DNA between the *loxP* sites, deleting the gene only in specific cell types
protein of interest
loxP recombination sequence
inactive Cre gene
active Cre gene
Cre recombinase

Fig. A.47 The P1 bacteriophage recombination system can be used to eliminate genes in particular cell lineages. The P1 bacteriophage protein Cre excises DNA that is bounded by recombination signal sequences called *loxP* sequences. These sequences can be introduced at either end of a gene by homologous recombination (left panel). Animals carrying genes flanked by *loxP* can also be made transgenic for the gene encoding the Cre protein, which is placed under the control of a tissue-specific promoter so that it is expressed only in certain cells or only at certain times during development (center panel). In the cells in which the Cre protein is expressed, it recognizes the *loxP* sequences and excises the DNA lying between them (right panel). Thus, individual genes can be deleted only in certain cell types or only at certain times. In this way, genes that are essential for the normal development of a mouse can be analyzed for their function in the developed animal and/or in specific cell types. Genes are shown as boxes, RNA as squiggles, and proteins as colored balls.

by homologous recombination (Fig. A.47). Usually, the introduction of these sequences into flanking or intronic DNA does not disrupt the normal function of the gene. Next, mice containing such *loxP* mutant genes are mated with mice made transgenic for Cre recombinase that has been placed under the control of a tissue-specific or inducible promoter. When the Cre recombinase is active, either in the appropriate tissue or when induced, it excises the DNA between the inserted *loxP* sites, thus inactivating the gene or exon. Thus, for example, using a T cell–specific promoter to drive expression of the Cre recombinase, a gene can be deleted only in T cells while remaining functional in all other cells of the animal. This extremely powerful genetic technique was used to demonstrate the importance of B-cell receptors in B-cell survival.

Recently, a new technology has been developed for inducing specific gene disruptions in mice; it is known as the CRISPR/Cas9 system. This technique is adapted from a bacterial system that uses an RNA-based strategy to generate double-strand DNA breaks in the genomes of invading pathogens or plasmids, a form of bacterial immunity. The Cas9 gene encodes an endonuclease; this has been modified for use in eukaryotic cells by incorporating a nuclear localization signal into the protein-coding sequence of the enzyme. To target mutations to a particular gene, a synthetic guide RNA is produced that incorporates a short sequence (~20 nucleotides) homologous to the gene being targeted along with sequences that bind the Cas9 enzyme. The guide RNA recruits Cas9 to the genomic location, where the endonuclease will produce a double-strand DNA break (Fig. A.48). When this break is repaired by the nonhomologous end-joining DNA repair pathway, small insertions or deletions are commonly introduced, leading to a disruption of the original sequence.

This powerful technique can be used to generate homozygous gene deficiencies in cultured cells and cell lines, but importantly, it can also be used as a single-step means of generating homozygous mutant mice. For this latter purpose, RNA molecules encoding Cas9 are mixed with guide RNAs and injected into single-cell mouse zygotes, using the same technique as that used to generate transgenic mouse lines (see Fig. A.44). Because of the efficiency of the CRISPR/Cas9 system, these embryos frequently harbor mutations on both alleles of the targeted gene. Thus, after transplantation of the embryos into



The guide RNA targets the Cas9 enzyme to a specific DNA sequence
Cas9 cleaves the DNA, allowing the break to be repaired by nonhomologous or homology-mediated DNA repair pathways
nonhomologous end joining creates small deletions or mutations
guide RNA
Cas9 protein
target DNA

template DNA
homology-mediated repair creates a sequence replacement

Fig. A.48 Genetic engineering using the bacterial CRISPR/Cas9 system. Genetic engineering can be targeted to a specific gene locus in cells by using two components, the bacterial Cas9 enzyme and a guide RNA (left panel). The guide RNA is a single-stranded RNA that contains two regions of sequence in tandem, the first with homology to the gene being targeted and a second recognized by the Cas9 enzyme. The guide RNA targets the enzyme to the homologous genomic region, promoting double-strand DNA cleavage by the Cas9 endonuclease 3–4 nucleotides upstream of the protospacer adjacent motif (PAM) sequence (right panel). The PAM sequence required by the Cas9 endonuclease is the dinucleotide GG (CC on the other strand). When the double-strand DNA break is repaired by the nonhomologous end-joining pathway, small deletions and/or point mutations are introduced into the target gene, often leading to loss of gene function. To induce a specific sequence replacement in the target gene, cells are provided with a template DNA, in addition to Cas9 and the guide RNA. This template is a double-strand DNA sequence homologous to the target gene but containing specific nucleotide changes. In the presence of this template, cells will repair the Cas9-mediated double-strand cleavage using homologous recombination, rather than nonhomologous end joining, thereby replacing the original sequence with the sequence provided in the template DNA.

foster mothers, the pups born from these embryos are already homozygous for the targeted gene, without the need for lengthy mouse breeding. A refinement of this technique has been developed that allows specific nucleotide changes to be introduced into the targeted gene, rather than the random changes resulting from nonhomologous end joining. This is accomplished by introducing a DNA oligonucleotide into the fertilized mouse zygotes along with the Cas9 and guide RNAs. The oligonucleotide contains the desired nucleotide changes flanked by sequences homologous to the targeted gene. When this oligonucleotide is present, the double-strand DNA break introduced by Cas9 is preferentially repaired by a homology-directed process that replaces the damaged DNA with the sequences from the oligonucleotide (see Fig. A.48).

A-37 Knockdown of gene expression by RNA interference (RNAi).

In some cases, the function of a gene can be assessed by reducing or even eliminating the expression of that gene in specific cells. This can be accomplished by harnessing a system known as RNA interference, or RNAi, that is present in many eukaryotic cell types. When small double-strand RNA molecules (referred to as small interfering RNAs, or siRNAs) are introduced into cells, the two RNA strands will be separated, and one will bind to an enzyme complex known as RISC (RNA-induced silencing complex). The bound siRNA targets the RISC to the mRNA to which it has homology, leading either to translation arrest or to degradation of the mRNA, and thus to silencing of the gene (Fig. A.49). For cells that are not easily transfected with siRNA molecules directly, such as primary lymphocytes and myeloid cells, gene silencing can be implemented by using recombinant viruses. In this case, genes encoding small

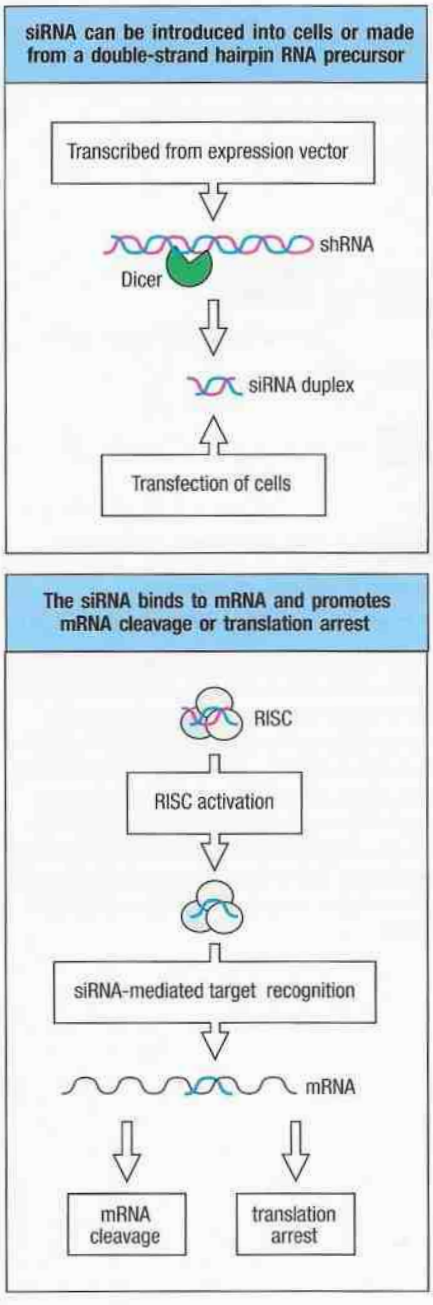

Fig. A.49 Knockdown of gene expression using the RNAi pathway. Small double-strand RNA molecules with homology to an mRNA transcript will target the mRNA for degradation or translation arrest. This pathway is initiated by expression of a short hairpin RNA (shRNA), which can be produced from an expression vector that is introduced into cells or by the direct transfection of cells with small double-strand RNA molecules called small interfering RNAs (siRNAs). shRNA molecules are processed by the enzyme Dicer to generate siRNA duplexes. The siRNA duplexes bind to the RNA-induced silencing complex (RISC), which separates the two RNA strands, retaining the noncoding strand of the siRNA. This noncoding strand targets the siRNA:RISC to the mRNA, leading to mRNA degradation or translation termination.

hairpin RNAs (shRNAs) are introduced into viral vectors that can be packaged into infectious viral particles. The shRNAs encode small RNAs that form a double-strand hairpin structure; these hairpins are processed by enzymes in the cell to generate the siRNAs needed for gene silencing (see Fig. A.49). Because many primary hematopoietic cell types are readily transduced with recombinant viruses, such as retroviruses and lentiviruses, shRNAs can be effectively used to silence genes in these cell types.

A-38 Cell-lineage tracing techniques

Studies of hematopoiesis and of immune responses *in vivo* pose challenges for the establishment of precise lineage relationships between precursor cells and their progeny. For example, in germinal centers where B cells undergo multiple rounds of somatic hypermutation, class switching, and proliferation, questions arise regarding the number of activated B-cell precursors that give rise to all of the B cells in a single germinal center. One approach to investigating this type of question is to irreversibly 'mark' the precursor cell, allowing identification of all its subsequent progeny, a process known as **lineage tracing**. In the example of germinal centers, the spatial localization of the cells is also essential information, necessitating analysis of lymphoid tissue sections by confocal microscopy. One popular method of lineage tracing for fluorescent microscopy is to utilize 'confetti' mice, also called 'brainbow' mice, the latter name referring to the original development of these mice for studies of neural development. Confetti mice carry a gene cassette encoding GFP and three variants of GFP, each of which emits in a different fluorescent wavelength (Fig. A.50). Upstream of the GFP genes is a strong promoter followed by a stop sequence that prevents transcription elongation; therefore, no GFP or GFP variant proteins are expressed from this cassette. Once the Cre enzyme is expressed, the *loxP* sites in the cassette (see Section A-36) are randomly chosen for recombination, leading to deletion or inversion of the intervening sequences, as shown in Figure A.50. Because each cell can utilize different *loxP* sites, the resulting population becomes a random mixture of cells expressing GFP, YFP, RFP, or CFP. If the cells carry the cassette on both alleles of the chromosome (that is, are homozygous), up to 10 different fluorescent signatures can be detected. If confetti mice are crossed to a line expressing Cre in all B cells, the pool of naive B cells would include a random mixture of fluorescent signatures. After immunization, germinal centers can be visualized by confocal microscopy to determine the likely number of precursors contributing to each germinal center.

Another approach to lineage tracing uses DNA bar codes to uniquely mark individual progenitor cells. For this method, a population of progenitor cells is transduced with a library of inheritable DNA bar-code sequences. Marked cells are then transferred into mice and allowed to mature and/or contribute to an immune response. Recovery of the transferred cells at later time points, often after immunization or infection, allows the identification of daughter cells that all derived from a single progenitor on the basis of the inheritance of the unique bar-code DNA sequence.

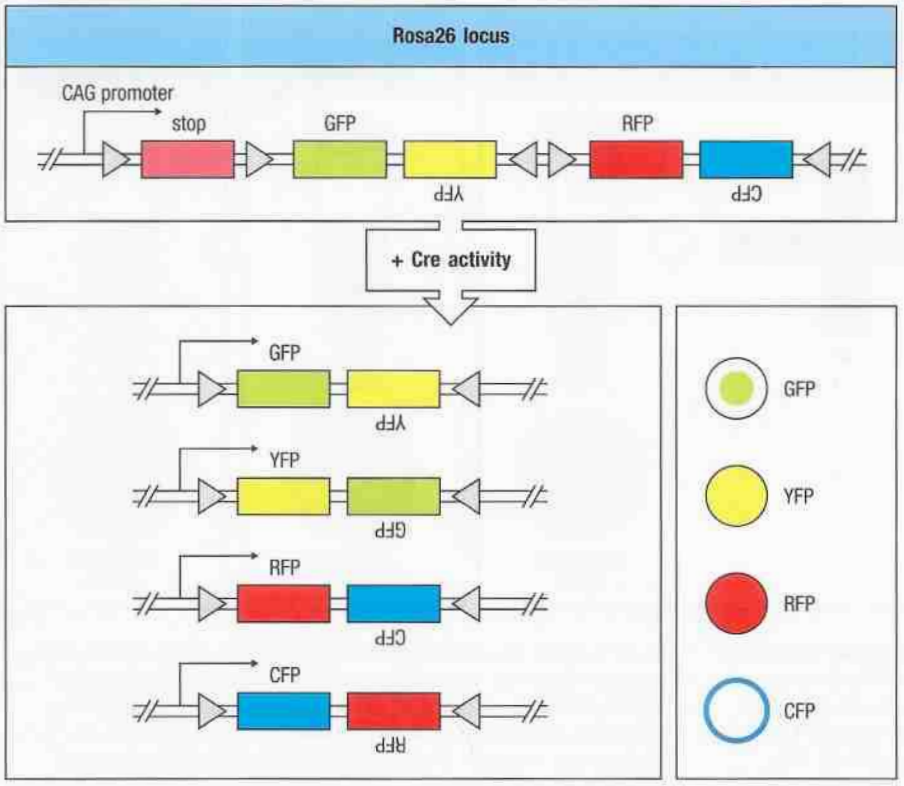

Fig. A.50 Cell-lineage tracing using multicolor fluorescent reporter mice. Confetti mice carry a gene cassette encoding four different variants of GFP [green (GFP), yellow (YFP), red (RFP), and cyan (CFP) fluorescent proteins], each of which emits in a different fluorescent wavelength (top panel). This cassette has been inserted into the Rosa26 locus, a site in the mouse genome that is highly permissive for gene expression in a wide array of cell types and tissues. The gene cassette has a strong promoter, called the CAG promoter, composed of elements from the cytomegalovirus early gene, the chicken β-actin gene, and the rabbit β-globin gene. A transcriptional 'stop' sequence prevents expression of any downstream genes. When Cre is induced in a cell lineage, this enzyme promotes recombination between two *loxP* elements (triangles). Depending on which *loxP* elements are chosen, deletions or inversions of sequences in the cassette can generate four different configurations, each of which expresses one of the GFP variants. Because individual cells in a lineage use different *loxP* elements, each cell and its progeny will be marked by expression of one variant. When the cassette is present in homozygous form, each copy recombines independently, creating up to 10 distinct fluorescent signals.

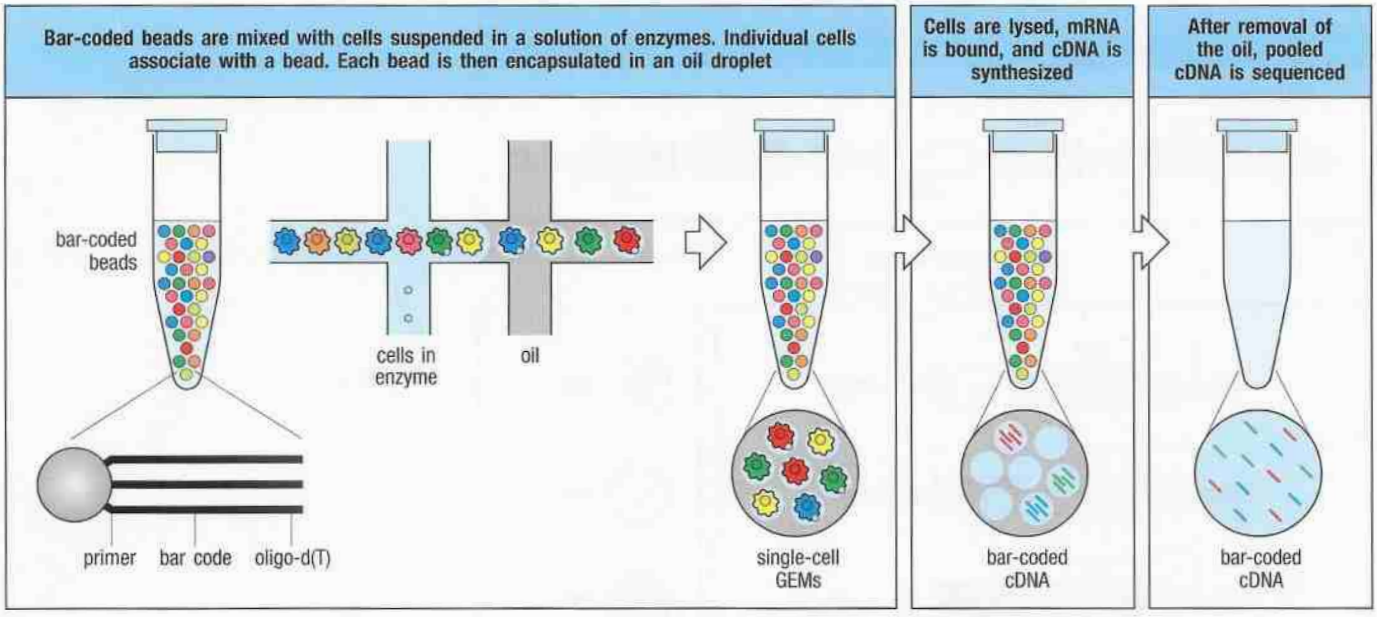
A-39 Single-cell analysis

Many questions about the immune system require analyses that assess differences between individual cells in a population. For several decades, this requirement has been met by flow cytometry techniques that use a panel of antibodies to assess the expression levels of specific proteins on a cell-by-cell basis. However, flow cytometry studies are limited to the detection of a modest number of proteins and, furthermore, require investigators to decide ahead of time which proteins to investigate. This restriction can largely be eliminated by unbiased approaches that assess mRNA expression profiles of each cell in a population. Collectively, these approaches are known as single-cell RNA-seq on the basis of their use of high-throughput parallel sequence analysis to determine the transcriptome (the totality of RNA molecules in the cell) of each single cell. One common platform for single-cell RNA-seq is the 10X Genomics Chromium System that separates single cells into GEMs (Gel Beads in Emulsion), generates cDNA from the mRNA molecules, tags each transcript with a cell-specific bar code, and then pools the cDNA to create libraries for parallel sequence analysis. Commonly, libraries are made with oligo-d(T)



Bar-coded beads are mixed with cells suspended in a solution of enzymes. Individual cells associate with a bead. Each bead is then encapsulated in an oil droplet
Cells are lysed, mRNA is bound, and cDNA is synthesized

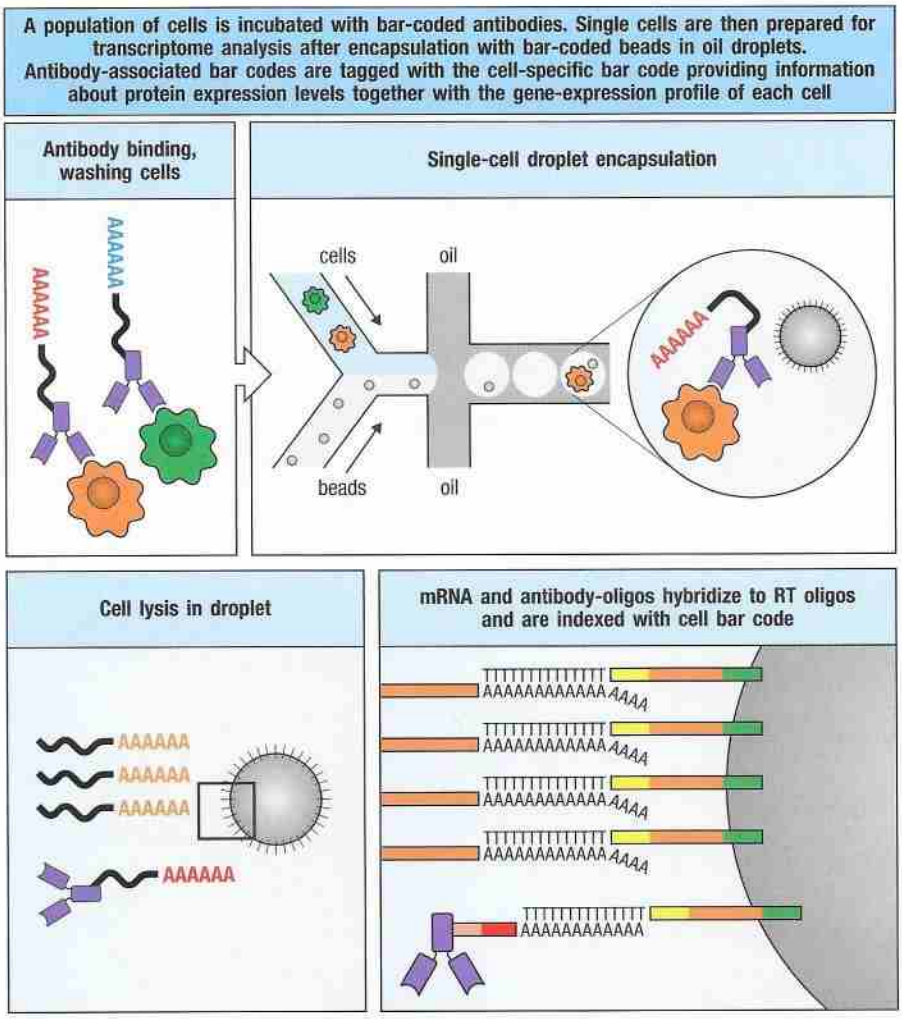
Fig. A.51 To obtain information on the gene expression profile of single cells, a common approach uses the 10X Genomics Chromium System. This system starts with bar-coded gel beads that are each attached to oligonucleotides containing a PCR primer sequence, a bead-specific bar code, and an oligo-d(T) tail. The bar-code sequence differs for each bead in the mixture. Beads are mixed with cells at a high bead-to-cell ratio in a solution containing enzymes for cDNA synthesis. On average, each bead will associate with one or zero cells. Each bead (with or without a cell) along with some enzyme solution is encapsulated in an oil droplet. The enzymes then lyse the cell, allowing the mRNA molecules from the cell to bind to the oligo-d(T) sequences on the bead-associated oligonucleotides, and enzymes reverse transcribe the mRNA to generate cDNA, which is then amplified by PCR. When the oil is removed, a mixture of cDNA, each containing a bar-code tag denoting its cell of origin, is produced. After library preparation and deep sequencing, the sequence information is computationally analyzed to compile all sequences sharing a bar code, as a measure of the transcriptional profile of each individual cell.

primers, and so are used for 3′-end sequencing (Fig. A.51). Computational analysis then deconvolutes the sequence data to assign each transcript to its cell of origin, compiling the transcriptional profile of each single cell. While extremely powerful, the major disadvantage of this technology is that only 10–40% of the transcripts in any given cell are captured and sequenced. In general, low-abundance transcripts are at particular risk of being missed in these experiments.

An advance in single-cell RNA-seq approaches has been the addition of bar-coded antibodies to the library preparation process, a technique known as CITE-seq, short for Cellular Indexing of Transcriptomes and Epitopes by Sequencing (Fig. A.52). For this approach, cells are first incubated with antibodies that are covalently linked to a DNA bar-code sequence followed by a poly(A) tail. When single cells are isolated and prepared for 3′-end sequencing of cDNA, the bar codes from any cell-associated antibodies are included in the libraries and are linked to the cell-specific bar code. After library sequencing, the transcriptome information for each cell will be associated with protein expression data on the basis of the numbers of cell-specific reads for each antibody-linked bar code.



A population of cells is incubated with bar-coded antibodies. Single cells are then prepared for transcriptome analysis after encapsulation with bar-coded beads in oil droplets. Antibody-associated bar codes are tagged with the cell-specific bar code providing information about protein expression levels together with the gene-expression profile of each cell

Fig. A.52 Combination of protein expression with transcriptional profiles of single cells. A variation of the single-cell RNA-seq procedure provides information about the protein expression levels on each cell simultaneously with information about the cell's transcriptional profile. Prior to isolating single cells with bar-coded gel beads, the population of cells is incubated with a set of antibodies, each of which is linked to a bar-coded oligonucleotide that contains a 3′ poly(A) tail. Single cells encapsulated with beads will bring their bound antibodies into the reaction. The antibody-linked bar-coded oligonucleotides will be amplified along with the cell's cDNA and will acquire the cell-specific bar code from the bead. After library preparation and deep sequencing, the antibody bar codes associated with each cell can be identified by computational analysis. RT refers to reverse transcription.

Glossary

-omab Suffix applied to fully murine monoclonal antibodies used for human therapies. (Chapter 16)

-umab Suffix applied to fully human monoclonal antibodies used for human therapies. (Chapter 16)

-ximab Suffix applied to chimeric (i.e., mouse/human) monoclonal antibodies used for human therapies. (Chapter 16)

-zumab Suffix applied to humanized monoclonal antibodies used for human therapies. (Chapter 16)

2B4 A receptor belonging to the signaling lymphocyte activation molecule (SLAM) family expressed by NK cells, which binds to CD48, another SLAM receptor. These signal through SAP and Fyn to promote survival and proliferation. (Chapter 3)

12/23 rule Phenomenon wherein two gene segments of an immunoglobulin or T-cell receptor can be joined only if one recognition signal sequence has a 12-base-pair spacer and the other has a 23-base-pair spacer. (Chapter 5)

19S regulatory caps Multi-subunit component of the proteasome that functions to capture ubiquitinated proteins for degradation in the catalytic core. (Chapter 6)

20S catalytic core Multi-subunit component of the proteasome that is responsible for protein degradation. (Chapter 6)

α-(1,3)-fucosyltransferase VII (FucT-VII) An enzyme (glycosyltransferase) that adds fucose residues to core glycans displayed by different cell-surface proteoglycans on immune cells and endothelial cells to generate ligands that are recognized by the E-, P-, and L-selectins, which mediate cell rolling during the process of immune-cell extravasation from blood vessels. (Chapter 11)

$\alpha_4\beta_1$ (VLA-4, or **CD49d:CD29)** *See* **integrins**. Properties of individual CD antigens can be found in eAppendix II. (Chapters 9, 11, 16)

$\alpha_4\beta_7$ *See* **integrin $\alpha_4\beta_7$**. (Chapters 9, 11, 16)

α_E integrin (CD103) Alpha integrin molecule (ITGAE) that pairs with β_7 integrin to form the heterodimeric integrin, $\alpha_E\beta_7$, which binds the cellular adhesion molecule E-cadherin expressed by intestinal epithelial cells. Expressed by intraepithelial lymphocytes (IELs) and some dendritic cells associated with barrier tissues such as the intestines. Note that CD103 is often used to refer to the $\alpha_E\beta_7$ heterodimer despite strictly referring only to the α_E molecule. (Chapter 12)

$\alpha_E\beta_7$ Integrin heterodimer that recognizes E-cadherin expressed on intestinal epithelial cells. *See* α_E integrin **(CD103)**. (Chapter 12)

αβ heterodimer The dimer of one α and one β chain that makes up the antigen-recognition portion of an αβ T-cell receptor. (Chapter 4)

αβ T-cell receptors *See* **T-cell receptor**. (Chapter 4)

αβ T cells T cells whose T-cell receptors are composed of rearranged TRA and TRB genes, typically recognizing peptide:MHC complexes but including NKT cells that recognize nonpeptide ligands expressed by nonclassical MHC class I–like proteins. (Chapter 6)

α-defensins A class of antimicrobial peptides produced by neutrophils and the Paneth cells of the intestine. (Chapter 2)

α-galactosylceramide (α-GalCer) An immunogenic glycolipid originally extracted from marine sponges but actually produced by various bacteria and which is a ligand presented by CD1 to invariant NKT (iNKT) cells. (Chapter 6)

abatacept An Fc fusion protein that contains the CTLA-4 extracellular domain and used in treatment of rheumatoid arthritis to block co-stimulation of T cells by binding B7 molecules. (Chapter 16)

ABO blood group Individuals in the human population vary in the expression of enzymes that modify carbohydrate antigens on the surfaces of red blood cells. Individuals with the A allele produce an enzyme that leads to carbohydrate structures distinct from those produced by the B allele–encoded enzyme. The O allele is a null allele and does not produce a functional glycosyltransferase. (Appendix I)

accelerated rejection The more rapid rejection of a second graft after rejection of the first graft. It was one of the pieces of evidence that showed that graft rejection was due to an adaptive immune response. (Chapter 15)

accessory effector cells Cells that aid in an adaptive immune response but are not involved in specific antigen recognition. They include phagocytes, neutrophils, mast cells, and NK cells. (Chapter 10)

acellular pertussis vaccines A formulation of pertussis used for vaccination containing chemically inactivated antigens, including pertussis toxoid. (Chapter 16)

acquired immune deficiency syndrome (AIDS) A disease caused by infection with the human immunodeficiency virus (HIV-1 or HIV-2). AIDS occurs when an infected individual has lost most of his or her CD4 T cells, so that infections with opportunistic pathogens occur. (Chapters 1, 13)

acquired immunodeficiency *See* **secondary immunodeficiency**. (Chapter 13)

activating receptors On NK cells, receptors whose stimulation results in activation of the cell's cytotoxic activity. (Chapter 3)

activation-induced cell death A process by which autoreactive T cells are induced to die if they complete thymic maturation and migrate to the periphery. (Chapter 8)

activation-induced cytidine deaminase (AID) Enzyme that initiates somatic hypermutation and isotype switching by deaminating DNA directly at cytosine in immunoglobulin V regions or switch regions. Loss of AID activity in patients leads to loss of both activities, causing hyper IgM and lack of affinity maturation. (Chapters 5, 10)

activation-induced cytidine deaminase deficiency (AID deficiency) *See* **hyper IgM syndrome**. (Chapter 10)

activator protein 1 (AP-1) A transcription factor formed as one of the outcomes of intracellular signaling by antigen receptors of lymphocytes. (Chapter 3)

active immunization Immunization with antigen to provoke adaptive immunity. (Appendix I)

acute desensitization An immunotherapeutic technique for rapidly inducing temporary tolerance to, for example, an essential drug such as insulin or penicillin in a person who is allergic to it. Also called rapid desensitization. When performed properly, it can produce symptoms of mild to moderate anaphylaxis. (Chapter 14)

acute phase In reference to HIV infection, the period that occurs soon after a person becomes infected. It is characterized by an influenza-like illness, abundant virus in the blood, and a decrease in the number of circulating CD4 T cells. (Chapter 13)

acute-phase proteins Proteins with innate immune function whose production is increased in the presence of an infection (the acute-phase response). They circulate in the blood and participate in early phases of host defense against infection. An example is mannose-binding lectin. (Chapter 3)

acute-phase response A change in the proteins present in the blood that occurs during the early phases of an infection. It includes the production of acute-phase proteins, many of which are produced in the liver. (Chapters 2, 3)

acute rejection The rejection of a tissue or organ graft from a genetically unrelated donor that occurs within 10–13 days of transplantation unless prevented by immunosuppressant treatment. (Chapter 15)

adaptive immunity Immunity to infection conferred by an adaptive immune response. (Chapter 1)

adaptors Nonenzymatic proteins that form physical links between members of a signaling pathway, particularly between a receptor and other signaling proteins. They recruit members of the signaling pathway into functional protein complexes. (Chapter 7)

ADCC *See* **antibody-dependent cell-mediated cytotoxicity**. (Chapter 3)

adenoids Paired mucosa-associated lymphoid tissue located in the nasal cavity. (Chapter 1)

adenosine deaminase (ADA) deficiency An inherited defect characterized by nonproduction of the enzyme adenosine deaminase, which leads to the accumulation of toxic purine nucleosides and nucleotides in cells, resulting in the death of most developing lymphocytes within the thymus. It is a cause of severe combined immune deficiency. (Chapter 13)

adhesins Cell-surface proteins on bacteria that enable them to bind to the surfaces of host cells. (Chapter 10)

adjuvant Any substance that enhances the immune response to an antigen with which it is mixed. (Chapters 1, 3, 9, 16)

adoptive immunity The immunity, or protection from infection, that is conferred on a recipient individual after transfer of lymphocytes from an immune donor. (Appendix I)

adoptive transfer (or **adoptive immunization**) The transfer of immune cells from one individual to another individual. Usually performed using syngeneic mice. (Appendix I)

aerobic glycolysis Originally described in tumor cells and referred to as the Warburg effect (after its discoverer, Otto Warburg), this is a form of glucose metabolism exhibited by activated lymphocytes preparing for rapid cell cycling, wherein glucose is converted into lactate instead of pyruvate to support biosynthesis of macromolecules. (Chapter 9)

afferent lymphatic vessels Vessels of the lymphatic system that drain extracellular fluid from the tissues and carry antigen, macrophages, and dendritic cells from sites of infection to lymph nodes or other peripheral lymphoid organs. (Chapter 1)

affinity The strength of binding of one molecule to another at a single site, such as the binding of a monovalent Fab fragment of antibody to a monovalent antigen. Cf. **avidity**. (Chapters 4, 5, Appendix I)

affinity chromatography Purification of a specific antigen from a complex mixture using small beads coupled to antibodies that bind to the antigen. The mixture is mixed with the antibody-coated beads, and all nonbinding components in the original mixture can be washed away. (Appendix I)

affinity hypothesis Hypothesis that proposes how the choice between negative selection and positive selection of T cells in the thymus is made, according to the strength of self-peptide:MHC binding by the T-cell receptor. Low-affinity interactions rescue the cell from death by neglect, leading to positive selection; high-affinity interactions induce apoptosis and thus negative selection. (Chapter 8)

affinity maturation The increase in affinity of antibodies for their specific antigen as an adaptive immune response progresses. This phenomenon is particularly prominent in secondary and subsequent immunizations. (Chapters 1, 10)

agammaglobulinemia An absence of antibodies in the blood. *See also* **X-linked agammaglobulinemia (XLA)**. (Chapter 13)

age-related macular degeneration (AMD) A leading cause of blindness in the elderly, for which some single-nucleotide polymorphisms (SNPs) in the factor H genes confer an increased risk. (Chapter 2)

agglutination The clumping together of particles in a solution. (Chapter 5, Appendix I)

agnathan paired receptors resembling Ag receptors (APARs) Multigene family of genes containing immunoglobulin domains present in hagfish and lamprey that possibly represent ancestral predecessors of mammalian antigen receptors. (Chapter 5)

agnathans A class of vertebrates comprising jawless fish lacking an adaptive immunity that is based on the RAG-mediated V(D)J recombination but possessing a distinct system of adaptive immunity that is based on somatically assembled VLRs. (Chapter 5)

agonist selection A process by which T cells are positively selected in the thymus by their interaction with relatively high-affinity ligands. (Chapter 12)

AID *See* **activation-induced cytidine deaminase**. (Chapter 10)

AIDS *See* **acquired immune deficiency syndrome**. (Chapters 1, 13)

AIM2 (absent in melanoma 2) A member of the PYHIN subfamily of the NLR (NOD-like receptor) family containing an N-terminal HIN domain. It activates caspase 1 in response to viral double-stranded DNA. (Chapter 3)

***AIRE* (autoimmune regulator)** Gene encoding a protein (autoimmune regulator) that is involved in the expression of numerous genes by thymic medullary epithelial cells, enabling developing T cells to be exposed to self proteins characteristic of other tissues, thereby promoting tolerance to these proteins. Deficiency of AIRE leads to an autoimmune disease, APECED. (Chapter 8)

airway tissue remodeling A thickening of the airway walls that occurs in chronic asthma due to hyperplasia and hypertrophy of the smooth muscle layer and mucus glands, with the eventual development of fibrosis. Often results in an irreversible decrease of lung function. (Chapter 14)

Akt Serine/threonine kinase activated downstream of PI 3-kinase with numerous downstream targets involved in cell growth and survival, including activation of the mTOR pathways. (Chapter 16)

alefacept Recombinant CD58–IgG1 fusion protein that blocks CD2 binding by CD58 and used in treatment of psoriasis. (Chapter 16)

alemtuzumab Antibody to CD52 used for lymphocyte depletion, such as for T-cell depletion during bone marrow allografts used in treating chronic lymphoid leukemia. (Chapter 16)

allele A variant form of a gene; many genes occur in several (or more) different forms within the general population. *See also* **heterozygous**, **homozygous**, **polymorphism**. (Chapters 4, 6)

allelic exclusion In a heterozygous individual, the expression of only one of the two alternative alleles of a particular gene. In immunology, the term describes the restricted expression of the individual chains of the antigen receptor genes, such that each individual lymphocyte produces immunoglobulin or T-cell receptors of a single antigen specificity. (Chapter 8)

allergen Any antigen that elicits an allergic reaction. (Chapter 14)

allergen desensitization An immunotherapeutic technique that aims either to change an allergic immune response to a symptom-free non-allergic response or to develop immunological tolerance to an allergen that

has been causing unpleasant clinical symptoms. The procedure involves exposing an allergic individual to increasing doses of allergen. (Chapter 14)

allergic asthma An allergic reaction to inhaled antigen, which causes constriction of the bronchi, increased production of airway mucus, and difficulty in breathing. (Chapter 14)

allergic conjunctivitis An allergic reaction involving the conjunctiva of the eye that occurs in sensitized individuals exposed to airborne allergens. It is usually manifested together with nasal allergy symptoms as allergic rhinoconjunctivitis, or hay fever. (Chapter 14)

allergic contact dermatitis A largely T cell–mediated immunological hypersensitivity reaction manifested by a skin rash at the site of contact with the allergen. Often the stimulus is a chemical agent, for example urushiol oil from the leaves of the poison ivy plant, which can haptenate normal host molecules to render them allergenic. (Chapter 14)

allergic reaction A specific response to an innocuous environmental antigen, or allergen, that is caused by sensitized B or T cells. Allergic reactions can be caused by various mechanisms, but the most common is the binding of allergen to IgE bound to mast cells, which causes the cells to release histamine and other biologically active molecules that cause the signs and symptoms of asthma, hay fever, and other common allergic responses. (Chapter 14)

allergic rhinitis An allergic reaction in the nasal mucosa that causes excess mucus production, nasal itching, and sneezing. (Chapter 14)

allergy The state in which a symptomatic immune reaction is made to a normally innocuous environmental antigen. It involves the interaction between the antigen and antibody or primed T cells produced by earlier exposure to the same antigen. (Chapter 1)

alloantibodies Antibodies produced against antigens from a genetically nonidentical member of the same species. (Chapter 15)

alloantigens Antigens from another genetically nonidentical member of the same species. (Chapter 15)

allogeneic Describes two individuals or two mouse strains that differ at genes in the MHC. The term can also be used for allelic differences at other loci. (Chapters 6, 15)

allograft A transplant of tissue from an allogeneic (genetically nonidentical) donor of the same species. Such grafts are invariably rejected unless the recipient is immunosuppressed. (Chapter 15)

allograft rejection The immunologically mediated rejection of grafted tissues or organs from a genetically nonidentical donor. It is due chiefly to recognition of nonself MHC molecules on the graft. (Chapter 1)

alloimmune response The general term for immune responses made by a host against the nonself antigens that are derived from transplanted organs. These responses can result from both direct and indirect allorecognition. (Chapter 15)

alloreaction, alloreactivity The recognition by T cells of MHC molecules other than self. Such responses are also called alloreactive responses. (Chapters 6, 15)

altered peptide ligands (APLs) Peptides in which amino acid substitutions have been made at the T-cell receptor contact positions of the peptides, which affects their binding to the receptor. (Chapter 16)

alternative pathway A form of complement activation that is initiated by spontaneous hydrolysis of C3 and which uses factor B and factor D to form the unique C3 convertase C3bBb. (Chapter 2)

alternative pathway C3 convertase The C3 convertase composed of C4b and C2a. This is also the C3 convertase of the classical complement pathway. (Chapter 2)

alternatively activated macrophages *See* **M2 macrophages**. (Chapter 11)

alum Inorganic aluminum salts (for example, aluminum phosphate and aluminum hydroxide); they act as adjuvants when mixed with antigens and are one of the few adjuvants permitted for use in humans. (Chapter 16)

alveolar macrophages Also referred to as 'dust cells'; resident macrophages within the pulmonary alveoli that are responsible for clearing inspired microbes and other particles. (Chapter 12)

amoeboid coelomocytes Phagocytic cells found in more primitive organisms (such as echinoderms and others) that carry out basic protective functions; these cells are a source of C3 homologs, thioester-containing proteins (TEPs), during infection by bacteria. (Chapter 2)

amorphic A type of genetic variation wherein the altered gene product lacks function. (Chapter 13)

amphipathic Describes molecules that have a positively charged (or hydrophilic) region separated from a hydrophobic region. (Chapter 2)

anakinra A recombinant IL-1 receptor antagonist (IL-1RA) that blocks IL-1 receptor activation and is used in treating rheumatoid arthritis. (Chapter 16)

anaphylactic shock *See* **anaphylaxis**. (Chapters 2, 14)

anaphylatoxins Pro-inflammatory complement fragments C5a and C3a released by cleavage during complement activation. They are recognized by specific receptors and recruit fluid and inflammatory cells to the site of their release. (Chapter 2)

anaphylaxis A rapid-onset and systemic allergic reaction to antigen; for example, to insect venom injected directly into the bloodstream or to foods such as peanuts. Severe systemic reactions can potentially be fatal due to circulatory collapse and suffocation from tracheal swelling. Anaphylaxis usually results from antigens binding to IgE bound by Fcε receptors on mast cells, leading to systemic release of inflammatory mediators. (Chapters 14, 16)

anchor residues Specific amino acid residues in antigenic peptides that determine peptide-binding specificity to MHC class I molecules. Anchor residues for MHC class II molecules exist but are less obvious than for MHC class I. (Chapter 4)

anergy A state of nonresponsiveness to antigen. People are said to be anergic when they cannot mount delayed-type hypersensitivity reactions to a test antigen, whereas T cells and B cells are said to be anergic when they cannot respond to their specific antigen under optimal conditions of stimulation. (Chapter 1)

angiotensin-converting enzyme 2 (ACE2) An ectoenzyme expressed on respiratory epithelial cells and other cells throughout the body that normally cleaves peptides, including the blood pressure regulator, angiotensin II. ACE2 is the host-cell entry receptor for SARS-CoV-2, bound by the receptor-binding domain (RBD) of the SARS-CoV-2 spike protein. (Chapter 12)

ankylosing spondylitis Inflammatory disease of the spine leading to vertebral fusion strongly associated with HLA-B27. (Chapter 16)

annexin V A protein that has high affinity for a plasma-membrane phospholipid, phosphatidylserine (PS). PS is normally present on the inner leaflet of the plasma membrane in healthy cells; however, cells undergoing apoptosis have PS on the outer cell surface. Addition of fluorescently labeled annexin V allows detection of the surface-exposed PS. (Appendix I)

antibody A protein that binds specifically to a particular substance—called its antigen. Each antibody molecule has a unique structure that enables it to bind specifically to its corresponding antigen, but all antibodies have the same overall structure and are known collectively as immunoglobulins. Antibodies are produced by differentiated B cells (plasma cells) in response to infection or immunization and bind to and neutralize pathogens or prepare them for uptake and destruction by phagocytes. (Chapters 1, 4)

antibody combining site *See* **antigen-binding site**. (Chapter 4)

antibody-dependent cell-mediated cytotoxicity (ADCC) The killing of antibody-coated target cells by cells with Fc receptors that recognize the constant region of the bound antibody. Most ADCC is mediated by NK cells that have the Fc receptor FcγRIII on their surface. (Chapters 3, 10, Appendix I)

antibody-directed enzyme/pro-drug therapy (ADEPT) Treatment in which an antibody is linked to an enzyme that metabolizes a nontoxic pro-drug to the active cytotoxic drug. (Chapter 16)

antibody repertoire The total variety of antibodies in the body of an individual. (Chapter 5)

antigen Any molecule that can bind specifically to an antibody or generate peptide fragments that are recognized by a T-cell receptor. (Chapters 1, 4)

antigen-binding site The site at the tip of each arm of an antibody that makes physical contact with the antigen and binds it noncovalently. The antigen specificity of the site is determined by its shape and the amino acids present. (Chapters 1, 4)

antigen-capture assay *See* **capture** (or **sandwich**) **ELISA**. (Appendix I)

antigenic determinant That portion of an antigenic molecule that is bound by the antigen-binding site of a given antibody or antigen receptor; it is also known as an epitope. (Chapters 1, 4)

antigenic drift The process by which influenza virus varies genetically in minor ways from year to year. Point mutations in viral genes cause small differences in the structure of the viral surface antigens. (Chapters 12, 13)

antigenic shift A radical change in the surface antigens of influenza virus, caused by reassortment of its segmented genome with that of another influenza virus, often from an animal. (Chapters 12, 13)

antigenic variation Alterations in surface antigens that occur in some pathogens (such as African trypanosomes) from one generation to another, which allows them to evade preexisting antibodies. (Chapter 13)

antigen presentation The display of antigen on the surface of a cell in the form of peptide fragments bound to MHC molecules. T cells recognize antigen when it is presented in this way. (Chapter 6)

antigen-presenting cells (APCs) Highly specialized cells that can process antigens and display their peptide fragments on the cell surface together with other, co-stimulatory, proteins required for activating naive T cells. The main antigen-presenting cells for naive T cells are dendritic cells, macrophages, and B cells. (Chapter 1)

antigen processing The intracellular degradation of foreign proteins into peptides that can bind to MHC molecules for presentation to T cells. All protein antigens must be processed into peptides before they can be presented by MHC molecules. (Chapter 6)

antigen receptor The cell-surface receptor by which lymphocytes recognize antigen. Each individual lymphocyte bears receptors of a single antigen specificity. (Chapter 1)

anti-lymphocyte globulin Antiserum raised in another species against human T cells. It is used in the temporary suppression of immune responses in transplantation. (Chapter 16)

antimicrobial enzymes Enzymes that kill microorganisms by their actions. An example is lysozyme, which digests bacterial cell walls. (Chapter 2)

antimicrobial peptides, antimicrobial proteins Amphipathic peptides or proteins secreted by epithelial cells and phagocytes that kill a variety of microbes nonspecifically, mainly by disrupting cell membranes. Antimicrobial peptides in humans include the defensins, the cathelicidins, the histatins, and RegIIIγ. (Chapters 1, 2)

antiserum (*pl.* antisera) The fluid component of clotted blood from an immune individual that contains antibodies against the antigen that was used for immunization. An antiserum contains a mixture of different antibodies that all bind the antigen, each of which has a different structure, its own epitope on the antigen, and its own set of cross-reactions. This heterogeneity makes each antiserum unique. (Appendix I)

antivenin Antibody raised against the venom of a poisonous snake or other organism and which can be used as an immediate treatment for the bite to neutralize the venom. (Chapters 10, 14)

aorta–gonad–mesonephros (AGM) An embryonic region in which hematopoietic cells arise during development. (Chapter 3)

AP-1 A heterodimeric transcription factor formed as one of the outcomes of intracellular signaling via the antigen receptors of lymphocytes and the TLRs of cells of innate immunity. Most often, it contains one Fos family member and one Jun family member. AP-1 mainly activates the expression of genes for cytokines and chemokines. (Chapter 7)

APECED *See* **autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy**. (Chapters 8, 13, 14)

APOBEC1 (apolipoprotein B mRNA editing catalytic polypeptide 1) An RNA-editing enzyme that deaminates cytidine to uracil in certain mRNAs, such as apolipoprotein B, and which is related to the enzyme AID involved in somatic hypermutation and isotype switching. (Chapter 10)

apoptosis A form of cell death common in the immune system, in which the cell activates an internal death program. It is characterized by nuclear DNA degradation, nuclear degeneration and condensation, and the rapid phagocytosis of cell remains. Proliferating lymphocytes experience high rates of apoptosis during their development and during immune responses. (Chapters 1, 9)

apoptosome A large, multimeric protein structure that forms in the process of apoptosis when cytochrome *c* is released from mitochondria and binds Apaf-1. A heptamer of cytochrome *c*–Apaf-1 heterodimers assembles into wheel-like structure that binds and activates pro-caspase 9, an initiator caspase, to initiate the caspase cascade. (Chapter 9)

appendix A gut-associated lymphoid tissue located at the beginning of the colon. (Chapters 1, 12)

APRIL A TNF family cytokine related to BAFF that binds the receptors TACI and BCMA on B cells to promote survival and regulate differentiation. (Chapter 10)

apurinic/apyrimidinic endonuclease-1 (APE1) A DNA repair endonuclease involved in class switch recombination. (Chapters 5, 10)

arginase-1 An enzyme that catalyzes the conversion of arginine to ornithine and urea in the last step of the urea cycle. This enzyme is highly expressed by, and is a marker for, M2 (alternatively activated) macrophages, where its degradation of arginine deprives NO synthase of its substrate for the generation of nitric oxide. The ornithine generated by this enzyme may also be directly toxic to helminths, and also stimulates smooth muscle contraction and contributes to the tissue repair response. (Chapter 11)

Artemis An endonuclease involved in the gene rearrangements that generate functional immunoglobulin and T-cell receptor genes. (Chapter 5)

Arthus reaction A local skin reaction that occurs when a sensitized individual with IgG antibodies against a particular antigen is challenged by injection of the antigen into the dermis. Antigen:IgG antibody immune complexes in the extracellular spaces in the dermis activate complement and phagocytic cells to produce a local inflammatory response. (Chapter 14)

aryl hydrocarbon receptor (AHR) A basic helix–loop–helix transcription factor that is activated by various aromatic ligands including, famously, dioxin. It functions in the normal activity of several types of immune cells including some ILCs and IELs. (Chapter 12)

ASC An adaptor protein containing pyrin and CARD domains involved in activating caspase 1 in the inflammasome. Also called PYCARD. (Chapter 3)

asymptomatic phase In reference to HIV infection, the period in which the infection is being partly held in check and no symptoms occur; it may last for many years. (Chapter 13)

ataxia telangiectasia A disease characterized by a staggering gait and multiple disorganized blood vessels and often accompanied by clinical immunodeficiency. It is caused by defects in the ATM protein, which is involved in DNA repair pathways that are also used in V(D)J recombination and class switch recombination. (Chapters 5, 10)

ATM A protein kinase that, when mutated, causes the disease ataxia telangiectasia. (Chapters 5, 10)

atopic march The clinical observation that it is common for children with atopic eczema to later develop allergic rhinitis and/or asthma. (Chapter 14)

atopy (*adj.* atopic) A genetically based increased tendency to produce IgE-mediated allergic reactions against innocuous substances. (Chapter 14)

ATP-binding cassette (ABC) A large family of proteins containing a particular domain for nucleotide binding that includes many transporters, such as TAP1 and TAP2, but also various NOD members. (Chapter 6)

attenuation The process by which human or animal pathogens are modified by growth in culture so that they can grow in their host and induce immunity without producing serious clinical disease. (Chapter 16)

atypical hemolytic uremic syndrome (aHUS) A condition characterized by damage to platelets and red blood cells and inflammation of the kidneys that is caused by uncontrolled complement activation in individuals with inherited deficiencies in complement-regulatory proteins. (Chapters 2, 13)

autoantibodies Antibodies specific for self antigens. (Chapter 15)

autoantigens A self antigen to which the immune system makes a response. (Chapter 15)

autocrine Describes a cytokine or other biologically active molecule acting on the cell that produces it. (Chapter 3)

autograft A graft of tissue from one site to another on the same individual. (Chapter 15)

autoimmune disease Disease in which the pathology is caused by adaptive immune responses to self antigens. (Chapters 1, 13, 14)

autoimmune hemolytic anemia A pathological condition with low levels of red blood cells (anemia), which is caused by autoantibodies that bind red blood cell surface antigens and target the red blood cell for destruction. (Chapter 15)

autoimmune lymphoproliferative syndrome (ALPS) An inherited syndrome in which a defect in the Fas gene leads to a failure in normal apoptosis, causing unregulated immune responses, including autoimmune responses. (Chapters 9, 11, 15)

autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) A disease characterized by a loss of tolerance to self antigens, caused by a breakdown of negative selection in the thymus. It is due to defects in the gene *AIRE*, which encodes a transcriptional regulatory protein that enables many self antigens to be expressed by thymic medullary epithelial cells. Also called autoimmune polyglandular syndrome type I. (Chapters 8, 13, 14)

autoimmune polyglandular syndrome type I *See* **autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy**. (Chapter 8)

autoimmune thrombocytopenic purpura An autoimmune disease in which antibodies against platelets are made. Antibody binding to platelets causes them to be taken up by cells with Fc receptors and complement receptors, resulting in a decrease in platelet count that leads to purpura (bleeding). (Chapter 15)

autoimmunity Adaptive immunity specific for self antigens. (Chapter 15)

autoinflammatory diseases Diseases due to unregulated inflammation in the absence of infection; they can have a variety of causes, including inherited genetic defects. (Chapter 3)

autophagosome A double bilayer membrane structure that functions in macroautophagy by engulfing cytoplasmic contents and fusing with lysosomes. (Chapter 12)

autophagy The digestion and breakdown by a cell of its own organelles and proteins in lysosomes. It may be one route by which cytosolic proteins can be processed for presentation on MHC class II molecules. (Chapters 6, 12)

avidity The sum total of the strength of binding of two molecules or cells to one another at multiple sites. It is distinct from affinity, which is the strength of binding of one site on a molecule to its ligand. (Chapters 2, 4, Appendix I)

avoidance Mechanisms that prevent a host's exposure to microbes, such as anatomic barriers or particular behaviors. (Chapter 1)

azathioprine A powerful cytotoxic drug that is converted to its active form *in vivo*, which then kills rapidly proliferating cells, including proliferating lymphocytes; it is used as an immunosuppressant to treat autoimmune disease and in transplantation. (Chapter 16)

β1i (LMP2), β2i (MECL-1), β5i (LMP7) Alternative proteasome subunits that replace the constitutive catalytic subunits β1, β2, and β5 and which are induced by interferons and produce the immunoproteasome. (Chapter 6)

β_2-microglobulin The light chain of the MHC class I proteins, encoded outside the MHC. It binds noncovalently to the heavy or α chain. (Chapter 4)

β5t Alternative proteasome subunit expressed by thymic epithelial cells that substitutes for β5 to produce the thymoproteasome involved in generating peptides encountered by thymocytes during development. (Chapter 6)

β-defensins Antimicrobial peptides made by virtually all multicellular organisms. In mammals they are produced by the epithelia of the respiratory and urogenital tracts, skin, and tongue. (Chapter 2)

β sandwich A secondary protein structure composed of two β sheets that fold such that one lies over the other, as in an immunoglobulin fold. (Chapter 4)

β sheet A secondary protein structure composed of β strands stabilized by noncovalent interactions between backbone amide and carbonyl groups. In 'parallel' β sheets, the adjacent strands run in the same direction; in 'antiparallel' β sheets, adjacent strands run in opposite directions. Immunoglobulin domains are made up of two antiparallel β sheets arranged in the form of a β barrel. (Chapter 4)

β strand A secondary protein structure in which the polypeptide backbone of several consecutive amino acids is arranged in a flat, or planar, conformation, and often illustrated as an arrow. (Chapter 4)

B-1 B cells A class of atypical, self-renewing B cells (also known as CD5 B cells) found mainly in the peritoneal and pleural cavities in adults and considered part of the innate rather than the adaptive immune system. They have a much less diverse antigen-receptor repertoire than conventional B cells and are the major source of natural antibody. (Chapters 8, 10)

B7.1 and B7.2 Cell-surface proteins on specialized antigen-presenting cells such as dendritic cells and which are the major co-stimulatory molecules for T cells. B7.1 (CD80) and B7.2 (CD86) are closely related members of the immunoglobulin superfamily, and both bind to the CD28 and CTLA-4 proteins on T cells. (Chapters 7, 9)

B and T lymphocyte attenuator (BTLA) An inhibitory CD28-related receptor expressed by B and T lymphocytes that interacts with the herpes virus entry molecule (HVEM). BTLA is a member of the TNF receptor family. (Chapter 7)

bacteria A vast kingdom of unicellular prokaryotic microorganisms, some species of which cause infectious diseases in humans and animals, while others make up most of the body's commensal microbiota. Disease-causing

bacteria may live in the extracellular spaces or inside cells in vesicles or in the cytosol. (Chapter 1)

BAFF Acronym for B-cell activating factor belonging to the TNF family, which binds the receptors BAFF-R and TACI to promote B cell survival. (Chapters 8, 10)

BAFF-R Receptor for BAFF that can activate canonical and non-canonical NFκB signaling and promote survival of B cells. (Chapter 10)

bare lymphocyte syndrome (BLS) *See* **MHC class I deficiency, MHC class II deficiency**. (Chapter 13)

base-excision repair Type of DNA repair that can lead to mutation and which is involved in somatic hypermutation and class switching in B cells. (Chapter 10)

basiliximab Antibody to human CD25 used to block IL-2 receptor signaling in T cells for treatment of rejection in renal transplantation. (Chapter 16)

basophil Type of white blood cell containing granules that stain with basic dyes. It is thought to have a function similar to that of mast cells. (Chapters 1, 3)

BATF3 A transcription factor expressed in dendritic cells belonging to the AP1 family, which includes many other factors such as c-Jun and Fos. (Chapter 6)

BCAP B-cell adaptor for PI 3-kinase (BCAP) is an adaptor that was recently found to link signaling by TLRs to activation of the PI 3-kinase and AKT pathway. (Chapter 3)

B cell, B lymphocyte One of the two types of antigen-specific lymphocytes responsible for adaptive immune responses, the other being the T cells. The function of B cells is to produce antibodies. B cells are divided into two classes. Conventional B cells have highly diverse antigen receptors and are generated in the bone marrow throughout life, emerging to populate the blood and lymphoid tissues. B-1 cells have much less diverse antigen receptors and form a population of self-renewing B cells in the peritoneal and pleural cavities. (Chapter 1)

B-cell antigen receptor, B-cell receptor (BCR) The cell-surface receptor on B cells for specific antigen. It is composed of a transmembrane immunoglobulin molecule (which recognizes antigen) associated with the invariant Igα and Igβ chains (which have a signaling function). On activation by antigen, B cells differentiate into plasma cells producing antibody molecules of the same antigen specificity as this receptor. (Chapters 1, 10)

B-cell co-receptor A transmembrane signaling receptor on the B-cell surface composed of the proteins CD19, CD81, and CD21 (complement receptor 2), which binds complement fragments on bacterial antigens also bound by the B-cell receptor. Co-ligation of this complex with the B-cell receptor increases responsiveness to antigen by about 100-fold. (Chapter 7)

B-cell co-receptor complex A transmembrane signaling receptor on the B-cell surface composed of the proteins CD19, CD81, and CD21 (complement receptor 2), which binds complement fragments on bacterial antigens also bound by the B-cell receptor. Co-ligation of this complex with the B-cell receptor increases responsiveness to antigen about 100-fold. (Chapter 10)

B-cell mitogens Any substance that nonspecifically causes B cells to proliferate. (Chapter 10)

Bcl-2 family Family of intracellular proteins that includes members that promote apoptosis (Bax, Bak, and Bok) and members that inhibit apoptosis (Bcl-2, Bcl-W, and Bcl-X_L). (Chapter 9)

Bcl-6 A transcriptional repressor that opposes differentiation of B cells into plasma cells. (Chapters 9, 10)

BCMA Receptor of the TNFR superfamily that binds APRIL. (Chapter 10)

Bcr–Abl tyrosine kinase Constitutively active tyrosine kinase fusion protein caused by a chromosomal translocation—the Philadelphia chromosome—between the *Bcr* and the *Abl* tyrosine kinase genes and which is associated with chronic myeloid leukemia. (Chapter 16)

BDCA-2 (blood dendritic cell antigen 2) A C-type lectin expressed selectively as a receptor on the surface of human plasmacytoid dendritic cells. (Chapter 3)

Berlin patient An American HIV patient, Timothy Ray Brown, who was treated in Berlin with a hematopoietic stem-cell (HSC) transplant from a donor deficient in a co-receptor for the virus (CCR5) for an unrelated illness (leukemia). He is believed to have been cured of HIV infection and is one of the only known patients in which the virus is thought to have been completely eliminated, a so-called 'sterilizing' cure. (Chapter 13)

biofilms A consortium of microorganisms (typically bacteria) that are adherent to each other and a living (biotic) surface or nonliving (abiotic) surface by an extracellular matrix composed of DNA, polysaccharide, lipid, or protein polymers. The extracellular matrix allows the consortium to establish 'residence' in a favorable ecological niche and allows for shared metabolic resources between organisms. It also shields the consortium against certain threats, such as the immune system or antibiotics. (Chapter 13)

biologics Medical treatments composed of natural proteins, such as antibodies and cytokines, and antisera or whole cells. (Chapter 16)

blast transformation Morphological changes, including an increase in size, that occur in T and B cells activated by antigen or mitogens. (Chapter 9)

Blau syndrome An inherited granulomatous disease caused by gain-of-function mutations in the NOD2 gene. (Chapters 3, 15)

BLIMP-1 A transcriptional repressor that promotes B-cell differentiation into plasma cells and suppresses proliferation, class switching, and affinity maturation. (Chapters 9, 10)

BLNK B-cell linker protein. *See* **SLP-65**. (Chapter 7)

B lymphocytes (B cells) *See* **B cells**. (Chapter 1)

bone marrow The tissue where all the cellular elements of the blood—red blood cells, white blood cells, and platelets—are initially generated from hematopoietic stem cells. The bone marrow is also the site of further B-cell development in mammals and the source of stem cells that give rise to T cells on migration to the thymus. Thus, bone marrow transplantation can restore all the cellular elements of the blood, including the cells required for adaptive immune responses. (Chapter 1)

booster immunization *See* **secondary immunization**. (Chapter 1)

bradykinin A vasoactive peptide that is produced as a result of tissue damage and acts as an inflammatory mediator. (Chapter 3)

branching (or **asymmetric division**) **model of memory-cell development** One of two general models of memory lymphocyte development that posits that memory and effector T (and B) cells arise from different daughter cells after the initial activation of naive T cells. *See also* **linear model of memory-cell development**. (Chapter 11)

broadly neutralizing antibodies Antibodies that block viral infection by multiple strains. In reference to HIV, these are antibodies that block binding of the virus to CD4 and/or chemokine co-receptors. (Chapters 10, 13)

bronchus-associated lymphoid tissue (BALT) Organized lymphoid tissue found in the bronchi in some animals. Adult humans do not normally have such organized lymphoid tissue in the respiratory tract, but it may be present in some infants and children. (Chapters 1, 12)

Bruton's tyrosine kinase (Btk) A Tec family tyrosine kinase important in B-cell receptor signaling. Btk is mutated in the human immunodeficiency disease X-linked agammaglobulinemia. (Chapter 7)

Bruton's X-linked agammaglobulinemia *See* **X-linked agammaglobulinemia**. (Chapters 8, 13)

BST2 (bone marrow stromal antigen 2) Bone marrow stromal antigen 2, also called tetherin and CD317, is a type II integral membrane protein that functions as a viral restriction element trapping virions in the plasma membrane

and inhibiting viral budding and which serves as a marker of plasmacytoid dendritic cells (pDCs), but is also expressed by B cells. (Chapter 3)

bursa of Fabricius Lymphoid organ associated with the gut that is the site of B-cell development in chickens. (Chapters 1, 5, 12)

butyrate A short-chain fatty acid produced abundantly by anaerobic digestion of carbohydrates in the intestine by commensals and which can influence host cells in several ways, acting as an energy source for enterocytes and as an inhibitor of histone deacetylases. (Chapter 12)

butyrophilin (BTN) A subtype of surface membrane glycoprotein within the immunoglobulin superfamily comprising approximately 11 unique members, expressed on a variety of somatic tissues and composed of typically two extracellular immunoglobulin domains. (Chapters 6, 12)

C1 complex (C1) Protein complex activated as the first step in the classical pathway of complement activation, composed of C1q bound to two molecules each of the proteases C1r and C1s. Binding of a pathogen or antibody to C1q activates C1r, which cleaves and activates C1s, which cleaves C4 and C2. (Chapter 2)

C1 inhibitor (C1INH) An inhibitor protein for C1 that binds and inactivates C1r:C1s enzymatic activity. Deficiency in C1INH causes hereditary angioedema through production of vasoactive peptides that cause subcutaneous and laryngeal swelling. (Chapter 2)

C1q A component of the C1 complex formed by a hexamer of trimers of a polypeptide with a globular domain that can bind bacterial surfaces or interact with Fc regions of antibodies and a carboxy-terminal collagen-like domain that mediates its assembly and association with C1r and C1s. (Chapter 2)

C1r A serine protease that associates with C1q and C1s to help form the C1 complex. Its autocatalytic activity is triggered by conformational changes resulting from C1q binding to Fc or bacterial surfaces; C1r then cleaves C1s. (Chapter 2)

C1s A serine protease that associates with C1q and C1r to help form the C1 complex. It is cleaved and activated by C1r and then functions to activate the downstream complement components 4 and 2 (C4 and C2). (Chapter 2)

C2 Complement protein of the classical and lectin pathways that is cleaved by the C1 complex to yield C2b and C2a. C2a is an active protease that forms part of the classical C3 convertase C4b2a. (Chapter 2)

C2a The large fragment of C2 formed when C2 is cleaved by C1s. When bound to C4b, C2a is the serine protease of the C3 convertase (C4b2a) of the classical and the lectin pathways. (Chapter 2)

C3 Complement protein on which all complement activation pathways converge. C3 cleavage forms C3b, which can bind covalently to microbial surfaces, where it promotes destruction by phagocytes. (Chapter 2)

C3 convertase Enzyme complex that cleaves C3 to C3b and C3a on the surface of a pathogen. The C3 convertase of the classical and lectin pathways is formed from membrane-bound C4b complexed with the protease C2a. The alternative pathway C3 convertase is formed from membrane-bound C3b complexed with the protease Bb. (Chapter 2)

C3a *See* **anaphylatoxins**. (Chapter 2)

C3b *See* **C3**. (Chapter 2)

C3bBb The C3 convertase of the alternative pathway of complement activation. (Chapter 2)

$C3b_2Bb$ The C5 convertase of the alternative pathway of complement activation. (Chapter 2)

C3dg Breakdown product of iC3b that remains attached to the microbial surface, where it can bind complement receptor 2 (CR2). (Chapter 2)

C3f A small fragment of C3b that is removed by factor I and MCP to leave iC3b on the microbial surface. (Chapter 2)

C3 glomerulopathy An inflammatory condition in the kidney in which C3b is abnormally deposited in the glomerulus leading to proteinuria and hematuria. It can be associated with autoantibodies, called nephritic factors, that can inhibit factor H, other complement-regulatory components, or that stabilize C3 convertase, leading to increased C3 deposition. (Chapter 2)

$C3(H_2O)Bb$ *See* **fluid-phase C3 convertase**. (Chapter 2)

C4 Complement protein of the classical and lectin pathways. C4 is cleaved by C1s to C4b, which forms part of the classical C3 convertase. (Chapter 2)

C4b-binding protein (C4BP) A complement-regulatory protein that inactivates the classical pathway C3 convertase formed on host cells by displacing C2a from the C4b2a complex. C4BP binds C4b attached to host cells, but cannot bind C4b attached to pathogens. (Chapter 2)

C4b2a C3 convertase of the classical and lectin pathways of complement activation. (Chapter 2)

C4b2a3b C5 convertase of the classical and lectin pathways of complement activation. (Chapter 2)

C5 convertase Enzyme complex that cleaves C5 to C5a and C5b. (Chapter 2)

C5a *See* **anaphylatoxins**. (Chapter 2)

C5a receptor 1 A G protein–coupled receptor expressed by macrophages and activated by C5a that facilitates ingestion of opsonized bacteria bound to CR1. (Chapter 2)

C5a receptor 2 A nonsignaling surface receptor expressed by neutrophils and macrophages and which may act as a decoy receptor for C5a and thus regulate activity of the C5a receptor. (Chapter 2)

C5b Fragment of C5 that initiates the formation of the membrane-attack complex (MAC). (Chapter 2)

C6, C7, C8, C9 Complement proteins that act with C5b to form the membrane-attack complex, producing a pore that leads to lysis of the target cell. (Chapter 2)

calcineurin A cytosolic serine/threonine phosphatase with a crucial role in signaling via the T-cell receptor. The immunosuppressive drugs cyclosporin A and tacrolimus inactivate calcineurin, suppressing T-cell responses. (Chapters 7, 16)

calmodulin Calcium-binding protein that is activated by binding Ca^{2+}; it is then able to bind to and regulate the activity of a wide variety of enzymes. (Chapter 7)

calnexin A chaperone protein in the endoplasmic reticulum (ER) that binds to partly folded members of the immunoglobulin superfamily of proteins and retains them in the ER until folding is complete. (Chapter 6)

calprotectin A complex of heterodimers of the antimicrobial peptides S100A8 and S100A9, which sequester zinc and manganese from microbes. Produced in abundance by neutrophils and in lesser amounts by macrophages and epithelial cells. (Chapters 2, 11)

calreticulin A chaperone protein in the endoplasmic reticulum that, together with ERp57 and tapasin, forms the peptide-loading complex that loads peptides onto newly synthesized MHC class I molecules. (Chapter 6)

cancer immunoediting A process that occurs during the development of a cancer when it is acquiring mutations that favor its survival and escape from immune responses, such that cancer cells with these mutations are selected for survival and growth. (Chapter 16)

cancer-testis antigens Proteins expressed by cancer cells that are normally expressed only in male germ cells in the testis. (Chapter 16)

canonical NFκB pathway This pathway relies on activation of the IκB kinase, or IKK, composed of IKKα, IKKβ, and IKKγ (NEMO). IKKβ phosphorylation by an upstream kinase, such as TAK1, activates IKK, which in turn phosphorylates IκB (inhibitor of κB), causing IκB degradation and release of the active NFκB p50:p65 heterodimer. (Chapter 10)

capping A process occurring in the nucleus in which the modified purine 7-methylguanosine is added to the 5′-phosphate of the first nucleotide of the RNA transcript. (Chapter 3)

capsular polysaccharides *See* **capsulated bacteria**. (Chapter 16)

capsulated bacteria Referring to bacteria surrounded by a polysaccharide shell that resists actions of phagocytes, resulting in pus formation at the site of infection. Also called pyogenic (pus-forming) bacteria. (Chapters 10, 16)

capture (or **sandwich**) **ELISA** An ELISA in which two antibodies recognizing different epitopes on the antigen are utilized. The first antibody is adhered to the assay plate well. The sample being tested is added, allowing antigen to bind. The bound antigen is detected with a second enzyme-linked antibody, followed by addition of substrate and measurement of the quantity of reaction product produced. This is also known as an antigen-capture assay. (Appendix I)

carboxypeptidase N (CPN) A metalloproteinase that inactivates C3a and C5a. CPN deficiency causes a condition of recurrent angioedema. (Chapter 2)

cardiolipin A lipid found in many bacteria and in the inner mitochondrial membrane that is a ligand recognized by some human γδ T cells. (Chapter 6)

caspase 1 Also known as interleukin-1 converting enzyme (ICE), caspase 1 is a protease that becomes activated in the inflammasome response, and which then functions to process a variety of targets, such as the pro-forms of IL-1β and IL-18, and gasdermin D. (Chapter 3)

caspase 4, caspase 5 These human proteases are cytosolic sensors, counterparts to mouse caspase 11, that are activated by LPS and directly cleave and activate gasdermin D, leading to pyroptosis. (Chapter 3)

caspase 8 An initiator caspase activated by various receptors that activates the process of apoptosis. (Chapter 3)

caspase 11 This caspase is homologous to human caspase 4 and caspase 5. Its expression is induced by TLR signaling. Intracellular LPS can directly activate it, leading to pyroptosis. (Chapter 3)

caspase recruitment domain (CARD) A protein domain present in some receptor tails that can dimerize with other CARD-containing proteins, including caspases, thus recruiting them into signaling pathways. (Chapter 3)

caspases A family of cysteine proteases that cleave proteins at aspartic acid residues. They have important roles in apoptosis and in the processing of cytokine pro-polypeptides. (Chapter 3)

cathelicidins Family of antimicrobial peptides that in humans has one member. (Chapter 2)

cathelin A cathepsin L inhibitor. (Chapter 2)

cathepsins A family of proteases using cysteine at their active site and which frequently function in processing antigens taken into the vesicular pathway. (Chapter 6)

cation-pi interaction Chemical interaction between a cation (e.g., Na^+) and the pi-electron system of an aromatic moiety. (Chapter 4)

CC chemokines One of the two main classes of chemokines, distinguished by two adjacent cysteines (C) near the amino terminus. They have names CCL1, CCL2, etc. *See* eAppendix IV for a list of individual chemokines. (Chapter 3)

CCL19 Chemokine made by dendritic cells and stromal cells in T-cell zones of lymph nodes that binds CCR7 and functions to attract naive T cells. (Chapters 9, 10, 12)

CCL21 Chemokine made by dendritic cells and stromal cells in T-cell zones of lymph nodes that binds CCR7 and functions to attract naive T cells. (Chapters 9, 10, 12)

CCL25 (TECK) Chemokine made by small-intestinal epithelial cells that binds CCR9 to recruit gut-homing T and B cells. (Chapter 12)

CCL28 (MEC, mucosal epithelial chemokine) Chemokine made by colonic intestinal cells, salivary gland cells, and lactating mammary gland cells that binds CCR10 to recruit B lymphocytes producing IgA into these tissues. (Chapter 12)

CCR7 Chemokine receptor expressed by all naive T and B cells, and some memory T and B cells, such as central memory T cells, and which binds CCL19 and CCL21 made by dendritic cells and stromal cells in lymphoid tissues. (Chapters 9, 10, 12)

CCR9 Chemokine receptor expressed by dendritic cells, T cells, thymocytes, and some γδ T cells that binds CCL25 and mediates recruitment of gut-homing cells. (Chapter 12)

CCR10 Chemokine receptor expressed by many cells that binds CCL27 and CCL28 and mediates intestinal recruitment of IgA-producing B lymphocytes. (Chapter 12)

CD1 Small family of MHC class I–like proteins that are not encoded in the MHC and can present glycolipid antigens to CD4 T cells. (Chapter 6)

CD3 complex The invariant proteins CD3γ, δ, and ε, and the dimeric ζ chains, which form the signaling complex of the T-cell receptor. Each of them contains one or more ITAM signaling motifs in their cytoplasmic tails. (Chapter 7)

CD4 The co-receptor for T-cell receptors that recognize peptide antigens bound to MHC class II molecules. It binds to the lateral face of the MHC molecule. (Chapters 1, 4)

CD8 The co-receptor for T-cell receptors that recognize peptide antigens bound to MHC class I molecules. It binds to the lateral face of the MHC molecule. (Chapters 1, 4)

CD8αα Homodimer of CD8α molecule that is up-regulated on natural and peripheral IELs in the intestinal epithelium. Recognizes the nonclassical MHC molecule TL (thymus leukemia antigen) on intestinal epithelial cells, loss of which may trigger cytolytic NK-like activity of IELs. May also provide a survival signal for IELs. (Chapters 9, 12)

CD11b (α_M integrin) Integrin expressed by macrophages and some dendritic cells that functions with β2 integrin (CD18) as complement receptor 3 (CR3). (Chapter 9)

CD11c (a_X integrin) Integrin expressed at high levels by dendritic cells and at lower levels by some other myeloid cells that functions with β2 integrin (CD18) as both an adhesion molecule and complement receptor 4 (CR4). (Chapter 9)

CD19 *See* **B-cell co-receptor**. (Chapter 7)

CD21 Another name for complement receptor 2 (CR2). *See also* **B-cell co-receptor**. (Chapters 2, 7, 10)

CD22 An inhibitory receptor on B cells that binds sialic acid–modified glycoproteins commonly found on mammalian cells and contains an ITIM motif in its cytoplasmic tail. (Chapter 7)

CD23 The low-affinity Fc receptor for IgE. (Chapter 14)

CD24 A GPI-linked sialoprotein that is expressed by conventional dendritic cells. (Chapter 9)

CD25 Also known as IL-2 receptor α (IL-2Rα), this is the high-affinity component of the IL-2 receptor, which also includes IL-2Rβ and the common γ chain. It is up-regulated by activated T cells and is constitutively expressed by T_{reg} cells to confer responsiveness to IL-2. (Chapter 9)

CD27 A TNF receptor family protein constitutively expressed on naive T cells that binds CD70 on dendritic cells and delivers a potent co-stimulatory signal to T cells early in the activation process. (Chapter 11)

CD28 An activating receptor on T cells that binds to the B7 co-stimulatory molecules present on specialized antigen-presenting cells such as dendritic cells. CD28 is the major co-stimulatory receptor on naive T cells. (Chapters 7, 9)

and inhibiting viral budding and which serves as a marker of plasmacytoid dendritic cells (pDCs), but is also expressed by B cells. (Chapter 3)

bursa of Fabricius Lymphoid organ associated with the gut that is the site of B-cell development in chickens. (Chapters 1, 5, 12)

butyrate A short-chain fatty acid produced abundantly by anaerobic digestion of carbohydrates in the intestine by commensals and which can influence host cells in several ways, acting as an energy source for enterocytes and as an inhibitor of histone deacetylases. (Chapter 12)

butyrophilin (BTN) A subtype of surface membrane glycoprotein within the immunoglobulin superfamily comprising approximately 11 unique members, expressed on a variety of somatic tissues and composed of typically two extracellular immunoglobulin domains. (Chapters 6, 12)

C1 complex (C1) Protein complex activated as the first step in the classical pathway of complement activation, composed of C1q bound to two molecules each of the proteases C1r and C1s. Binding of a pathogen or antibody to C1q activates C1r, which cleaves and activates C1s, which cleaves C4 and C2. (Chapter 2)

C1 inhibitor (C1INH) An inhibitor protein for C1 that binds and inactivates C1r:C1s enzymatic activity. Deficiency in C1INH causes hereditary angioedema through production of vasoactive peptides that cause subcutaneous and laryngeal swelling. (Chapter 2)

C1q A component of the C1 complex formed by a hexamer of trimers of a polypeptide with a globular domain that can bind bacterial surfaces or interact with Fc regions of antibodies and a carboxy-terminal collagen-like domain that mediates its assembly and association with C1r and C1s. (Chapter 2)

C1r A serine protease that associates with C1q and C1s to help form the C1 complex. Its autocatalytic activity is triggered by conformational changes resulting from C1q binding to Fc or bacterial surfaces; C1r then cleaves C1s. (Chapter 2)

C1s A serine protease that associates with C1q and C1r to help form the C1 complex. It is cleaved and activated by C1r and then functions to activate the downstream complement components 4 and 2 (C4 and C2). (Chapter 2)

C2 Complement protein of the classical and lectin pathways that is cleaved by the C1 complex to yield C2b and C2a. C2a is an active protease that forms part of the classical C3 convertase C4b2a. (Chapter 2)

C2a The large fragment of C2 formed when C2 is cleaved by C1s. When bound to C4b, C2a is the serine protease of the C3 convertase (C4b2a) of the classical and the lectin pathways. (Chapter 2)

C3 Complement protein on which all complement activation pathways converge. C3 cleavage forms C3b, which can bind covalently to microbial surfaces, where it promotes destruction by phagocytes. (Chapter 2)

C3 convertase Enzyme complex that cleaves C3 to C3b and C3a on the surface of a pathogen. The C3 convertase of the classical and lectin pathways is formed from membrane-bound C4b complexed with the protease C2a. The alternative pathway C3 convertase is formed from membrane-bound C3b complexed with the protease Bb. (Chapter 2)

C3a *See* **anaphylatoxins**. (Chapter 2)

C3b *See* **C3**. (Chapter 2)

C3bBb The C3 convertase of the alternative pathway of complement activation. (Chapter 2)

$C3b_2Bb$ The C5 convertase of the alternative pathway of complement activation. (Chapter 2)

C3dg Breakdown product of iC3b that remains attached to the microbial surface, where it can bind complement receptor 2 (CR2). (Chapter 2)

C3f A small fragment of C3b that is removed by factor I and MCP to leave iC3b on the microbial surface. (Chapter 2)

C3 glomerulopathy An inflammatory condition in the kidney in which C3b is abnormally deposited in the glomerulus leading to proteinuria and hematuria. It can be associated with autoantibodies, called nephritic factors, that can inhibit factor H, other complement-regulatory components, or that stabilize C3 convertase, leading to increased C3 deposition. (Chapter 2)

$C3(H_2O)Bb$ *See* **fluid-phase C3 convertase**. (Chapter 2)

C4 Complement protein of the classical and lectin pathways. C4 is cleaved by C1s to C4b, which forms part of the classical C3 convertase. (Chapter 2)

C4b-binding protein (C4BP) A complement-regulatory protein that inactivates the classical pathway C3 convertase formed on host cells by displacing C2a from the C4b2a complex. C4BP binds C4b attached to host cells, but cannot bind C4b attached to pathogens. (Chapter 2)

C4b2a C3 convertase of the classical and lectin pathways of complement activation. (Chapter 2)

C4b2a3b C5 convertase of the classical and lectin pathways of complement activation. (Chapter 2)

C5 convertase Enzyme complex that cleaves C5 to C5a and C5b. (Chapter 2)

C5a *See* **anaphylatoxins**. (Chapter 2)

C5a receptor 1 A G protein–coupled receptor expressed by macrophages and activated by C5a that facilitates ingestion of opsonized bacteria bound to CR1. (Chapter 2)

C5a receptor 2 A nonsignaling surface receptor expressed by neutrophils and macrophages and which may act as a decoy receptor for C5a and thus regulate activity of the C5a receptor. (Chapter 2)

C5b Fragment of C5 that initiates the formation of the membrane-attack complex (MAC). (Chapter 2)

C6, C7, C8, C9 Complement proteins that act with C5b to form the membrane-attack complex, producing a pore that leads to lysis of the target cell. (Chapter 2)

calcineurin A cytosolic serine/threonine phosphatase with a crucial role in signaling via the T-cell receptor. The immunosuppressive drugs cyclosporin A and tacrolimus inactivate calcineurin, suppressing T-cell responses. (Chapters 7, 16)

calmodulin Calcium-binding protein that is activated by binding Ca^{2+}; it is then able to bind to and regulate the activity of a wide variety of enzymes. (Chapter 7)

calnexin A chaperone protein in the endoplasmic reticulum (ER) that binds to partly folded members of the immunoglobulin superfamily of proteins and retains them in the ER until folding is complete. (Chapter 6)

calprotectin A complex of heterodimers of the antimicrobial peptides S100A8 and S100A9, which sequester zinc and manganese from microbes. Produced in abundance by neutrophils and in lesser amounts by macrophages and epithelial cells. (Chapters 2, 11)

calreticulin A chaperone protein in the endoplasmic reticulum that, together with ERp57 and tapasin, forms the peptide-loading complex that loads peptides onto newly synthesized MHC class I molecules. (Chapter 6)

cancer immunoediting A process that occurs during the development of a cancer when it is acquiring mutations that favor its survival and escape from immune responses, such that cancer cells with these mutations are selected for survival and growth. (Chapter 16)

cancer-testis antigens Proteins expressed by cancer cells that are normally expressed only in male germ cells in the testis. (Chapter 16)

canonical NFκB pathway This pathway relies on activation of the IκB kinase, or IKK, composed of IKKα, IKKβ, and IKKγ (NEMO). IKKβ phosphorylation by an upstream kinase, such as TAK1, activates IKK, which in turn phosphorylates IκB (inhibitor of κB), causing IκB degradation and release of the active NFκB p50:p65 heterodimer. (Chapter 10)

capping A process occurring in the nucleus in which the modified purine 7-methylguanosine is added to the 5′-phosphate of the first nucleotide of the RNA transcript. (Chapter 3)

capsular polysaccharides *See* **capsulated bacteria**. (Chapter 16)

capsulated bacteria Referring to bacteria surrounded by a polysaccharide shell that resists actions of phagocytes, resulting in pus formation at the site of infection. Also called pyogenic (pus-forming) bacteria. (Chapters 10, 16)

capture (or **sandwich**) **ELISA** An ELISA in which two antibodies recognizing different epitopes on the antigen are utilized. The first antibody is adhered to the assay plate well. The sample being tested is added, allowing antigen to bind. The bound antigen is detected with a second enzyme-linked antibody, followed by addition of substrate and measurement of the quantity of reaction product produced. This is also known as an antigen-capture assay. (Appendix I)

carboxypeptidase N (CPN) A metalloproteinase that inactivates C3a and C5a. CPN deficiency causes a condition of recurrent angioedema. (Chapter 2)

cardiolipin A lipid found in many bacteria and in the inner mitochondrial membrane that is a ligand recognized by some human γδ T cells. (Chapter 6)

caspase 1 Also known as interleukin-1 converting enzyme (ICE), caspase 1 is a protease that becomes activated in the inflammasome response, and which then functions to process a variety of targets, such as the pro-forms of IL-1β and IL-18, and gasdermin D. (Chapter 3)

caspase 4, caspase 5 These human proteases are cytosolic sensors, counterparts to mouse caspase 11, that are activated by LPS and directly cleave and activate gasdermin D, leading to pyroptosis. (Chapter 3)

caspase 8 An initiator caspase activated by various receptors that activates the process of apoptosis. (Chapter 3)

caspase 11 This caspase is homologous to human caspase 4 and caspase 5. Its expression is induced by TLR signaling. Intracellular LPS can directly activate it, leading to pyroptosis. (Chapter 3)

caspase recruitment domain (CARD) A protein domain present in some receptor tails that can dimerize with other CARD-containing proteins, including caspases, thus recruiting them into signaling pathways. (Chapter 3)

caspases A family of cysteine proteases that cleave proteins at aspartic acid residues. They have important roles in apoptosis and in the processing of cytokine pro-polypeptides. (Chapter 3)

cathelicidins Family of antimicrobial peptides that in humans has one member. (Chapter 2)

cathelin A cathepsin L inhibitor. (Chapter 2)

cathepsins A family of proteases using cysteine at their active site and which frequently function in processing antigens taken into the vesicular pathway. (Chapter 6)

cation-pi interaction Chemical interaction between a cation (e.g., Na^+) and the pi-electron system of an aromatic moiety. (Chapter 4)

CC chemokines One of the two main classes of chemokines, distinguished by two adjacent cysteines (C) near the amino terminus. They have names CCL1, CCL2, etc. *See* eAppendix IV for a list of individual chemokines. (Chapter 3)

CCL19 Chemokine made by dendritic cells and stromal cells in T-cell zones of lymph nodes that binds CCR7 and functions to attract naive T cells. (Chapters 9, 10, 12)

CCL21 Chemokine made by dendritic cells and stromal cells in T-cell zones of lymph nodes that binds CCR7 and functions to attract naive T cells. (Chapters 9, 10, 12)

CCL25 (TECK) Chemokine made by small-intestinal epithelial cells that binds CCR9 to recruit gut-homing T and B cells. (Chapter 12)

CCL28 (MEC, mucosal epithelial chemokine) Chemokine made by colonic intestinal cells, salivary gland cells, and lactating mammary gland cells that binds CCR10 to recruit B lymphocytes producing IgA into these tissues. (Chapter 12)

CCR7 Chemokine receptor expressed by all naive T and B cells, and some memory T and B cells, such as central memory T cells, and which binds CCL19 and CCL21 made by dendritic cells and stromal cells in lymphoid tissues. (Chapters 9, 10, 12)

CCR9 Chemokine receptor expressed by dendritic cells, T cells, thymocytes, and some γδ T cells that binds CCL25 and mediates recruitment of gut-homing cells. (Chapter 12)

CCR10 Chemokine receptor expressed by many cells that binds CCL27 and CCL28 and mediates intestinal recruitment of IgA-producing B lymphocytes. (Chapter 12)

CD1 Small family of MHC class I–like proteins that are not encoded in the MHC and can present glycolipid antigens to CD4 T cells. (Chapter 6)

CD3 complex The invariant proteins CD3γ, δ, and ε, and the dimeric ζ chains, which form the signaling complex of the T-cell receptor. Each of them contains one or more ITAM signaling motifs in their cytoplasmic tails. (Chapter 7)

CD4 The co-receptor for T-cell receptors that recognize peptide antigens bound to MHC class II molecules. It binds to the lateral face of the MHC molecule. (Chapters 1, 4)

CD8 The co-receptor for T-cell receptors that recognize peptide antigens bound to MHC class I molecules. It binds to the lateral face of the MHC molecule. (Chapters 1, 4)

CD8αα Homodimer of CD8α molecule that is up-regulated on natural and peripheral IELs in the intestinal epithelium. Recognizes the nonclassical MHC molecule TL (thymus leukemia antigen) on intestinal epithelial cells, loss of which may trigger cytolytic NK-like activity of IELs. May also provide a survival signal for IELs. (Chapters 9, 12)

CD11b (α_M integrin) Integrin expressed by macrophages and some dendritic cells that functions with β2 integrin (CD18) as complement receptor 3 (CR3). (Chapter 9)

CD11c (a_X integrin) Integrin expressed at high levels by dendritic cells and at lower levels by some other myeloid cells that functions with β2 integrin (CD18) as both an adhesion molecule and complement receptor 4 (CR4). (Chapter 9)

CD19 *See* **B-cell co-receptor**. (Chapter 7)

CD21 Another name for complement receptor 2 (CR2). *See also* **B-cell co-receptor**. (Chapters 2, 7, 10)

CD22 An inhibitory receptor on B cells that binds sialic acid–modified glycoproteins commonly found on mammalian cells and contains an ITIM motif in its cytoplasmic tail. (Chapter 7)

CD23 The low-affinity Fc receptor for IgE. (Chapter 14)

CD24 A GPI-linked sialoprotein that is expressed by conventional dendritic cells. (Chapter 9)

CD25 Also known as IL-2 receptor α (IL-2Rα), this is the high-affinity component of the IL-2 receptor, which also includes IL-2Rβ and the common γ chain. It is up-regulated by activated T cells and is constitutively expressed by T_{reg} cells to confer responsiveness to IL-2. (Chapter 9)

CD27 A TNF receptor family protein constitutively expressed on naive T cells that binds CD70 on dendritic cells and delivers a potent co-stimulatory signal to T cells early in the activation process. (Chapter 11)

CD28 An activating receptor on T cells that binds to the B7 co-stimulatory molecules present on specialized antigen-presenting cells such as dendritic cells. CD28 is the major co-stimulatory receptor on naive T cells. (Chapters 7, 9)

CD31 A cell-adhesion molecule found both on lymphocytes and at endothelial cell junctions. CD31–CD31 interactions are thought to enable leukocytes to leave blood vessels and enter tissues. (Chapter 3)

CD35 *See* **CR1**. (Chapter 2)

CD40, CD40 ligand (CD40L) CD40 on B cells and CD40 ligand (CD40L, or CD154) on activated helper T cells are co-stimulatory molecules whose interaction is required for the proliferation and class switching of antigen-activated naive B cells. CD40 is also expressed by dendritic cells, and here the CD40–CD40L interaction provides co-stimulatory signals to naive T cells. (Chapters 10, 16)

CD40 ligand deficiency An immunodeficiency disease in which little or no IgG, IgE, or IgA antibody is produced and even IgM responses are deficient, but serum IgM levels are normal to high. It is due to a defect in the gene encoding CD40 ligand (CD154), which prevents class switching from occurring. Also known as X-linked hyper IgM syndrome, reflecting the location of the gene that encodes CD40L on the X chromosome and the phenotype of elevated IgM antibody relative to other immunoglobulins. (Chapters 11, 13)

CD44 Also known as phagocytic glycoprotein-1 (Pgp1), CD44 is a cell-surface glycoprotein expressed by naive lymphocytes and up-regulated on activated T cells. It is a receptor for hyaluronic acid and functions in cell–cell and cell–extracellular matrix adhesion. High expression of CD44 is used as a marker for effector and memory T cells. (Chapter 11)

CD45 A transmembrane tyrosine phosphatase found on all leukocytes. It is expressed in different isoforms on different cell types, including the different subtypes of T cells. Also called leukocyte common antigen, it is a generic marker for hematopoietically derived cells, with the exception of erythrocytes. (Chapters 3, 7)

CD45RA A full-length variant of CD45 that serves as a marker for naive human T cells. (Chapter 11)

CD45RO An alternatively spliced variant of CD45 that serves as a marker for memory T cells. (Chapter 11)

CD48 *See* **2B4**. (Chapter 3)

CD59, protectin Cell-surface protein that protects host cells from complement damage by blocking binding of C9 to the C5b678 complex, thus preventing MAC formation. (Chapter 2)

CD69 A cell-surface protein that is rapidly expressed by antigen-activated T cells. It acts to down-modulate the expression of the sphingosine 1-phosphate receptor 1 (S1PR1), thereby retaining activated T cells within T-cell zones of secondary lymphoid tissues as they divide and differentiate into effector T cells. (Chapter 9)

CD70 The ligand for CD27 that is expressed on activated dendritic cells and delivers a potent co-stimulatory signal to T cells early in the activation process. (Chapter 11)

CD81 *See* **B-cell co-receptor**. (Chapter 7)

CD84 *See* **SLAM**. (Chapter 10)

CD86 (B7-2) A transmembrane protein of the immunoglobulin superfamily that is expressed on antigen-presenting cells and binds to CD28 expressed by T cells. (Chapter 6)

CD94 A C-type lectin that is a subunit of the killer cell lectin-like receptors (KLRs) of NK cells. (Chapter 3)

CD103 Integrin $\alpha_E\beta_7$, a cell-surface marker on a subset of dendritic cells in the gastrointestinal tract that are involved in inducing tolerance to antigens from food and the commensal microbiota. Note that CD103 is often used to refer to the $\alpha_E\beta_7$ heterodimer despite strictly referring only to the α_E molecule. *See* **α_E integrin**. (Chapter 9)

CD127 Also known as IL-7 receptor α (IL-7Rα), which pairs with the common γ chain of the IL-2 receptor family to form the IL-7 receptor. It is expressed by naive T cells and a subset of memory T cells to support their survival. (Chapter 11)

cDC1 Type 1 conventional dendritic cell. A subset of conventional dendritic cell (cDC) that is specialized for the priming of CD8 T cells and for recruiting CD4 T-cell help for CD8 T-cell priming. These cDCs are responsible for cross-priming. (Chapter 9)

cDC2 Type 2 conventional dendritic cell. A subset of conventional dendritic cell (cDC) that is specialized for the priming of CD4 T cells. (Chapter 9)

celiac disease A chronic condition of the upper small intestine caused by an immune response directed at gluten, a complex of proteins present in wheat, oats, and barley. The gut wall becomes chronically inflamed, the villi are destroyed, and the gut's ability to absorb nutrients is compromised. (Chapters 12, 14)

cell-adhesion molecules Cell-surface proteins of several different types that mediate the binding of one cell to other cells or to extracellular matrix proteins. Integrins, selectins, and members of the immunoglobulin gene superfamily (such as ICAM-1) are among the cell-adhesion molecules important in the operation of the immune system. (Chapter 3)

cell-mediated immune responses An adaptive immune response in which antigen-specific effector T cells have the main role. The immunity to infection conferred by such a response is called cell-mediated immunity. A primary cell-mediated immune response is the T-cell response that occurs the first time a particular antigen is encountered. (Chapter 1)

cell-mediated immunity Immunity that can be transferred to a recipient individual by transfer of lymphocytes, but not by transfer of serum, from an immune donor. (Appendix I)

cellular hypersensitivity reactions A hypersensitivity reaction mediated largely by antigen-specific T lymphocytes. (Chapter 14)

cellular immunology The study of the cellular basis of immunity. (Chapter 1)

cellular tropism The host-cell types that are infected by a particular pathogen. (Chapter 12)

central lymphoid organs, central lymphoid tissues The sites of lymphocyte development; in humans, these are the bone marrow and thymus. B lymphocytes develop in bone marrow, whereas T lymphocytes develop within the thymus from bone marrow–derived progenitors. Also called the primary lymphoid organs and tissues. (Chapters 1, 8)

central memory T (T_{CM}) cells Memory lymphocytes that express CCR7 and recirculate between blood and secondary lymphoid tissues similarly to naive T cells. They require restimulation in secondary lymphoid tissues to become fully mature effector T cells. (Chapter 11)

central tolerance Immunological tolerance to self antigens that is established while lymphocytes are developing in central lymphoid organs. Cf. **peripheral tolerance**. (Chapters 8, 9, 15)

centroblasts Large, rapidly dividing activated B cells present in the dark zone of germinal centers in follicles of peripheral lymphoid organs. (Chapter 10)

centrocytes Small B cells that derive from centroblasts in the germinal centers of follicles in peripheral lymphoid organs; they populate the light zone of the germinal center. (Chapter 10)

cGAS (cyclic GAMP synthase) A cytosolic enzyme that is activated by double-stranded DNA to form cyclic guanosine monophosphate–adenosine monophosphate. *See* **cyclic dinucleotides (CDNs)**. (Chapter 3)

Charcot–Leyden crystals These result from the crystallization in tissues of the abundant protein galectin-10, which is abundantly produced by eosinophils. In chronic inflammation where eosinophils accumulate and die, this protein may acquire a crystalline form, which appears to be inherently inflammatory because of direct NLRP3 activation, thus producing positive feedback that may perpetuate the allergic state. (Chapter 14)

checkpoint blockade Approach to tumor therapy that attempts to interfere with the normal inhibitory signals that regulate lymphocytes. (Chapters 7, 13, 16)

checkpoint inhibitors Cancer therapeutics that target immune checkpoints to activate immune responses against cancers that have evaded immune attack by triggering immune checkpoints. (Chapter 9)

Chediak–Higashi syndrome A defect in phagocytic cell function caused by a defect in a protein involved in intracellular vesicle fusion. Lysosomes fail to fuse properly with phagosomes, and killing of ingested bacteria is impaired. (Chapter 13)

chemokines Small chemoattractant proteins that stimulate the migration and activation of cells, especially phagocytic cells and lymphocytes. Chemokines have a central role in inflammatory responses. Properties of individual chemokines are listed in eAppendix IV. (Chapters 1, 3)

chemotaxis Cellular movement occurring in response to chemical signals in the environment. (Chapter 3)

chimeric antigen receptor (CAR) Engineered fusion proteins composed of extracellular antigen-specific receptors (e.g., single-chain antibody) and intracellular signaling domains that activate and co-stimulate; expressed in T cells for use in cancer immunotherapy. (Chapter 16)

chronic allograft vasculopathy Chronic damage that can lead to late failure of transplanted organs. Arteriosclerosis of graft blood vessels leads to hypoperfusion of the graft and its eventual fibrosis and atrophy. (Chapter 15)

chronic granulomatous disease (CGD) An immunodeficiency in which multiple granulomas form as a result of defective elimination of bacteria by phagocytic cells. It is caused by defects in the NADPH oxidase system of enzymes that generate the superoxide radical involved in bacterial killing. (Chapters 3, 13)

chronic infantile neurologic cutaneous and articular syndrome (CINCA) An autoinflammatory disease that is due to defects in the gene *NLRP3*, which encodes one of the components of the inflammasome. (Chapter 13)

chronic rejection Late failure of a transplanted organ, which can be due to immunological or non-immunological causes. (Chapter 15)

CIIV (MHC class II vesicle) An early endocytic compartment containing MHC class II molecules in dendritic cells. (Chapter 6)

circulating vaccine-derived poliovirus (cVDPV) A form of poliovirus that arises from a mutation in the vaccine strain of poliovirus (frequently type 2 oral vaccine strain) that causes the reversion of the vaccine strain to acquire enhanced capacity for replication. This allows it to spread within unvaccinated populations. (Chapter 16)

class I cytokine receptors A group of receptors for the hematopoietin superfamily of cytokines. These include receptors using the common β chain for IL-2, IL-4, IL-7, IL-15, and IL-21, and a common β chain for GM-CSF, IL-3, and IL-5. (Chapter 3)

class II–associated invariant chain peptide (CLIP) A peptide of variable length cleaved from the invariant chain (Ii) by proteases. It remains associated with the MHC class II molecule in an unstable form until it is removed by the HLA-DM protein. (Chapter 6)

class II cytokine receptors A group of heterodimeric receptors for a family of cytokines that includes interferon (IFN)-α, IFN-β, IFN-γ, and IL-10.

classes The class of an antibody is defined by the type of heavy chain it contains. There are five main antibody classes: IgA, IgD, IgM, IgG, and IgE, containing heavy chains α, δ, μ, γ, and ε, respectively. The IgG class has several subclasses. *See also* **isotypes**. (Chapters 1, 4, 10)

classical C3 convertase The complex of activated complement components C4b2a, which cleaves C3 to C3b on pathogen surfaces in the classical pathway of complement activation. (Chapter 2)

classical MHC class I genes MHC class I genes whose proteins function by presenting peptide antigens for recognition by T cells. Cf. **nonclassical MHC class Ib genes**. (Chapter 5)

classical monocyte The major form of monocyte in circulation capable of recruitment to sites of inflammation and differentiation into macrophages. (Chapter 3)

classical pathway The complement-activation pathway that is initiated by C1 binding either directly to bacterial surfaces or to antibody bound to the bacteria, thus flagging the bacteria as foreign. *See also* **alternative pathway**, **lectin pathway**. (Chapters 2, 10)

classically activated macrophage *See* **M1 macrophages**. (Chapter 11)

class switching, class switch recombination A somatic gene recombination process in activated B cells that replaces one heavy-chain constant region with one of a different isotype, switching the isotype of antibodies from IgM to the production of IgG, IgA, or IgE. This affects the antibody effector functions but not their antigen specificity. Also known as isotype switching. Cf. **somatic hypermutation**. (Chapters 5, 10)

cleavage stimulation factor A multi-subunit protein complex involved in the modification of the 3′ end of pre-messenger RNA for the addition of the polyadenine (polyA) tail. (Chapter 5)

CLEC9A A cell-surface receptor expressed by type 1 conventional dendritic cells (cDC1) and which recognizes filamentous actin to enhance the uptake of dead cells, such as those killed during viral infections, thus contributing to antigen processing of viral proteins. (Chapter 6)

clonal contraction The phase the of T-cell infection response whereby most of the T-cell population dies via apoptosis, and the remaining 5–10% persists to seed a long-term memory T-cell population. (Chapters 9, 11)

clonal deletion The elimination of immature lymphocytes when they bind to self antigens, which produces tolerance to self as required by the clonal selection theory of adaptive immunity. Clonal deletion is the main mechanism of central tolerance and can also occur in peripheral tolerance. (Chapters 1, 8)

clonal expansion The proliferation of antigen-specific lymphocytes in response to antigenic stimulation that precedes their differentiation into effector cells. It is an essential step in adaptive immunity, allowing rare antigen-specific cells to increase in number so that they can effectively combat the pathogen that elicited the response. (Chapters 1, 9)

clonal selection theory The central paradigm of adaptive immunity. It states that adaptive immune responses derive from individual antigen-specific lymphocytes that are self-tolerant. These specific lymphocytes proliferate in response to antigen and differentiate into antigen-specific effector cells that eliminate the eliciting pathogen and into memory cells to sustain immunity. The theory was formulated by Frank Macfarlane Burnet and in earlier forms by Niels K. Jerne and David Talmage. (Chapter 1)

clone A population of cells all derived from the same progenitor cell. (Chapter 1, Appendix I)

clonotypic Describes a feature unique to members of a clone. For example, the distribution of antigen receptors in the lymphocyte population is said to be clonotypic, as the cells of a given clone all have identical antigen receptors. (Chapters 1, 4)

Clostridium difficile Gram-positive anaerobic toxogenic spore-forming bacterium frequently associated with severe colitis after treatment with certain broad-spectrum antibiotics. (Chapter 12)

club cells Columnar cells that are decorated with microvilli and are found in the small airways of the lungs, where they protect the bronchiolar epithelium through a variety of secretory molecules. (Chapter 12)

c-Maf A transcription factor acting in the development of T_{FH} cells. (Chapter 10)

coagulation system A collection of proteases and other proteins in the blood that trigger blood clotting when blood vessels are damaged. (Chapter 3)

coding joint DNA joint formed by the imprecise joining of a V gene segment to a DJ gene segment during recombination of the immunoglobulin or T-cell receptor genes. It is the joint retained in the rearranged gene. Cf. **signal joint**. (Chapter 5)

codominant Describes the situation in which the two alleles of a gene are expressed in roughly equal amounts in the heterozygote. Most genes show this property, including the highly polymorphic MHC genes. (Chapter 6)

co-immunoprecipitation An extension of the immunoprecipitation technique aimed at determining the proteins that physically interact with the target protein recognized by the immunoprecipitating antibody. *See also* **immunoprecipitation**. (Appendix I)

'cold' pyogenic infection Infection by pyogenic bacteria, such as *Staphylococcus aureus*, that elicits little or no inflammation in individuals with inherited deficiency of signaling molecules normally activated downstream of TLRs and IL-1 family receptors (e.g., MyD88 or IRAK4). (Chapter 13)

collectins A family of calcium-dependent sugar-binding proteins (lectins) containing collagen-like sequences. An example is mannose-binding lectin (MBL). (Chapter 2)

colonization resistance The ability of a healthy microbiota to resist incursion of new microbial species, including potential pathogens, thereby contributing to general host defense. Multiple mechanisms may be contributory, including nutrient competition and production of antimicrobial products. (Chapter 12)

combinatorial diversity The diversity among antigen receptors generated by combining separate units of genetic information, comprising two types. First, receptor gene segments are joined in many different combinations to generate diverse receptor chains; second, two different receptor chains (heavy and light in immunoglobulins; α and β, or γ and δ, in T-cell receptors) are combined to make the antigen-recognition site. (Chapters 1, 4, 5)

commensal bacteria *See* **commensal microbiota**. (Chapter 2)

commensal microbiota, commensal microorganisms Microorganisms (predominantly bacteria) that normally live harmlessly in symbiosis with their host (e.g., the gut bacteria in humans and other animals). Many commensals confer a positive benefit on their host in some way. (Chapters 1, 8)

common β chain (β_c) A transmembrane polypeptide (CD131) that is a common subunit for receptors of the cytokines IL-3, IL-5, and GM-CSF. (Chapter 3)

common γ chain (γ_c) A transmembrane polypeptide chain (CD132) that is common to a subgroup of cytokine receptors. (Chapter 3)

common lymphoid progenitor (CLP) Stem cell that can give rise to all the types of lymphocytes but is biased toward producing B cells. (Chapters 1, 3)

common mucosal immune system The mucosal immune system as a whole, the name reflecting the fact that lymphocytes that have been primed in one part of the mucosal system can recirculate as effector cells to other parts of the mucosal system. (Chapter 12)

common myeloid progenitor (CMP) Stem cell that can give rise to the myeloid cells of the immune system (the macrophages, granulocytes, mast cells, and dendritic cells of the innate immune system). This stem cell also gives rise to megakaryocytes and red blood cells. (Chapter 1)

common variable immunodeficiencies (CVIDs) Relatively common deficiencies in antibody production in which only one or a few isotypes are affected. CVIDs can be due to a variety of genetic defects. (Chapter 13)

competitive inhibition assay An assay to determine the presence as well as the amount of antigen in a sample of unknown composition. The assay is based on the ability of antigen in the sample, if present, to compete with a known amount of that antigen, but labeled, for binding to a specific antibody. (Appendix I)

complement A set of plasma proteins that act together as a defense against pathogens in extracellular spaces. The pathogen becomes coated with complement proteins that facilitate its removal by phagocytes and that can also kill certain pathogens directly. Activation of the complement system can be initiated in several different ways. *See* **classical pathway**, **alternative pathway**, **lectin pathway**. (Chapters 1, 2)

complement activation The activation of the normally inactive proteins of the complement system that occurs on infection. *See* **classical pathway, alternative pathway, lectin pathway**. (Chapters 1, 2, 10)

complement proteins *See* **C1, C2, C3,** etc. (Chapter 2)

complement receptors (CRs) Cell-surface proteins of various types that recognize and bind complement proteins that have become bound to an antigen such as a pathogen. Complement receptors on phagocytes enable them to identify and bind pathogens coated with complement proteins and to ingest and destroy them. *See* **CR1, CR2, CR3, CR4, CRIg,** and the **C1 complex**. (Chapters 1, 2)

complement-regulatory proteins Proteins that control complement activity and prevent complement from being activated on the surfaces of host cells. (Chapter 2)

complement system A set of plasma proteins that act together as a defense against pathogens in extracellular spaces. The pathogen becomes coated with complement proteins that facilitate its removal by phagocytes and which can also kill certain pathogens directly. Activation of the complement system can be initiated in several different ways. *See* **classical pathway, alternative pathway, lectin pathway**. (Chapter 2)

complementarity-determining regions (CDRs) Parts of the V domains of immunoglobulins and T-cell receptors that determine their antigen specificity and make contact with the specific ligand. The CDRs are the most variable part of the antigen receptor and contribute to the diversity of these proteins. There are three such regions (CDR1, CDR2, and CDR3) in each V domain. (Chapters 4, 5)

confocal fluorescent microscope A confocal microscope outfitted to capture fluorescent emission signals. Confocal microscopy provides enhanced image resolution over standard light microscopy by using a small, highly focused beam of light to produce images with reduced out-of-focus light interference. (Appendix I)

conformational epitope, discontinuous epitope Antigenic structure (epitope) on a protein antigen that is formed from several separate regions in the sequence of the protein brought together by protein folding. Antibodies that bind conformational epitopes bind only native folded proteins. (Chapter 4)

congenic Two individuals, usually mice, that are genetically identical at all loci with the exception of a single gene. (Appendix I)

conjugate vaccines Antibacterial vaccines made from bacterial capsular polysaccharides bound to proteins of known immunogenicity, such as tetanus toxoid. (Chapter 16)

constant Ig domains (C domains) Type of protein domain that makes up the constant regions of each chain of an immunoglobulin molecule. (Chapter 4)

constant region (C region) That part of an immunoglobulin or a T-cell receptor that is relatively constant in amino acid sequence between different molecules. Also known as the Fc region in antibodies. The constant region of an antibody determines its particular effector function. Cf. **variable region**. (Chapters 1, 4)

continuous epitope, linear epitope Antigenic structure (epitope) in a protein that is formed by a single small region of amino acid sequence.

Antibodies that bind continuous epitopes can bind to the denatured protein. The epitopes detected by T cells are continuous. (Chapter 4)

contraction phase The period of the clonal lymphocyte response (T or B cell) that is marked by the rapid decline of daughter-cell numbers after pathogen clearance and decline in the antigenic load. (Chapter 11)

conventional (or **classical**) **dendritic cells (cDCs)** The lineage of dendritic cells that mainly participates in antigen presentation to, and activation of, naive T cells. Cf. **plasmacytoid dendritic cells**. (Chapters 3, 9)

co-receptor Cell-surface protein that increases the sensitivity of a receptor to its ligand by binding to associated ligands and participating in signaling. The antigen receptors on T cells and B cells act in conjunction with co-receptors, which are either CD4 or CD8 on T cells, and a co-receptor complex of three proteins, one of which is the complement receptor CR2, on B cells. (Chapters 1, 4)

coronavirus disease-2019 (COVID-19) A respiratory illness caused by SARS-CoV-2, likely of zoonotic origin and responsible for the COVID-19 pandemic. (Chapter 12)

coronavirus spike protein (S) The coronavirus surface protein that binds host-cell receptors to mediate viral entry. (Chapter 12)

cortex The outer part of a tissue or organ; in lymph nodes it refers to the follicles, which are mainly populated by B cells. (Chapter 1)

corticosteroids Family of drugs related to natural steroids such as cortisone. Corticosteroids can kill lymphocytes, especially developing thymocytes, inducing apoptotic cell death. They are medically useful anti-inflammatory and immunosuppressive agents. (Chapter 16)

co-stimulatory molecules Cell-surface proteins on antigen-presenting cells that deliver co-stimulatory signals to naive T cells. Examples are the B7 molecules on dendritic cells, which are ligands for CD28 on naive T cells. (Chapters 1, 3)

co-stimulatory receptors Cell-surface receptors on naive lymphocytes through which the cells receive signals additional to those received through the antigen receptor, and which are necessary for the full activation of the lymphocyte. Examples are CD30 and CD40 on B cells and CD27 and CD28 on T cells. (Chapters 3, 7)

CR1 (CD35) A receptor expressed by phagocytic cells that binds to C3b. It stimulates phagocytosis and inhibits C3 convertase formation on host-cell surfaces. It also acts in conjunction with factor I to cleave C3b to its inactive derivative iC3b and thus prevent convertase formation. (Chapter 2)

CR2 (CD21) Complement receptor that is part of the B-cell co-receptor complex. It binds to antigens coated with breakdown products of C3b, especially C3dg, and, by cross-linking the B-cell receptor, enhances sensitivity to antigen at least 100-fold. It is also the receptor used by the Epstein–Barr virus to infect B cells. (Chapter 2)

CR3 (CD11b:CD18) Complement receptor 3. A β2 integrin that acts both as an adhesion molecule and as a complement receptor. CR3 on phagocytes binds iC3b, a breakdown product of C3b on pathogen surfaces, and stimulates phagocytosis. (Chapters 2, 3)

CR4 (CD11c:CD18) A β2 integrin that acts both as an adhesion molecule and as a complement receptor. CR4 on phagocytes binds iC3b, a breakdown product of C3b on pathogen surfaces, and stimulates phagocytosis. (Chapters 2, 3)

CRAC channel Channels in the lymphocyte plasma membrane that open to let calcium flow into the cell during the response of the cell to antigen. Channel opening is induced by release of calcium from the endoplasmic reticulum. (Chapter 7)

C-reactive protein An acute-phase protein that binds to phosphocholine, a constituent of the surface C-polysaccharide of the bacterium *Streptococcus pneumoniae* and of many other bacteria, thus opsonizing them for uptake by phagocytes. (Chapter 3)

CRIg (complement receptor of the immunoglobulin superfamily) A complement receptor that binds to inactivated forms of C3b. (Chapters 2, 10)

Crohn's disease Chronic inflammatory bowel disease thought to result from an abnormal overresponsiveness to the commensal gut microbiota. (Chapters 3, 12, 15)

cross-matching A test used in blood typing and histocompatibility typing to determine whether donor and recipient have antibodies against each other's cells that might interfere with successful transfusion or grafting. (Chapter 15)

cross-presentation The process by which extracellular proteins taken up by dendritic cells can give rise to peptides presented by MHC class I molecules. It enables antigens from extracellular sources to be presented by MHC class I molecules and activate CD8 T cells. (Chapters 6, 9)

cross-priming Activation of CD8 T cells by dendritic cells in which the antigenic peptide presented by MHC class I molecules is derived from an exogenous protein (i.e., by cross-presentation) rather than produced within the dendritic cells directly. Cf. **direct presentation**. (Chapters 6, 9)

cryptdins α-Defensins (antimicrobial peptides) made by the Paneth cells of the small intestine. (Chapter 2)

cryptic epitopes Any epitope that cannot be recognized by a lymphocyte receptor until the antigen has been broken down and processed. (Chapter 15)

cryptopatches Aggregates of lymphoid tissue in the gut wall that are thought to give rise to isolated lymphoid follicles. (Chapter 12)

CstF-64 Subunit of cleavage stimulation factor that favors polyadenylation at pA_1 leading to the secreted form of IgM. (Chapter 5)

cTECs Epithelial cells of the thymic cortex responsible for expression of MHC class I and class II proteins bearing self peptides involved in the selection of αβ T cells. (Chapter 8)

C-terminal Src kinase (Csk) A kinase that phosphorylates the C-terminal tyrosine of Src family kinases in lymphocytes, thus inactivating them. (Chapter 7)

CTLA-4 A high-affinity inhibitory receptor on T cells for B7 molecules; its binding inhibits T-cell activation. (Chapters 7, 9)

C-type lectins Large class of carbohydrate-binding proteins that require Ca^{2+} for binding, including many that function in innate immunity. (Chapter 2)

cutaneous lymphocyte antigen (CLA) A cell-surface molecule that is involved in lymphocyte homing to the skin in humans. (Chapter 11)

CVIDs *See* **common variable immunodeficiencies**. (Chapter 13)

CX3CR1 Chemokine receptor expressed by monocytes, macrophages, NK cells, and activated T cells that binds CX3CL1 (fractalkine). (Chapter 12)

CXC chemokines One of the two main classes of chemokines, distinguished by a Cys-X-Cys (CXC) motif near the amino terminus. They have names CXCL1, CXCL2, etc. See eAppendix IV for a list of individual chemokines. (Chapter 3)

CXCL12 (SDF-1) Chemokine produced by stromal cells in the dark zone of the germinal center that binds CXCR4 expressed by centroblasts. (Chapter 10)

CXCL13 Chemokine produced in the follicle and the light zone of the germinal center that binds CXCR5 expressed on circulating B cells and centrocytes. (Chapters 9, 10, 12)

CXCR5 A chemokine receptor expressed by circulating B cells and activated T cells that binds the chemokine CXCL13 and directs cell migration into the follicle. (Chapters 9, 10, 12)

cyclic dinucleotides (CDNs) Cyclic dimers of guanylate and/or adenylate monophosphate that are produced by various bacteria as second messengers and detected by STING. (Chapter 3)

cyclic guanosine monophosphate–adenosine monophosphate (cyclic GMP–AMP, or cGAMP) *See* **cyclic dinucleotides (CDNs)**. (Chapter 3)

cyclic neutropenia A dominantly inherited disease in which neutrophil numbers fluctuate from near normal to very low or absent, with an approximate cycle time of 21 days. This is in contrast to severe congenital neutropenia (SCN), in which the inherited defect results in persistently low neutrophil numbers. (Chapter 13)

cyclic reentry model An explanation of the behavior of B cells in lymphoid follicles, proposing that activated B cells in germinal centers lose and gain expression of the chemokine receptor CXCR4 and thus move from the light zone to the dark zone and back again under the influence of the chemokine CXCL12. (Chapter 10)

cyclophilins A family of prolyl isomerases that affect protein folding and also bind cyclosporin A to produce a complex that associates with calcineurin, preventing its activation by calmodulin. (Chapter 16)

cyclophosphamide A DNA-alkylating agent that is used as an immunosuppressive drug. It acts by killing rapidly dividing cells, including lymphocytes proliferating in response to antigen. (Chapter 16)

cyclosporin A (CsA) A powerful noncytotoxic immunosuppressive drug that inhibits signaling from the T-cell receptor, preventing T-cell activation and effector function. It binds to cyclophilin, and the complex formed binds to and inactivates the phosphatase calcineurin. (Chapters 7, 16)

cystic fibrosis Disease caused by defect in the CFTR gene, leading to abnormally thick mucus and causing serious recurrent infections of the lung. (Chapter 2)

cytidine deaminase activity (CDA) An enzymatic activity exhibited by AID-APOBEC family proteins of agnathan species that may mediate rearrangement and assembly of complete VLR genes. (Chapter 5)

cytokines Proteins made by a cell that affect the behavior of other cells, particularly immune cells. Cytokines made by lymphocytes are often called interleukins (abbreviated ILs). Cytokines and their receptors are listed in eAppendix III. Cf. **chemokines**. (Chapters 1, 3)

cytomegalovirus UL16 protein A nonessential glycoprotein of cytomegalovirus that is recognized by innate receptors expressed by NK cells. (Chapter 3)

cytosol One of several major compartments within cells containing elements such as the cytoskeleton and mitochondria and separated by membranes from distinct compartments such as the nucleus and vesicular system. (Chapter 6)

cytotoxic T cells, cytotoxic T lymphocytes (CTLs) T cells that can kill other cells, typically CD8 T cells defending against intracellular pathogens that live or reproduce in the cytosol, but in some cases also CD4 T cells. (Chapters 1, 6, 9)

daclizumab Antibody to human CD25 used to block IL-2 receptor signaling in T cells for treatment of rejection in renal transplantation. (Chapter 16)

DAG *See* **diacylglycerol**. (Chapters 6, 7)

damage-associated molecular patterns (DAMPs) *See* **pathogen-associated molecular patterns (PAMPs)**. (Chapter 3)

DAP10, DAP12 Signaling chains containing ITAMs that are associated with the tails of some activating receptors on NK cells. (Chapter 3)

dark zone A region of a germinal center enriched in rapidly dividing activated B cells. (Chapter 10)

DC-SIGN A lectin on the dendritic-cell surface that binds ICAM-3 with high affinity. (Chapter 9)

death domain A protein domain involved in protein–protein interactions with death domains in other proteins. The death domain was first identified in proteins involved in apoptosis. (Chapter 3)

death-inducing signaling complex (DISC) A multiprotein complex that is formed by signaling through members of the 'death receptor' family of apoptosis-inducing cellular receptors, such as Fas. It activates the caspase cascade to induce apoptosis. (Chapters 9, 11)

decay-accelerating factor (DAF or CD55) A cell-surface protein that protects cells from lysis by complement. Its absence causes the disease paroxysmal nocturnal hemoglobinuria. (Chapter 2)

Dectin-1 A phagocytic receptor on neutrophils and macrophages that recognizes β-(1,3)–linked glucans, which are common components of fungal cell walls. (Chapters 3, 9, 12)

defective ribosomal products (DRiPs) Peptides translated from introns in improperly spliced mRNAs, translations of frameshifts, or improperly folded proteins, which are recognized and tagged by ubiquitin for degradation by the proteasome. (Chapter 6)

defensins *See* **α-defensins**, **β-defensins**. (Chapter 2)

delayed-type hypersensitivity (DTH) A form of cell-mediated immunity elicited by antigen in the skin stimulating sensitized T_H1 CD4 lymphocytes and CD8 lymphocytes. It is called delayed-type hypersensitivity because the reaction appears hours to days after antigen is injected. Referred to as type IV hypersensitivity in the historic Gell and Coombs classification. (Chapters 11, 14)

dendritic cells Bone marrow–derived cells found in most tissues, including lymphoid tissues. There are two main functional subsets. Conventional dendritic cells take up antigen in peripheral tissues, are activated by contact with pathogens, and travel to the peripheral lymphoid organs, where they are the most potent stimulators of T-cell responses. Plasmacytoid dendritic cells can also take up and present antigen, but their main function in an infection is to produce large amounts of the antiviral interferons as a result of pathogen recognition through receptors such as TLRs. Both these types of dendritic cells are distinct from the follicular dendritic cell that presents antigen to B cells in lymphoid follicles. (Chapters 1, 3)

dendritic epidermal T cells (DETCs) A specialized class of γδ T cells found in the skin of mice and some other species, but not humans. They express $V_\gamma5V_\delta1$ and may interact with ligands such as Skint-1 expressed by keratinocytes. (Chapters 6, 8)

dephosphorylation The removal of a phosphate group from a molecule, usually a protein. (Chapter 7)

depleting antibodies Immunosuppressive monoclonal antibodies that trigger the destruction of lymphocytes *in vivo*. They are used for treating episodes of acute graft rejection. (Chapter 16)

Der p 1 A cysteine protease that is present in the feces of the house dust mite, *Dermatophagoides pteronyssinus*. Der p 1 induces an allergic reaction, likely through its ability to cleave the intercellular tight-junction protein occludin that is present in the airway mucosa. (Chapter 14)

diacyl and triacyl lipoproteins Ligands for the Toll-like receptors TLR-1–TLR-2 and TLR-2–TLR-6. (Chapter 3)

diacylglycerol (DAG) A lipid intracellular signaling molecule formed from membrane inositol phospholipids that are cleaved by the action of phospholipase C-γ after the activation of many different receptors. The diacylglycerol stays in the membrane and activates protein kinase C and RasGRP, which further propagate the signal. (Chapters 6, 7)

diapedesis The movement of blood cells, particularly leukocytes, from the blood across blood vessel walls into tissues. (Chapter 3)

differentiation antigens Referring to a category of genes with restricted expression patterns that can be targeted as antigens by immunotherapies in treatment of cancers. (Chapter 16)

DiGeorge syndrome Recessive genetic immunodeficiency disease in which there is a failure to develop thymic epithelium. Parathyroid glands

are also absent, and there are anomalies in the large blood vessels. (Chapters 8, 13)

direct allorecognition Host recognition of a grafted tissue that involves host T-cell recognition of donor antigen-presenting cells (APCs) directly without antigen processing by host APCs. This may occur in the graft itself, or upon the migration of donor APCs from the graft to regional lymph nodes, where they may activate host T cells. (Chapter 15)

direct Coombs test This assay directly tests for antibodies bound to the surface of cells and is used to detect maternal anti-Rh IgG bound to fetal red blood cells. Anti-human immunoglobulin antibodies are mixed with the cells. If the red blood cells agglutinate, this indicates that they are coated with maternal antibodies. (Appendix I)

direct presentation The process by which proteins produced within a given cell give rise to peptides presented by MHC class I molecules. This may refer to antigen-presenting cells, such as dendritic cells, or to nonimmune cells that will become the targets of cytotoxic T lymphocytes (CTLs). (Chapter 6)

dislocation In reference to viral defense mechanisms, the degradation of newly synthesized MHC class I molecules by viral proteins. (Chapter 13)

disseminated intravascular coagulation (DIC) Blood clotting occurring simultaneously in small vessels throughout the body in response to disseminated TNF-α, which leads to the massive consumption of clotting proteins, so that the individual's blood cannot clot appropriately. Seen in septic shock. (Chapter 3)

diversity gene segment, D_H gene segment Short DNA sequences that form a join between the V and J gene segments in rearranged immunoglobulin heavy-chain genes and in T-cell receptor β- and δ-chain genes. *See* **gene segments**. (Chapter 5)

DN1, DN2, DN3, DN4 Stages in the development of $CD4^+CD8^+$ double-positive T cells in the thymus. Rearrangement of the TCR β-chain locus starts at DN2 and is completed by DN4. (Chapter 8)

DNA-dependent protein kinase (DNA-PK) Protein kinase in the DNA repair pathway involved in the rearrangement of immunoglobulin and T-cell receptor genes. (Chapter 5)

DNA ligase IV Enzyme responsible for joining the DNA ends to produce the coding joint during V(D)J recombination. (Chapter 5)

DNA transposons Genetic elements encoding their own transposase that can insert themselves into and excise themselves from the DNA genomes of a host. (Chapter 5)

DNA vaccination Vaccination by introduction into skin and muscle of DNA encoding the desired antigen; the expressed protein can then elicit antibody and T-cell responses. (Chapter 16)

donor lymphocyte infusion (DLI) Transfer of mature lymphocytes (i.e., T cells) from donor into patient during bone marrow transplantation for cancer treatment to help eliminate residual tumor. (Chapter 16)

double-negative thymocytes Immature T cells in the thymus that lack expression of the two co-receptors CD4 and CD8 and represent the progenitors to the remaining T cells developing in the thymus. In a normal thymus, these represent about 5% of thymocytes. (Chapter 8)

double-positive thymocytes Immature T cells in the thymus that are characterized by expression of both the CD4 and the CD8 co-receptor proteins. They represent the majority (about 80%) of thymocytes and are the progenitors to the mature CD4 and CD8 T cells. (Chapter 8)

double-strand break repair (DSBR) A nonhomologous end joining pathway of DNA repair used in the completion of isotype switching. (Chapter 5)

double-stranded RNA (dsRNA) A chemical structure that is a replicative intermediate of many viruses and is recognized by TLR-3. (Chapter 3)

Down syndrome cell adhesion molecule (Dscam) *See* **Dscam**.

DR4, DR5 Members of the TNFR superfamily expressed by many cell types and which can be activated by TRAIL to induce apoptosis. (Chapter 3)

draining lymph node A lymph node downstream of a site of infection that receives antigens and microbes from the site via the lymphatic system. Draining lymph nodes often enlarge enormously during an immune response and can be palpated; they were originally called swollen glands. (Chapter 1)

Dscam A member of the immunoglobulin superfamily that in insects is thought to opsonize invading bacteria and aid their engulfment by phagocytes. It can be made in a multiplicity of different forms as a result of alternative splicing. (Chapter 5)

dysbiosis Altered balance of microbial species composing the microbiota resulting from a variety of causes (e.g., antibiotics, genetic disorders) and frequently associated with outgrowth of pathogenic organisms such as *Clostridium difficile*. (Chapter 12)

dysregulated self Refers to changes that take place in infected or malignant cells that alter expression of various surface receptors that can be detected by the innate immune system. (Chapter 3)

E3 ligase An enzymatic activity that directs the transfer of a ubiquitin molecule from an E2 ubiquitin-conjugating enzyme onto a specific protein target. (Chapters 6, 10)

early innate lymphoid progenitor (EILP) A subset of progenitor cells arising from LMPPs. EILPs give rise to the three lineages of innate lymphoid cells, ILC1 (including NK cells), ILC2, and ILC3. (Chapter 8)

early-onset sarcoidosis Disease associated with activating NOD2 mutations characterized by inflammation in tissues such as liver. (Chapter 3)

early pro-B cell *See* **pro-B cells**. (Chapter 8)

early thymic progenitor (ETP) The major subset of progenitor cells that gives rise to T cells. (Chapter 8)

EBI2 (GPR183) A chemokine receptor that binds oxysterols and regulates B-cell movement to the outer follicular and interfollicular regions during early phases of B-cell activation in lymphoid tissues. (Chapter 10)

edema Swelling caused by the entry of fluid and cells from the blood into the tissues; it is one of the cardinal features of inflammation. (Chapter 3)

effector caspases Intracellular proteases that are activated as a result of an apoptotic signal and mediate the cellular changes associated with apoptosis. To be distinguished from initiator caspases, which act upstream of effector caspases to initiate the caspase cascade. (Chapter 9)

effector CD4 T cells The subset of differentiated effector T cells carrying the CD4 co-receptor molecule, which includes the T_H1, T_H2, T_H17, and regulatory T cells. (Chapter 6)

effector lymphocytes The cells that differentiate from naive lymphocytes after initial activation by antigen and can then mediate the removal of pathogens from the body without further differentiation. They are distinct from memory lymphocytes, which must undergo further differentiation to become effector lymphocytes. (Chapter 1)

effector mechanisms Those processes by which pathogens are destroyed and cleared from the body. Innate and adaptive immune responses use most of the same effector mechanisms to eliminate pathogens. (Chapter 1)

effector memory T (TEM) cells Memory lymphocytes that recirculate between blood and peripheral tissues and are specialized for rapid maturation into effector T cells after restimulation with antigen in nonlymphoid tissues. (Chapter 11)

effector module A collection of cell-mediated and humoral mechanisms that involve components of both the innate and adaptive immune systems. These mechanisms act together to achieve elimination of a particular category of pathogen. (Chapter 1)

effector regulatory T (eT_{reg}) cells T_{reg} cells that have received additional differentiative signals that cause them to migrate into peripheral tissues where they can regulate effector T-cell response. A signature cytokine of eT_{reg} cells is IL-10. (Chapters 9, 12)

effector T lymphocytes, effector T cells The T cells that perform the functions of an immune response (such as cell killing and cell activation) that clear the infectious agent from the body. There are several different subsets, each with a specific role in an immune response. (Chapters 1, 9)

efferocytosis The process of removal of apoptotic cells by phagocytes (from the Latin *effere*, meaning 'to take to the grave'). (Chapter 12)

electrostatic interaction Chemical interaction occurring between charged atoms, as in the charged amino acid side chains and an ion in a salt bridge. (Chapter 4)

elimination phase Stage of antitumor immune response that detects and eliminates cancer cells, also called immune surveillance. (Chapter 16)

ELISPOT assay A technique for enumerating lymphocytes in a population capable of secreting effector molecules, such as cytokines or antibodies. In the case of T cells, antibodies to a cytokine of interest are coated onto a plastic culture well, and activated T cells are allowed to settle on the plate. If a given T cell is secreting the cytokine of interest, the cytokine will be captured by the antibody on the plate and will be localized to a discrete spot. This spot of cytokine can be detected with a colorimetric assay and the number of spots on the plate counted. For B cells, this technique can be used to enumerate antibody-secreting cells in a population. (Appendix I)

elite controllers A subset of HIV-infected, long-term nonprogressors who have clinically undetectable levels of virus without antiretroviral therapy. (Chapter 13)

ELL2 A transcription elongation factor that favors the polyadenylation at pA_1 leading to the secreted form of IgM. (Chapter 5)

embryonic stem cells (ES cells) A continually growing cell line that can give rise to all cell lineages in a mouse after implantation into a developing mouse embryo at the blastocyst stage. (Appendix I)

endocrine Describes the action of a biologically active molecule such as a hormone or cytokine that is secreted by one tissue into the blood and acts on a distant tissue. Cf. **autocrine**, **paracrine**. (Chapter 3)

endogenous pyrogens Cytokines that can induce a rise in body temperature. (Chapter 3)

endoplasmic reticulum aminopeptidase associated with antigen processing (ERAAP) Also called ERAP1. Enzyme in the endoplasmic reticulum that trims polypeptides to a size at which they can bind to MHC class I molecules. (Chapter 6)

endoplasmic reticulum–associated protein degradation (ERAD) A system of enzymes in the endoplasmic reticulum that recognizes incompletely or misfolded proteins and ensures their eventual degradation. (Chapter 6)

endosteum The region in bone marrow adjacent to the inner surface of the bone; hematopoietic stem cells are initially located there. (Chapter 8)

endothelial activation The changes that occur in the endothelial walls of small blood vessels as a result of inflammation, such as increased permeability and the increased production of cell-adhesion molecules and cytokines. (Chapter 3)

endothelial cell Cell type that forms the endothelium, the epithelium of a blood vessel wall. (Chapter 1)

endothelial protein C receptor (EPCR) A nonclassical MHC class I protein induced on endothelial cells that can interact with the blood coagulation factor XIV (protein C) and can be recognized by some γδ T cells. (Chapter 6)

endothelium The epithelium that forms the walls of blood capillaries and the lining of larger blood vessels. (Chapter 1)

endotoxins Toxins derived from bacterial cell walls released by damaged cells. They can potently induce cytokine synthesis and in large amounts can cause a systemic reaction called septic shock or endotoxic shock. (Chapter 2)

enterocytes The cells that line the intestines. Also known as intestinal epithelial cells, or IECs. There are two general subtypes: absorptive (e.g., absorptive enterocyte) and secretory (e.g., Paneth cells), both of which differentiate from intestinal stem cells located in the base of the crypts of the small and large intestines. (Chapter 12)

enteroendocrine cells (EECs) A broad family of specialized intestinal epithelial cells (IECs) that produce hormones in response to a number of stimuli. EECs compose the largest collection of endocrine cells in humans. The secreted products of different types of EECs can act locally, via the bloodstream, or via the enteric nervous system to coordinate responses with other cells. (Chapter 12)

enzyme-linked immunosorbent assay (ELISA) An assay to measure quantities of a specific compound, such as a viral protein, in a complex mixture such as serum. The sample being tested is adhered to an assay plate well, and the antigen concentration in the sample is determined by binding an enzyme-linked antibody. The amount of bound antibody is determined by adding the enzyme's substrate and measuring the accumulation of a reaction product derived from the substrate. (Appendix I)

eosinophilia An abnormally large number of eosinophils in the blood. (Chapter 14)

eosinophil A type of white blood cell containing granules that stain with eosin. It is thought to be important chiefly in defense against parasitic infections but is also medically important as an effector cell in allergic reactions. (Chapters 1, 3)

eotaxins CC chemokines that act predominantly on eosinophils, including CCL11 (eotaxin 1), CCL24 (eotaxin 2), and CCL26 (eotaxin 3). (Chapter 14)

epitope A site on an antigen recognized by an antibody or an antigen receptor. T-cell epitopes are short peptides bound to MHC molecules. B-cell epitopes are typically structural motifs on the surface of the antigen. Also called an antigenic determinant. (Chapters 1, 4)

epitope spreading Increase in diversity of responses to autoantigens as the response persists, as a result of responses being made to epitopes other than the original one. (Chapter 15)

equilibrium phase Stage of antitumor immune response when immunoediting allows the immune response to continually shape the antigenic character of cancer cells. (Chapter 16)

ERAP1 *See* **endoplasmic reticulum aminopeptidase associated with antigen processing (ERAAP)**. (Chapter 6)

ERAP2 Enzyme in the endoplasmic reticulum in human cells that trims polypeptides to a size at which they can bind to MHC class I molecules. (Chapter 6)

Erk (extracellular signal-related kinase) A protein kinase that is the MAPK for one module of the T-cell receptor signaling pathway. Erk also functions in other receptors in other cell types. (Chapter 7)

ERp57 A chaperone protein involved in loading peptide onto MHC class I molecules in the endoplasmic reticulum. (Chapter 6)

error-prone 'translesion' DNA polymerases A DNA polymerase operates during DNA repair, such as Polη, which can repair a basic lesion by incorporating untemplated nucleotides into the newly formed DNA strand. (Chapter 10)

escape mutants Mutants of pathogens that are changed in such a way that they can evade the immune response against the original pathogen. (Chapter 13)

escape phase Final stage of antitumor immune response when immunoediting has removed the expression of antigenic targets such that

the cancer cells are no loner detected by the immune system. (Chapter 16)

E-selectin *See* **selectins**. (Chapter 3)

etanercept Fc fusion protein containing the p75 subunit of the TNF receptor that neutralizes TNF-α and is used for treatment of rheumatoid arthritis and other inflammatory diseases. (Chapter 16)

eukaryotic initiation factor 3 (eIF3) Multi-subunit complex that acts in formation of the 43S pre-initiation complex. It can bind IFN-induced protein with tetratricoid repeats (IFIT) proteins, which thereby suppress translation of viral proteins. (Chapter 3)

exogenous pyrogen Any substance originating outside the body that can induce fever, such as the bacterial lipopolysaccharide LPS. Cf. **endogenous pyrogens**. (Chapter 3)

exotoxin A protein toxin produced and secreted by a bacterium. (Chapter 2)

expansion phase The period of the clonal lymphocyte response (T or B cell) that is initiated after antigen recognition, during which there is rapid cell division and a marked increase in the number of daughter cells of individual lymphocyte clones that can contribute to the adaptive immune response. (Chapter 11)

experimental autoimmune encephalomyelitis (EAE) An inflammatory disease of the central nervous system that develops after mice are immunized with neural antigens in a strong adjuvant. (Chapters 15, 16)

extrachromosomal DNA DNA not contained within chromosomes, such as the circular DNA produced by V(D)J recombination occurring between RSSs in the same chromosomal orientation and eventually lost from the cell. (Chapter 5)

extravasation The movement of cells or fluid from within blood vessels into the surrounding tissues. (Chapter 3)

extrinsic (or **death receptor**) **pathway of apoptosis** A pathway triggered by extracellular ligands binding to specific cell-surface receptors (death receptors) that signal the cell to undergo programmed cell death (apoptosis). (Chapters 9, 11)

Fab fragment Antibody fragment composed of a single antigen-binding arm of an antibody without the Fc region, produced by cleavage of IgG by the enzyme papain. It contains the complete light chain plus the amino-terminal variable region and first constant region of the heavy chain, held together by an interchain disulfide bond. (Chapter 4)

F(ab′)$_2$ fragment Antibody fragment composed of two linked antigen-binding arms (Fab fragments) without the Fc regions, produced by cleavage of IgG with the enzyme pepsin. (Chapter 4)

factor B Protein in the alternative pathway of complement activation, in which it is cleaved to Ba and an active protease, Bb, the latter binding to C3b to form the alternative pathway C3 convertase, C3bBb. (Chapter 2)

factor D A serine protease in the alternative pathway of complement activation, which cleaves factor B into Ba and Bb. (Chapter 2)

factor H Complement-regulatory protein in plasma that binds C3b and competes with factor B to displace Bb from the convertase. It also acts in conjunction with factor I to cleave C3b to its inactive derivative iC3b and thus prevent convertase formation. (Chapter 2)

factor H binding protein (fHbp) A protein produced by the pathogen *Neisseria meningitidis* that recruits factor H to its membrane, thereby inactivating C3b deposited on its surface, and evading destruction by complement. (Chapter 2)

factor I Complement-regulatory protease in plasma that cleaves C3b to the inactive derivative iC3b, thus preventing the formation of a C3 convertase. (Chapter 2)

factor I deficiency A genetically determined lack of the complement-regulatory protein factor I. This results in uncontrolled complement activation, so that complement proteins rapidly become depleted. Those with the deficiency suffer repeated bacterial infections, especially with ubiquitous pyogenic bacteria. (Chapters 2, 13)

factor P Plasma protein released by activated neutrophils that stabilizes the C3 convertase C3bBb of the alternative pathway. Also known as properdin. (Chapter 2)

familial cold autoinflammatory syndrome (FCAS) An episodic autoinflammatory disease caused by gain-of-function mutations in the genes *NLRP3* or *NLRP12*, encoding NLRP3 or NLRP12, respectively, members of the NOD-like receptor family and components of inflammasomes. The symptoms are caused by unregulated overproduction of inflammatory cytokines and are induced by exposure to cold. (Chapter 3)

familial cold autoinflammatory syndrome 1 (FCAS1) A form of FCAS caused by gain-of-function mutations in *NLRP3*. (Chapter 13)

familial cold autoinflammatory syndrome 2 (FCAS2) A form of FCAS caused by gain-of-function mutations in *NLRP12*. (Chapter 13)

familial hemophagocytic lymphohistiocytosis (FHL) A family of progressive and potentially lethal inflammatory diseases caused by an inherited deficiency of one of several proteins involved in the formation or release of cytolytic granules. Large numbers of polyclonal CD8-positive T cells accumulate in lymphoid and other organs, and this is associated with activated macrophages that phagocytose blood cells, including erythrocytes and leukocytes. (Chapter 13)

familial Mediterranean fever (FMF) A severe autoinflammatory disease, inherited as an autosomal recessive disorder. It is caused by mutation in the gene (*MEFV*) that encodes the protein Pyrin, which is expressed in granulocytes and monocytes. In individuals with this disorder, defective Pyrin is thought to spontaneously activate inflammasomes. (Chapter 13)

farmer's lung A hypersensitivity disease caused by the interaction of IgG antibodies with large amounts of an inhaled antigen in the alveolar wall of the lung, causing alveolar wall inflammation and compromising respiratory gas exchange. (Chapter 14)

Fc fragment, Fc region The carboxy-terminal halves of the two heavy chains of an IgG molecule disulfide-bonded to each other by the residual hinge region. It is produced by cleavage of IgG by papain. In the complete antibody this portion is often called the Fc region. (Chapters 1, 4)

Fc receptors Family of cell-surface receptors that bind the Fc portions of different immunoglobulins: Fcγ receptors bind IgG, for example, and Fcε receptors bind IgE. (Chapters 1, 10)

FCAS *See* **familial cold autoinflammatory syndrome**. (Chapter 3)

FcγRI (CD64) Fc receptor highly expressed by monocytes and macrophages that has the highest affinity of the Fc receptors for IgG. (Chapter 12)

FcγRIIB An inhibitory receptor on B cells that recognizes the Fc portion of IgG antibodies. FcγRIIB contains an ITIM motif in its cytoplasmic tail. (Chapter 7)

FcγRIII Cell-surface receptor that binds the Fc portion of IgG molecules. Most Fcγ receptors bind only aggregated IgG, allowing them to discriminate bound antibody from free IgG. Expressed variously on phagocytes, B lymphocytes, NK cells, and follicular dendritic cells, the Fcγ receptors have a key role in humoral immunity, linking antibody binding to effector cell functions. (Chapter 7)

FcεRI The high-affinity receptor for the Fc region of IgE. Expressed primarily on the surface of mast cells and basophils. When multivalent antigen interacts with IgE that is bound to FcεRI and cross-links nearby receptors, it causes activation of the receptor-bearing cell. (Chapter 14)

FcRn (neonatal Fc receptor) A receptor that transports IgG from mother to fetus across the placenta and across other epithelia such as the epithelium of the gut. (Chapters 10, 12)

fecal microbiota transplantation (FMT) The transfer of healthy donor stool (i.e., a healthy intestinal microbiota) to an individual with a damaged microbiota via colonoscopy, enema, nasoenteric tube, or capsules. FMT can be curative in treatment of some diseases, such as recurrent *C. difficile* infection caused by a broad-spectrum antibiotic, by engrafting a healthy microbiota that displaces a dysbiotic one. (Chapter 12)

FHL *See* **familial hemophagocytic lymphohistiocytosis**. (Chapter 13)

fibrinogen-related proteins (FREPs) Members of the immunoglobulin superfamily that are thought to have a role in innate immunity in the freshwater snail *Biomphalaria glabrata*. (Chapter 5)

fibroblast reticular cells (FRCs) A lymph node stromal cell found in the T-cell zone of the lymph node cortex. FRCs create networks of collagen-rich reticular fibers that guide dendritic cells, T lymphocytes, and B lymphocytes in the lymphoid tissue. (Chapter 9)

ficolins Carbohydrate-binding proteins that can initiate the lectin pathway of complement activation. They are members of the collectin family and bind to the *N*-acetylglucosamine present on the surface of some pathogens. (Chapter 2)

fingolimod Small-molecule immunosuppressive drug that interferes with the actions of sphingosine, leading to retention of effector T cells in lymphoid organs. (Chapter 16)

FK506 *See* **tacrolimus**. (Chapters 7, 16)

FK-binding proteins (FKBPs) Group of prolyl isomerases related to the cyclophilins and which bind the immunosuppressive drug tacrolimus (FK506). (Chapter 16)

flagellin A protein that is the major constituent of the flagellum, the tail-like structure used in bacterial locomotion. TLR-5 recognizes intact flagellin protein that has dissociated from the flagellum. (Chapter 12)

fluid-phase C3 convertase Short-lived alternative pathway C3 convertase, $C3(H_2O)Bb$, that is continually produced at a low level in the plasma that can initiate activation of the alternative pathway of complement activation. (Chapter 2)

fluorescence-activated cell sorter (FACS) An instrument that assesses the presence of fluorescently tagged antibodies on each cell in a complex mixture using a laser that excites the fluorescent tags and detectors to measure the emission from each fluorochrome. The fluorescent signal derived from each cell can be used for analytical purposes or can be used to divert cells with a desired fluorescent signal into a collection tube for isolation. (Appendix I)

fMet-Leu-Phe (fMLF) receptor A pattern-recognition receptor for the peptide fMet-Leu-Phe, which is specific to bacteria, on neutrophils and macrophages. fMet-Leu-Phe acts as a chemoattractant. (Chapter 3)

follicle-associated epithelium (FAE) Specialized epithelium separating the lymphoid tissues of the gut wall from the intestinal lumen. As well as enterocytes it contains microfold cells, through which antigens enter the lymphoid organs from the gut. (Chapter 12)

follicles An area of predominantly B cells in a peripheral lymphoid organ, such as a lymph node, which also contains follicular dendritic cells. (Chapter 1)

follicular B cells The majority population of long-lived recirculating conventional B cells found in the blood, the spleen, and the lymph nodes. Also known as B-2 B cells. (Chapter 8)

follicular dendritic cell (FDC) A cell type of uncertain origin in B-cell follicles of peripheral lymphoid organs that captures antigen:antibody complexes using non-internalized Fc receptors and presents them to B cells for internalization and processing during the germinal center reaction. (Chapters 9, 10)

FoxP3 A transcription factor that is a master regulator in the development and immune-inhibitory function of regulatory T cells. (Chapter 9)

fragment crystallizable region *See* **Fc region**. (Chapter 1)

framework regions Relatively invariant regions that provide a protein scaffold for the hypervariable regions in the V domains of immunoglobulins and T-cell receptors. (Chapter 4)

Freund's complete adjuvant Emulsion of oil and water containing killed mycobacteria used to enhance immune responses to experimental antigens. (Chapter 16)

fungi A kingdom of single-celled and multicellular eukaryotic organisms, including the yeasts and molds, that can cause a variety of diseases. Immunity to fungi is complex and involves both humoral and cell-mediated responses. (Chapter 1)

Fyn *See* **Src family protein tyrosine kinases**. (Chapter 7)

γδ T cells Subset of T lymphocytes bearing a T-cell receptor composed of the antigen-recognition chains, γ and δ, assembled in a γδ heterodimer. (Chapter 6)

γδ T-cell receptors Antigen receptor carried by a subset of T lymphocytes that is distinct from the αβ T-cell receptor. It is composed of a γ and a δ chain, which are produced from genes that undergo gene rearrangement. (Chapter 4)

γ-glutamyl diaminopimelic acid (iE-DAP) A product of degradation of the peptidoglycan of Gram-negative bacteria. It is sensed by NOD1. (Chapter 3)

GAPs *See* **GTPase-activating proteins**. (Chapter 7)

gasdermin D A cytosolic protein that undergoes proteolytic cleavage by caspases (caspase 1) and inserts into the plasma membrane, forming a pore. The pore is required for release of the active forms of IL-1β and IL-18 and also leads to a form of cell death called pyroptosis. (Chapter 3)

GATA3 Transcription factor that has multiple functions in hematopoietic and non-hematopoietic cells but is indispensable for the development of T_H2 cells and ILC2 cells. (Chapter 9)

GEFs *See* **guanine nucleotide exchange factors**. (Chapters 3, 7)

GEM T cells A subset of NKT cells that recognize the mycobacterial lipid antigen glucose monomycolate presented by CD1b and use a very restricted TCRα chain repertoire $V_\alpha1$–2 and $J_\alpha9$. (Chapter 6)

gene knockout The experimental inactivation of a gene, generally in mice, by targeted mutation using homologous recombination. (Appendix I)

gene rearrangement The process of somatic recombination of gene segments in the immunoglobulin and T-cell receptor genetic loci to produce a functional gene. This process generates the diversity found in immunoglobulin and T-cell receptor variable regions. (Chapter 5)

gene segments Sets of short DNA sequences at the immunoglobulin and T-cell receptor loci that encode different regions of the variable domains of antigen receptors. Gene segments of each type are joined together by somatic recombination to form a complete variable-domain exon. There are three types of gene segments: V gene segments encode the first 95 amino acids, D gene segments (in heavy-chain and TCRα chain loci only) encode about 5 amino acids, and J gene segments encode the last 10–15 amino acids of the variable domain. There are multiple copies of each type of gene segment in the germline DNA, but only one of each type is joined together to form the variable domain. (Chapters 1, 5)

gene targeting The experimental use of homologous recombination to generate specific mutations or deletions in a gene with the goal of generating a mouse line carrying the desired genetic alteration in all cells. (Appendix I)

genetic locus The site of a gene on a chromosome. In the case of the genes for the immunoglobulin and T-cell receptor chains, the term locus

refers to the complete collection of gene segments and C-region genes for the given chain. (Chapter 5)

genome-wide association studies (GWASs) Genetic association studies in the general population that look for a correlation between disease frequency and variant alleles by scanning the genomes of many people for the presence of informative single-nucleotide polymorphisms (SNPs). (Chapter 15)

germ-free mice Mice that are raised in the complete absence of intestinal and other microorganisms. Such mice have very depleted immune systems, but they can respond virtually normally to any specific antigen, provided it is mixed with a strong adjuvant. (Chapter 12)

germinal centers Sites of intense B-cell proliferation and differentiation that develop in lymphoid follicles during an adaptive immune response. Somatic hypermutation and class switching occur in germinal centers. (Chapters 1, 9, 10)

germline theory An excluded hypothesis that antibody diversity was encoded by a separate germline gene for each antibody, known not to be true for most vertebrates, although cartilaginous fishes do have some rearranged V regions in the germline. (Chapter 5)

glucosidase II (GlsII) An enzyme in the endoplasmic reticulum that acts to recognize and fully deglucosylate properly folded peptide:MHC class I complexes to release them from the peptide-loading complex and allow their transport to the Golgi apparatus and eventual expression on the cell surface. (Chapter 6)

gluten A type of protein found in certain common grains, including wheat, barley, and rye. In individuals with certain genetic risk factors, an aberrant immune response to gluten leads to inflammatory injury in the small intestine, causing celiac disease. (Chapter 12)

glycosylphosphatidylinositol (GPI) tail A glycolipid modification of proteins that can allow attachment to host membranes without the requirement of a transmembrane protein domain. (Chapter 2)

gnathostomes The class of jawed vertebrates comprising most fish and all mammals. These possess an adaptive immunity that is based on RAG-mediated V(D)J recombination. (Chapter 5)

gnotobiotic Reared in a controlled environment wherein microorganisms are either defined or absent. In the case of the latter, the organism so reared is referred to as germ-free. (Chapter 13)

gnotobiotic mice *See* **germ-free mice**. (Chapter 12)

goblet cell Specialized epithelial cell located in many sites throughout the body and responsible for mucus production; important in protection of the epithelium. (Chapter 12)

goblet cell–associated passages (GAPs) Route by which soluble antigens are transported across goblet cells in the intestinal tract. May be a principal route for the induction of oral tolerance. (Chapter 12)

Goodpasture's syndrome An autoimmune disease in which autoantibodies against type IV collagen (found in basement membranes) are produced, causing extensive inflammation in kidneys and lungs. (Chapter 15)

gout Disease caused by monosodium urate crystals deposited in the cartilaginous tissues of joints, causing inflammation. Urate crystals activate the NLRP3 inflammasome, which induces inflammatory cytokines. (Chapter 3)

G proteins Intracellular GTPases that act as molecular switches in signaling pathways. They bind GTP to induce their active conformation, which is lost when GTP is hydrolyzed to GDP. There are two kinds of G proteins: the heterotrimeric (α, β, γ subunits) receptor-associated G proteins, and the small G proteins, such as Ras and Raf, which act downstream of many transmembrane signaling events. (Chapter 3)

G protein–coupled receptors (GPCRs) A large class of seven-span transmembrane cell-surface receptors that associate with intracellular heterotrimeric G proteins after ligand binding and signal by activation of the G protein. Important examples are the chemokine receptors. (Chapters 2, 3)

G-quadruplex A structure formed from G-rich regions of DNA in which four guanine bases form a planar hydrogen-bonded network, or guanine tetrad, that can further stack on other guanine tetrads. G-quadruplexes processed from intronic switch region RNA may target AID back to the switch regions during isotype switching. (Chapter 10)

graft rejection *See* **allograft rejection**. (Chapter 1)

graft-versus-host disease (GVHD) An attack on the tissues of the recipient by mature T cells in a bone marrow graft from a nonidentical donor, which can cause a variety of symptoms; sometimes these are severe. (Chapters 13, 15)

graft-versus-leukemia effect A beneficial side-effect of bone marrow grafts given to treat leukemia, in which mature T cells in the graft recognize minor histocompatibility antigens or tumor-specific antigens on the recipient's leukemic cells and attack them. (Chapter 15)

Gram-negative bacteria Bacteria that fail to retain crystal violet stain after alcohol wash because of a thin peptidoglycan layer. (Chapter 2)

Gram-negative binding proteins (GNBPs) Proteins that act as the pathogen-recognition proteins in the Toll pathway of immune defense in *Drosophila*. (Chapter 3)

granulocyte–macrophage colony-stimulating factor (GM-CSF) A cytokine involved in the growth and differentiation of cells of the myeloid lineage, including dendritic cells, monocytes and tissue macrophages, and granulocytes. (Chapter 3)

granulocytes White blood cells with multilobed nuclei and cytoplasmic granules. They comprise the neutrophils, eosinophils, and basophils. Also known as polymorphonuclear leukocytes. (Chapter 1)

granuloma A site of chronic inflammation usually triggered by persistent infectious agents such as mycobacteria or by a nondegradable foreign body. Granulomas have a central area of macrophages, often fused into multinucleated giant cells, surrounded by T lymphocytes. (Chapter 11)

granulysin A cytolytic, pro-inflammatory protein released by cytotoxic immune cells. (Chapter 9)

granzymes Pro-apoptotic proteases released by cytotoxic T lymphocytes and natural killer cells. (Chapter 9)

Grass A serine protease of *Drosophila* that functions downstream of peptidoglycan-recognition proteins (PGRPs) and Gram-negative binding proteins (GNBPs) to initiate the proteolytic cascade leading to Toll activation. (Chapter 3)

Graves' disease An autoimmune disease in which antibodies against the thyroid-stimulating hormone receptor cause overproduction of thyroid hormone and thus hyperthyroidism. (Chapter 15)

Griscelli syndrome An inherited immunodeficiency disease that affects the pathway for secretion of lysosomes. It is caused by mutations in a small GTPase, Rab27a, which controls the movement of vesicles within cells. (Chapter 13)

group 1 ILCs (ILC1s) The subtype of innate lymphoid cells (ILCs) characterized by IFN-γ production. (Chapter 3)

group 2 ILCs (ILC2s) A subset of innate lymphoid cells characterized by production of IL-4, IL-5, and IL-13. (Chapter 3)

group 3 ILCs (ILC3s) A subset of innate lymphoid cells characterized by production of IL-17 and IL-22. (Chapter 3)

GTPase-activating proteins (GAPs) Regulatory proteins that accelerate the intrinsic GTPase activity of G proteins and thus facilitate the conversion of G proteins from the active (GTP-bound) state to the inactive (GDP-bound) state. (Chapter 7)

guanine nucleotide exchange factors (GEFs) Proteins that can remove the bound GDP from G proteins, thus allowing GTP to bind and activate the G protein. (Chapters 3, 7)

gut-associated lymphoid tissue (GALT) Lymphoid tissues associated with the gastrointestinal tract, comprising Peyer's patches, the appendix, and isolated lymphoid follicles found in the intestinal wall, where adaptive immune responses are initiated. (Chapters 1, 12)

GVHD *See* **graft-versus-host disease**. (Chapters 13, 15)

H-2 locus, H-2 genes The major histocompatibility complex of the mouse. Haplotypes are designated by a lowercase superscript, as in $H\text{-}2^b$. (Chapters 1, 6)

H-2DM *See* **HLA-DM**. (Chapter 6)

H-2O *See* **HLA-DO**. (Chapter 6)

H2-M3 A nonclassical MHC class Ib protein in mice that can bind and present peptides having an *N*-formylated amino terminus for recognition by CD8 T cells. (Chapter 6)

H5N1 avian flu A highly pathogenic influenza subtype responsible for 'bird flu.' (Chapter 16)

haploinsufficient Describes the situation in which the presence of only one normal allele of a gene is not sufficient for normal function. (Chapter 13)

hapten carrier effect Antibody production against a small chemical group, the hapten, after its attachment to a carrier protein for which an immune response has been generated. (Chapter 10)

hapten Any small molecule that can be recognized by a specific antibody but cannot by itself elicit an immune response. A hapten must be chemically linked to a protein molecule to elicit antibody and T-cell responses. (Chapter 4, Appendix I)

Hashimoto's thyroiditis An autoimmune disease characterized by persistent high levels of antibody against thyroid-specific antigens. These antibodies recruit NK cells to the thyroid, leading to damage and inflammation. (Chapter 15)

heavy chain, H chain One of the two types of protein chains in an immunoglobulin molecule, the other being called the light chain. There are several different classes, or isotypes, of heavy chain (α,δ, ε, γ, and μ), each of which confers a distinctive functional activity on the antibody molecule. Each immunoglobulin molecule contains two identical heavy chains. (Chapters 1, 4)

heavy-chain-only IgGs (hcIgGs) Antibodies that are produced by some camelid species and composed of heavy-chain dimers without an associated light chain that retain antigen-binding capacity. (Chapter 4)

heavy-chain variable region (V_H) Referring to the V region of the heavy chain of an immunoglobulin. (Chapter 5)

helper CD4 T cells, helper T cells Effector CD4 T cells that stimulate or 'help' B cells to make antibody in response to antigenic challenge. T_H2, T_H1, and the T_{FH} subsets of effector CD4 T cells can perform this function. (Chapter 1)

hemagglutination The clumping of red blood cells, often caused by the binding of antibodies to target antigens on the surface of the cells. (Appendix I)

hemagglutinin Substances that can cause hemagglutination, such as human antibodies that recognize the ABO blood group antigens on red blood cells, or the influenza virus hemagglutinin (H), a glycoprotein that functions in viral fusion with endosome membranes. (Chapters 10, 12, 16)

hematopoietic stem cells (HSCs) Type of pluripotent (or multipotent) cell in the bone marrow that can give rise to all the different blood cell types. (Chapters 1, 8)

hematopoietin superfamily Large family of structurally related cytokines that includes growth factors and many interleukins with roles in both adaptive and innate immunity. (Chapter 3)

hemochromatosis protein A protein expressed by intestinal epithelial cells that regulates iron uptake and transport by interacting with the transferrin receptor to decrease its affinity for iron-loaded transferrin. (Chapter 6)

hemolytic disease of the newborn (erythroblastosis fetalis) A severe form of Rh hemolytic disease in which maternal anti-Rh antibody enters the fetus and produces a hemolytic anemia so severe that the fetus has mainly immature erythroblasts in the peripheral blood. (Chapter 11, Appendix I)

hemophagocytic lymphohistiocytic (HLH) syndrome A dysregulated expansion of CD8-positive lymphocytes that is associated with macrophage activation. The activated macrophages phagocytose blood cells, including erythrocytes and leukocytes. (Chapter 13)

hepatobiliary route Route whereby mucosally produced dimeric IgA enters the portal veins in the lamina propria, is transported to the liver, and reaches the bile duct by transcytosis. This pathway is not of great significance in humans. (Chapter 12)

heptamer The conserved seven-nucleotide DNA sequence in the recombination signal sequences (RSSs) flanking gene segments in the immunoglobulin and T-cell receptor loci. (Chapter 5)

HER-2/neu A receptor tyrosine kinase overexpressed in many cancers, particularly breast cancer, that is the target of trastuzumab (Herceptin) used in its treatment. (Chapter 16)

herd immunity Protection conferred to unvaccinated individuals in a population that is produced by vaccination of others and reduction in the natural reservoir for infection. (Chapter 16)

hereditary angioedema (HAE) A genetic deficiency of the C1 inhibitor of the complement system. In the absence of C1 inhibitor, spontaneous activation of the complement system can cause diffuse fluid leakage from blood vessels, the most serious consequence of which is swelling of the larynx, leading to suffocation. (Chapters 2, 13)

hereditary hemochromatosis A disease caused by defects in the HFE gene characterized by abnormally high retention of iron in the liver and other organs. (Chapter 6)

herpes virus entry molecule (HVEM) *See* **B and T lymphocyte attenuator**. (Chapter 7)

herpes zoster *See* **shingles**. (Chapter 13)

heterosubtypic immunity Immune protection against a pathogen conferred by infection with a distinct strain, typically with reference to different influenza A serotypes. (Chapter 16)

heterotrimeric G proteins *See* **G proteins**. (Chapter 3)

heterozygous Describes individuals that have two different alleles of a given gene, one inherited from the mother and one from the father. (Chapter 6)

HFE *See* **hemochromatosis protein**. (Chapter 6)

high endothelial cells, high endothelial venules (HEVs) Specialized small venous blood vessels in lymphoid tissues. Lymphocytes migrate from the blood into lymphoid tissues by attaching to the high endothelial cells in the walls of the venules and squeezing between them. (Chapters 1, 9, 12)

hinge region The flexible domain that joins the Fab arms to the Fc piece in an immunoglobulin. The flexibility of the hinge region in IgG and IgA molecules allows the Fab arms to adopt a wide range of angles, permitting binding to epitopes spaced variable distances apart. (Chapter 4)

HIP/PAP An antimicrobial C-type lectin secreted by intestinal cells in humans. Also known as RegIIIα. (Chapter 2)

histamine A vasoactive amine stored in mast-cell granules. Histamine released by antigen binding to IgE antibodies that are bound to mast cells causes the dilation of local blood vessels and the contraction of smooth

muscle, producing some of the symptoms of IgE-mediated allergic reactions. Antihistamines are drugs that counter histamine action. (Chapter 14)

histatins Antimicrobial peptides constitutively produced by the parotid, sublingual, and submandibular glands in the oral cavity. Active against pathogenic fungi such as *Cryptococcus neoformans* and *Candida albicans*. (Chapter 2)

HIV *See* **human immunodeficiency virus**. (Chapter 13)

HLA The genetic designation for the human MHC. Individual loci are designated by uppercase letters, as in HLA-A, and alleles are designated by numbers, as in HLA-A*0201. (Chapter 6)

HLA-DM An invariant MHC protein resembling MHC class II in humans that is involved in loading peptides onto MHC class II molecules. A homologous protein in mice is called H-2M, or sometimes H2-DM. (Chapter 6)

HLA-DO An invariant MHC class II molecule that binds HLA-DM, inhibiting the release of CLIP from MHC class II molecules in intracellular vesicles. A homologous protein in mice is called H-2O or H2-DO. (Chapter 6)

homeostatic chemokines Chemokines that are produced at steady state to direct the localization of immune cells to lymphoid tissues. (Chapter 11)

homing The direction of a lymphocyte into a particular tissue. (Chapter 9)

homing receptors Receptors on lymphocytes for chemokines, cytokines, and adhesion molecules specific to particular tissues and which enable the lymphocyte to enter that tissue. (Chapter 11)

homologous recombination A genetic process in which sequences in the DNA of a cell are replaced by similar, but not identical, sequences at the precise location of the original sequences. (Appendix I)

homozygous Describes a genetic locus in an individual where the individual has two identical alleles of a given gene, inherited separately from each parent. (Chapter 6)

host-versus-graft disease (HVGD) Another name for the allograft rejection reaction. The term is used mainly in relation to bone marrow transplantation when immune cells of the host recognize and destroy transplanted bone marrow or hematopoietic stem cells (HSCs). (Chapter 13)

human immunodeficiency virus (HIV) The causative agent of the acquired immune deficiency syndrome (AIDS). HIV is a retrovirus of the lentivirus family that selectively infects macrophages and CD4 T cells, leading to their slow depletion, which eventually results in immunodeficiency. There are two major strains of the virus, HIV-1 and HIV-2, of which HIV-1 causes most disease worldwide. HIV-2 is endemic to West Africa but is spreading. (Chapter 13)

human leukocyte antigen (HLA) *See* **HLA**. (Chapter 6)

humanization The genetic engineering of mouse hypervariable loops of a desired specificity into otherwise human antibodies for use as therapeutic agents. Such antibodies are less likely to cause an immune response in people treated with them than are wholly mouse antibodies. (Chapter 16)

humoral Referring to effector proteins in the blood or body fluids, such as antibodies in adaptive immunity or complement proteins in innate immunity. (Chapter 2)

humoral immunity, humoral immune response Immunity due to proteins circulating in the blood, such as antibodies (in adaptive immunity) or complement (in innate immunity). Adaptive humoral immunity can be transferred to unimmunized recipients by the transfer of serum containing specific antibody. (Chapters 1, 10, Appendix I)

HVGD *See* **host-versus-graft disease**. (Chapter 13)

hybridoma Cells created by the fusion of two different parental cell types. Antibody-secreting hybridomas are generated by fusing a plasma cell with a non-antibody-secreting myeloma tumor cell to produce an immortalized antibody-secreting cell line. (Appendix I)

hydrophobic interaction Chemical interaction occurring between nearby hydrophobic moieties typically excluding water molecules. (Chapter 4)

3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase Rate-limiting enzyme in the production of cholesterol and a target of cholesterol-lowering drugs such as the statins. (Chapter 16)

21-hydroxylase An enzyme of nonimmune function but encoded in the MHC locus required for normal cortisol synthesis by the adrenal gland. (Chapter 6)

hygiene hypothesis A hypothesis first proposed in 1989 that reduced exposure to ubiquitous environmental microorganisms was a cause of the increased frequency of patients with allergies observed over the course of the mid- to late-20th century. (Chapter 14)

hyper IgE syndrome (HIES) Also called Job syndrome. A disease characterized by recurrent skin and pulmonary infections and high serum concentrations of IgE. (Chapter 13)

hyper IgM syndrome A group of genetic diseases in which there is overproduction of IgM antibody, among other symptoms. They are due to defects in various genes for proteins involved in class switching such as CD40 ligand and the enzyme AID. *See* **activation-induced cytidine deaminase**; **CD40 ligand deficiency**. (Chapters 10, 13)

hyper IgM type 2 immunodeficiency *See* **activation-induced cytidine deaminase**. (Chapter 10)

hyperacute graft rejection Immediate rejection reaction caused by preformed natural antibodies that react against antigens on the transplanted organ. The antibodies bind to endothelium and trigger the blood-clotting cascade, leading to an engorged, ischemic graft and rapid death of the organ. (Chapter 15)

hypereosinophilic syndrome Disease associated with an overproduction of eosinophils. (Chapter 14)

hypermorphic A type of genetic variation wherein the affected wild-type gene is expressed at an increased level or its gene product has increased function. (Chapter 13)

hypervariable regions *See* **complementarity-determining regions**. (Chapters 4, 5)

hypomorphic A type of genetic variation wherein the affected gene has diminished, but not entirely lost, expression or the gene product has reduced, but not absent, function compared to wild type. (Chapter 13)

IκB A cytoplasmic protein that constitutively associates with the NFκB homodimer, which is composed of p50 and p65 subunits. When IκB is phosphorylated by activated IKK (IκB kinase), IκB becomes degraded and allows the NFκB dimer to be released as an active transcription factor. (Chapter 3)

IκB kinase (IKK) *See* **IKK**. (Chapter 3)

iC3b Inactive complement fragment produced by cleavage of C3b. (Chapter 2)

ICAMs ICAM-1, ICAM-2, ICAM-3. Cell-adhesion molecules of the immunoglobulin superfamily that bind to the leukocyte integrin CD11a:CD18 (LFA-1). They are crucial in the binding of lymphocytes and other leukocytes to antigen-presenting cells and endothelial cells. (Chapter 3)

ICOS (inducible co-stimulatory) A CD28-related co-stimulatory receptor that is induced on activated T cells and can enhance T-cell responses. It binds a co-stimulatory ligand known as ICOSL (ICOS ligand), which is distinct from the B7 molecules. (Chapter 10)

ICOSL *See* **ICOS**. (Chapter 10)

IFIT (IFN-induced protein with tetratricoid repeats) A small family of host proteins induced by interferons that regulate protein translation during infection in part by interactions with eIF3. (Chapter 3)

IFIT1, IFIT2 IFN-induced protein with tetratricoid repeats (IFIT) 1 and 2 are proteins encoded by interferon-stimulated genes (ISGs) that regulate the translation of normally capped mRNAs and lead to reduced cellular proliferation. IFIT1 can also suppress translation of some viral RNAs that lack 2′-*O*-methylation (cap-0), such as Sindbis virus. In this way, IFIT1 and IFIT2 serve as restriction factors in certain viral infections. (Chapter 3)

IFITM (interferon-induced transmembrane protein) A small family of host transmembrane proteins induced by interferons that function in the cell's vesicular compartment to restrain various steps in viral replication. (Chapter 3)

IFITM1, IFITM3 Interferon-induced transmembrane protein (IFITM) 1 and 3 are proteins encoded by interferon-stimulated genes (ISGs) that interfere with membrane fusion between viral membranes and membranes of the lysosome (IFITM1) or endosome (IFITM3), and so serve as restriction factors in various viral infections. (Chapter 3)

IFN-α, IFN-β Antiviral cytokines produced by a wide variety of cells in response to infection by a virus, and which also help healthy cells resist viral infection. They act through the same receptor, which signals through a Janus-family tyrosine kinase. Also known as the type I interferons. (Chapter 3)

IFN-γ A cytokine of the interferon structural family produced by effector CD4 T_H1 cells, CD8 T cells, and NK cells. Its primary function is the activation of macrophages, and it acts through a different receptor from that of the type I interferons. (Chapters 1, 3)

IFN-γ–induced lysosomal thiol reductase (GILT) An enzyme present in the endosomal compartment of many antigen-presenting cells that denatures disulfide bonds to facilitate the degradation and processing of proteins. (Chapter 6)

IFN-λ Also called type III interferons, this family includes IL-28A, IL-28B, and IL-29, which bind a common receptor expressed by a limited set of epithelial tissues. (Chapters 3, 9)

IFN-λ receptor Heterodimeric receptor composed of a unique IL-28Rα subunit and the β subunit of the IL-10 receptor that recognizes IL-28A, IL-28B, and IL-29. (Chapter 3)

Igα, Igβ *See* **B-cell receptor**. (Chapter 7)

IgA Immunoglobulin class composed of α heavy chains that can occur in a monomeric and a polymeric (mainly dimeric) form. Polymeric IgA is the main antibody secreted by mucosal lymphoid tissues. (Chapter 4)

IgA deficiency The most common type of primary immunodeficiency. (Chapter 13)

IgD Immunoglobulin class composed of δ heavy chains that appears as surface immunoglobulin on mature B cells. (Chapter 4)

IgE Immunoglobulin class composed of ε heavy chains that acts in defense against parasite infections and in allergic reactions. (Chapters 4, 14)

IgG Immunoglobulin class composed of γ heavy chains that is the most abundant class of immunoglobulin in the plasma. (Chapter 4)

IgM Immunoglobulin class composed of μ heavy chains that is the first to appear on B cells and the first to be secreted. (Chapter 4)

IgM deficiency A rare genetic immunodeficiency characterized by selective low or absent IgM production with normal or elevated levels of IgG and IgA. (Chapter 13)

IgNAR *See* **immunoglobulin new antigen receptor**.

IgW Type of heavy-chain isotype present in cartilaginous fishes that is composed of six immunoglobulin domains. (Chapter 5)

IKK The IκB kinase, IKK, is a multi-subunit protein complex composed of IKKα, IKKβ, and IKKγ (the latter also known as NEMO). (Chapter 3)

IKKε A kinase that interacts with TBK1 (TANK-binding kinase 1) in the phosphorylation of IRF3 downstream of TLR-3 signaling. (Chapter 3)

IL-1 family One of four major families of cytokines, this family contains 11 cytokines that are structurally similar to IL-1α and are largely pro-inflammatory in function. (Chapter 3)

IL-1α, IL-1β Interleukin-1α and interleukin-1β are cytokines produced by activated macrophages that have many effects in the immune response, including the activation of vascular endothelium, activation of lymphocytes, and the induction of fever. IL-1β must be cleaved by caspase 1 before having biological activity, while IL-1α does not require cleavage. (Chapter 3)

IL-2Rα *See* **CD25**. (Chapter 9)

IL-4 *See* **interleukin (IL)**. (Chapter 9)

IL-5 *See* **interleukin (IL)**. (Chapter 9)

IL-6 Interleukin-6, a cytokine produced by activated macrophages and which has many effects, including lymphocyte activation, the stimulation of antibody production, and the induction of fever. (Chapters 3, 9)

IL-7Rα (CD127) *See* **CD127**. (Chapter 11)

IL-10 *See* **interleukin (IL)**. (Chapter 9)

IL-13 *See* **interleukin (IL)**. (Chapter 9)

IL-17A *See* **interleukin (IL)**. (Chapter 9)

IL-17F *See* **interleukin (IL)**. (Chapter 9)

IL-21 A cytokine produced by T cells (e.g., T_{FH} cells) that activates STAT3 and promotes survival and proliferation, particularly of germinal center B cells. (Chapters 9, 10)

IL-22 *See* **interleukin (IL)**. (Chapter 9)

ILC1 A subset of innate lymphoid cells characterized by production of IFN-γ. (Chapters 1, 11)

ILC2 *See* **ILCs**. (Chapter 11)

ILC3 *See* **ILCs**. (Chapter 11)

ILCs (innate lymphoid cells) These are a class of innate immune cells having overlapping characteristics with T cells but lacking an antigen receptor. They arise in several groups, ILC1, ILC2, ILC3, and NK cells, which exhibit properties roughly similar to T_H1, T_H2, T_H17, and CD8 T cells. (Chapters 1, 3)

Imd (immunodeficiency) signaling pathway A defense against Gram-negative bacteria in insects that results in the production of antimicrobial peptides such as diptericin, attacin, and cecropin. (Chapter 3)

imiquimod Drug (Aldara) approved for treatment of basal-cell carcinoma, genital warts, and actinic keratoses known to activate TLR-7, although not approved as an adjuvant for vaccines. (Chapter 16)

immature B cells B cells that have rearranged a heavy- and a light-chain V-region gene and express surface IgM, but have not yet matured sufficiently to express surface IgD as well. (Chapter 8)

immature cDCs Conventional dendritic cells that have yet to be activated for antigenic priming of naive T cells. Immature cDCs typically are actively phagocytic but lack high expression of co-stimulatory molecules. (Chapter 9)

immediate hypersensitivity reactions Allergic reactions that occur within seconds to minutes of encounter with antigen, caused largely by activation of mast cells or basophils. (Chapters 11, 14)

immune complexes Complexes formed by the binding of antibody to its cognate antigen. Activated complement proteins, especially C3b, are often bound in immune complexes. Large immune complexes form when sufficient antibody is available to cross-link multivalent antigen; these are cleared by cells of the reticuloendothelial system that bear Fc receptors and complement receptors. Small, soluble immune complexes form when antigen is in excess; these can be deposited in small blood vessels and damage them. (Chapter 14)

immune effector modules Sets of innate and adaptive immune cells whose responses are coordinated to focus host defense on different classes of pathogens. There are two broad classes of immune modules, cytotoxic and helper, the latter of which is further subdivided into types 1, 2, and 3, dedicated to the elimination of intracellular pathogens, helminths, and extracellular bacteria and fungi, respectively. Underpinning the orchestration of each module are ILCs and T lymphocytes that have shared transcriptional and effector programs: NK and cytotoxic CD8 T cells (cytotoxic module); ILC1 and T_H1 cells (type 1 module); ILC2 and T_H2 cells (type 2 module); and ILC3 and T_H17 cells (type 3 module). (Chapter 11)

immune evasion Mechanisms used by pathogens to avoid detection and/or elimination by host immune defenses. (Chapters 2, 13)

immune synapse The highly organized interface that develops between a T cell and the target cell it is in contact with, formed by T-cell receptors binding to antigen and cell-adhesion molecules binding to their counterparts on the two cells. Also known as the supramolecular activation complex (SMAC). (Chapter 7)

immune surveillance The recognition, and in some cases the elimination, of tumor cells by the immune system before they become clinically detectable. (Chapter 16)

immune system The tissues, cells, and molecules involved in innate immunity and adaptive immunity. (Chapter 1)

immunization The deliberate induction of an immune response by exposing an individual to a specific antigen. Often called vaccination when used to induce a protective immune response to a microbial pathogen. (Appendix I)

immunodeficiency diseases Any inherited or acquired disorder in which some aspect or aspects of host defense are absent or functionally defective. (Chapter 1)

immunodominant Describes epitopes in an antigen that are preferentially recognized by T cells, such that T cells specific for those epitopes come to dominate the immune response. (Chapter 13)

immunoblotting A technique in which proteins separated by SDS-PAGE are transferred from the acrylamide gel to a nylon or nitrocellulose membrane. A specific protein of interest is identified by incubating the membrane with an antibody to that protein, followed by an enzyme-linked anti-immunoglobulin antibody. Finally, the membrane is incubated with a colorless substrate, which is converted to a colored product on the membrane at the location of bound antibody. Also called western blotting. *See also* **SDS-PAGE**. (Appendix I)

immunoevasins Viral proteins that prevent the appearance of peptide:MHC class I complexes on the infected cell, thus preventing the recognition of virus-infected cells by cytotoxic T cells. (Chapter 13)

immunofluorescence microscopy Cells or tissue sections are incubated with fluorescently labeled antibodies to target molecules present in the cells or tissue. Binding of these antibodies is determined using a microscope that is outfitted to detect fluorescent dyes. (Appendix I)

immunogen Any substance that can elicit an adaptive immune response. (Appendix I)

immunogenic Elicitation of an adaptive immune response. (Chapter 1, Appendix I)

immunoglobulin (Ig) The protein family to which antibodies and B-cell receptors belong. (Chapters 1, 4)

immunoglobulin A (IgA) *See* **IgA**. (Chapter 4)

immunoglobulin D (IgD) *See* **IgD**. (Chapter 4)

immunoglobulin domain, Ig domain Protein domain first described in antibody molecules but present in many proteins. (Chapter 4)

immunoglobulin E (IgE) *See* **IgE**. (Chapter 4)

immunoglobulin fold The tertiary structure of an immunoglobulin domain, comprising a sandwich of two β sheets held together by a disulfide bond. (Chapters 4, 5)

immunoglobulin G (IgG) *See* **IgG**. (Chapter 4)

immunoglobulin-like domain (Ig-like domain) Protein domain structurally related to the immunoglobulin domain. (Chapter 4)

immunoglobulin-like proteins Proteins containing one or more immunoglobulin-like domains, which are protein domains structurally similar to those of immunoglobulins. (Chapter 3)

immunoglobulin M (IgM) *See* **IgM.** (Chapter 4)

immunoglobulin new antigen receptor (IgNAR) A form of heavy-chain-only Ig molecule made by shark species. (Chapter 4)

immunoglobulin repertoire The variety of antigen-specific immunoglobulins (antibodies and B-cell receptors) present in an individual. Also known as the antibody repertoire. (Chapter 5)

immunoglobulin superfamily Large family of proteins with at least one Ig or Ig-like domain, many of which are involved in antigen recognition and cell–cell interaction in the immune system and other biological systems. (Chapter 4)

immunohistochemistry Use of an enzyme-coupled antibody to detect a target antigen in cells or tissue samples. After antibody binding, the sample is incubated with a substrate that is converted from a colorless to a colored state by the coupled enzyme. Visualization of the colored reaction product indicates the location of the target antigen. (Appendix I)

immunological ignorance A form of self-tolerance in which reactive lymphocytes and their target antigen are both detectable within an individual, yet no autoimmune attack occurs. (Chapter 15)

immunologically privileged sites Certain sites in the body, such as the brain, that do not mount an immune response against tissue allografts. Immunological privilege can be due both to physical barriers to cell and antigen migration and to the presence of immunosuppressive cytokines. (Chapter 15)

immunological memory The ability of the immune system to respond more rapidly and more effectively on a second encounter with an antigen. Immunological memory is specific for a particular antigen and is long-lived. (Chapters 1, 11)

immunological tolerance *See* **tolerance**. (Chapter 1)

immunology The study of all aspects of host defense against infection and also of the adverse consequences of immune responses. (Chapter 1)

immunomodulatory therapy Treatments that seek to modify an immune response in a beneficial way; for example, to reduce or prevent an autoimmune or allergic response. (Chapter 16)

immunophilins *See* **cyclophilins, FK-binding proteins**. (Chapter 16)

immunoprecipitation A complex mixture, such as a cell lysate, is incubated with an antibody to a target antigen of interest. Antibody:antigen complexes are isolated by incubation with an anti-immunoglobulin antibody coupled to a solid matrix such as a latex bead. The latex beads are then separated from the remaining cell lysate. (Appendix I)

immunoproteasome A form of proteasome found in cells exposed to interferons. It contains three subunits that are different from the normal proteasome. (Chapter 6)

immunoreceptor tyrosine-based activation motif (ITAM) Sequence motifs in the signaling chains of receptors, such as antigen receptors on lymphocytes, that are the site of tyrosine phosphorylation after receptor activation, leading to recruitment of other signaling proteins. (Chapters 3, 7)

immunoreceptor tyrosine-based inhibition motif (ITIM) Sequence motifs in the signaling chains of inhibitory receptors that are sites of tyrosine

phosphorylation, leading to inhibitory signaling, such as through recruitment of phosphatases that remove phosphate groups added by tyrosine kinases. (Chapters 3, 7)

immunoreceptor tyrosine-based switch motif (ITSM) A sequence motif present in the cytoplasmic tails of some inhibitory receptors. (Chapter 7)

immunotoxin Antibodies that are chemically coupled to toxic proteins usually derived from plants or microbes. The antibody targets the toxin moiety to the required cells. (Chapter 16)

indirect allorecognition Recognition of a grafted tissue that involves the uptake of allogeneic proteins from the donor tissue by the recipient's antigen-presenting cells, followed by antigen processing and presentation to T cells by self MHC molecules. (Chapter 15)

indirect Coombs test This assay tests for anti-Rh antibody in maternal serum. The serum is mixed with Rh-positive red blood cells, followed by anti-human immunoglobulin antibodies. If the serum contains anti-Rh antibody, this antibody will bind to the Rh-positive cells, which will then be agglutinated by the addition of anti-human immunoglobulin antibodies. (Appendix I)

indirect immunofluorescence Cells or tissue sections are incubated with antibodies to target molecules present in the cells or tissue. The samples are then incubated with a fluorescently labeled anti-immunoglobulin antibody specific for the first antibody. Binding of the second anti-immunoglobulin antibody is determined using a microscope that is outfitted to detect fluorescent dyes. (Appendix I)

indoleamine 2,3-dioxygenase (IDO) Enzyme expressed by immune cells and some tumors that catabolizes tryptophan into kynurenine metabolites that can have immunosuppressive functions. (Chapter 16)

infectious mononucleosis The common form of infection with the Epstein–Barr virus. It consists of fever, malaise, and swollen lymph nodes. Also called glandular fever. (Chapter 13)

inflammasome A pro-inflammatory protein complex that is formed after stimulation of the intracellular NOD-like receptors. Production of an active caspase in the complex processes cytokine proproteins into active cytokines. (Chapters 3, 12)

inflammation General term for the local accumulation of fluid, plasma proteins, and white blood cells that is initiated by physical injury, infection, or a local immune response. (Chapters 1, 2)

inflammation-anergic macrophages Macrophages in the homeostatic, noninflamed gastrointestinal mucosa that are hyporesponsive to inflammatory stimuli because of down-regulation of the LPS co-receptor CD14, IgA and IgG Fc receptors, and NFκB signaling molecules downstream of tonic TGF-β signaling. (Chapter 12)

inflammatory bowel disease (IBD) General name for a set of inflammatory conditions in the gut, such as Crohn's disease and ulcerative colitis, that have an immunological component. (Chapters 12, 15)

inflammatory cells Cells such as macrophages, neutrophils, and effector T_H1 lymphocytes that invade inflamed tissues and contribute to the inflammation. (Chapter 1)

inflammatory chemokines Chemokines that are produced in response to infection or injury to direct the localization of immune cells to sites of inflammation. (Chapter 11)

inflammatory inducers Chemical structures that indicate the presence of invading microbes or cellular damage, such as bacterial lipopolysaccharides, extracellular ATP, or urate crystals. (Chapter 1)

inflammatory mediators Chemicals such as cytokines produced by immune cells that act on target cells to promote defense against microbes. (Chapter 1)

inflammatory monocytes An activated form of monocytes producing a variety of pro-inflammatory cytokines. (Chapter 3)

inflammatory response *See* **inflammation**. (Chapter 2)

infliximab Chimeric antibody to TNF-α used in the treatment of inflammatory diseases, such as Crohn's disease and rheumatoid arthritis. (Chapter 16)

inherited immunodeficiency *See* **primary immunodeficiency**. (Chapter 13)

inhibitory receptors On NK cells, receptors whose stimulation results in suppression of the cell's cytotoxic activity. (Chapter 3)

initiator caspases Proteases that promote apoptosis by cleaving and activating other caspases. (Chapter 9)

injectisome Needle-like molecular complex employed by pathogenic bacteria to inject bacterial effector molecules into eukaryotic cells or other bacteria. (Chapters 12, 13)

iNKT cells *See* **invariant NKT cells**. (Chapters 6, 8, 12)

innate immunity The various innate resistance mechanisms that are encountered first by a pathogen, before adaptive immunity is induced, such as anatomical barriers, antimicrobial peptides, the complement system, and macrophages and neutrophils carrying nonspecific pathogen-recognition receptors. Innate immunity is present in all individuals at all times, does not increase with repeated exposure to a given pathogen, and discriminates between groups of similar pathogens, rather than responding to a particular pathogen. Cf. **adaptive immunity**. (Chapters 1, 2)

innate lymphoid cells (ILCs) *See* **ILCs**. (Chapters 1, 3, 11)

innate recognition receptors General term for a large group of proteins that recognize many different inflammatory inducers and that are encoded in the germline and do not need gene rearrangement in somatic cells to be expressed. (Chapter 1)

inositol 1,4,5-trisphosphate (IP_3) A soluble second messenger produced by the cleavage of membrane inositol phospholipids by phospholipase C-γ. It acts on receptors in the endoplasmic reticulum membrane, resulting in the release of stored Ca^{2+} into the cytosol. (Chapter 7)

integrins Heterodimeric cell-surface proteins involved in cell–cell and cell–matrix interactions. They are important in adhesive interactions between lymphocytes and antigen-presenting cells and in lymphocyte and leukocyte adherence to blood vessel walls and migration into tissues. (Chapter 3)

integrin $\alpha_4\beta_1$ (VLA-4, or CD49d:CD29) *See* **integrins**. (Chapter 16)

integrin $\alpha_4\beta_7$ Integrin binding to VCAM-1, MAdCAM-1, and fibronectin and expressed by various cells, such as IELs, that traffic to intestinal lamina propria. Also called lamina propria–associated molecule 1. (Chapters 9, 16)

intercellular adhesion molecules (ICAMs) *See* **ICAMs**. (Chapter 3)

interferon-α receptor (IFNAR) This receptor recognizes IFN-α and IFN-β to activate STAT1 and STAT2 and induce expression of many ISGs. (Chapter 3)

interferon-γ *See* **IFN-γ**. (Chapter 1)

interferon-induced transmembrane protein (IFITM) *See* **IFITM**. (Chapter 3)

interferon-producing cells (IPCs) *See* **plasmacytoid dendritic cells**. (Chapter 3)

interferon regulatory factor (IRF) A family of nine transcription factors that regulate a variety of immune responses. For example, IRF3 and IRF7 are activated as a result of signaling from some TLRs. Several IRFs promote expression of the genes for type I interferons. (Chapter 3)

interferons (IFNs) Several related families of cytokines originally named for their interference with viral replication. IFN-α and IFN-β are antiviral in their effects; IFN-γ has other roles in the immune system. (Chapter 3)

interferon-stimulated genes (ISGs) A category of genes induced by interferons, which include many whose products promote innate defense against pathogens, such as oligoadenylate synthetase, PKR, and the Mx, IFIT, and IFITM proteins. (Chapter 3)

interleukin (IL) A generic name for cytokines produced by leukocytes. The more general term cytokine is used in this book, but the term interleukin is used in the naming of specific cytokines such as IL-2. Some key interleukins are listed in the glossary under their abbreviated names; for example, IL-1β and IL-2. Cytokines are listed in eAppendix III. (Chapter 3)

intestinal stem cells (ISCs) Multipotent adult stem cells located in the basal region of crypts in the large and small intestine. (Chapter 12)

intracellular cytokine staining A technique for visualizing cells in a population capable of producing a cytokine of interest. Stimulated T cells are treated with a protein secretion inhibitor for several hours, then fixed and permeabilized. Cells are then incubated with a fluorescently tagged anti-cytokine antibody and analyzed by FACS. *See also* **fluorescence-activated cell sorter**. (Appendix I)

intradermal (i.d.) Into the dermal layer of the skin. (Appendix I)

intraepithelial lymphocytes (IELs) Lymphocytes present in the epithelium of mucosal surfaces such as the gut. They are predominantly T cells, and in the gut are predominantly CD8 T cells. (Chapter 12)

intramuscular (i.m.) Into the muscle. (Appendix I)

intranasal (i.n.) Introduced through the nose, often by inhalation. (Appendix I)

intraperitoneal (i.p.) Within the peritoneal cavity (the site containing the abdominal organs). (Appendix I)

intrathymic dendritic cells *See* **dendritic cells**. (Chapter 8)

intravenous (i.v.) Into a vein. (Appendix I)

intrinsic (or **mitochondrial**) **pathway of apoptosis** Signaling pathway that mediates apoptosis in response to noxious stimuli including UV irradiation, chemotherapeutic drugs, starvation, or lack of the growth factors required for survival. It is initiated by mitochondrial damage. (Chapters 9, 11)

invariant chain (Ii, CD74) A polypeptide that binds in the peptide-binding cleft of newly synthesized MHC class II proteins in the endoplasmic reticulum and blocks other peptides from binding there. It is degraded in the endosome, allowing for loading of antigenic peptides there. (Chapters 4, 6)

invariant NKT (iNKT) cells A type of innate-like lymphocyte that carries a T-cell receptor with an invariant α chain and a β chain of limited diversity that recognizes glycolipid antigens presented by CD1 MHC class Ib molecules. This cell type also carries the surface marker NK1.1, which is usually associated with NK cells. (Chapters 6, 8, 12)

IPEX (immune dysregulation, polyendocrinopathy, enteropathy, X-linked) Immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome. A very rare inherited condition in which CD4 CD25 regulatory T cells are lacking as a result of a mutation in the gene for the transcription factor FoxP3, leading to the development of autoimmunity. (Chapter 15)

ipilimumab Antibody to human CTLA-4 used to treat melanoma, and first checkpoint blockade immunotherapy. (Chapter 16)

Ir (immune response) genes An archaic term for genetic polymorphisms controlling the intensity of the immune response to a particular antigen, now known to result from allelic differences in MHC molecules, especially MHC class II molecules, that influence binding of particular peptides. (Chapter 6)

IRAK1, IRAK4 Protein kinases that are part of the intracellular signaling pathways leading from TLRs. (Chapter 3)

IRAK4 deficiency An immunodeficiency characterized by recurrent bacterial infections, caused by inactivating mutations in the IRAK4 gene that result in a block in TLR signaling. (Chapter 3)

IRF9 A member of the IRF family of transcription factors that interacts with activated STAT1 and STAT2 to form the complex called ISGF3, which induces transcription of many ISGs. (Chapter 3)

ISGF3 *See* **IRF9**. (Chapter 3)

isoelectric focusing An analytical technique that separates proteins on the basis of the pH at which their net charge is zero. A pH gradient is established within a matrix, such as a polyacrylamide gel, and subjected to an electric current. Proteins added to this matrix will migrate until they reach the pH at which they are electrically neutral. (Appendix I)

isoforms Different forms of the same protein; for example, the different forms encoded by different alleles of the same gene. (Chapter 6)

isolated lymphoid follicles (ILFs) A type of organized lymphoid tissue in the gut wall that is composed mainly of B cells. (Chapter 12)

isolation membrane *See* **phagophore**. (Chapter 12)

isotype The designation of an immunoglobulin chain with respect to the type of constant region it has. Light chains can be of either κ or λ isotype. Heavy chains can be of μ, δ, γ, α, or ε isotype. The different heavy-chain isotypes have different effector functions and determine the class and functional properties of antibodies (IgM, IgD, IgG, IgA, and IgE, respectively). (Chapters 1, 4, 10)

isotype switching *See* **class switching**. (Chapter 10)

isotypic exclusion Describes the use of one or other of the light-chain isotypes, κ or λ, by a given B cell or antibody. (Chapter 8)

JAK inhibitors ('jakinibs') Small-molecule kinase inhibitors with relative selectivity for one or more of the Janus kinases. (Chapter 16)

Janus kinase (JAK) family, Janus kinases (JAKs) Enzymes of the JAK–STAT intracellular signaling pathways that link many cytokine receptors with gene transcription in the nucleus. The kinases phosphorylate STAT proteins in the cytosol, which then move to the nucleus and activate a variety of genes. (Chapters 3, 16)

J chain Small polypeptide chain made by B cells that attaches to polymeric immunoglobulins IgM and IgA by disulfide bonds and is essential for formation of the binding site for the polymeric immunoglobulin receptor. (Chapters 4, 12)

JNK *See* **Jun kinase**. (Chapter 7)

Job syndrome *See* **hyper IgE syndrome**. (Chapter 13)

joining gene segment, J gene segment Short DNA sequences that encode the J regions of immunoglobulin and T-cell receptor variable domains. In a rearranged light-chain, TCRα, or TCRγ genes, the J gene segment is joined to a V gene segment. In a rearranged heavy-chain, TCRβ, or TCRδ locus, a J gene segment is joined to a D gene segment. (Chapter 5)

junctional diversity The variability in sequence present in antigen-specific receptors that is created during the process of joining V, D, and J gene segments and which is due to imprecise joining and insertion of non-templated nucleotides at the joins between gene segments. (Chapters 1, 5)

Jun kinase (JNK) A protein kinase that phosphorylates the transcription factor c-Jun, enabling it to bind to c-Fos to form the AP-1 transcription factor. (Chapter 7)

κ chain One of the two classes or isotypes of immunoglobulin light chains. (Chapters 4, 5)

K63 linkages In polyubiquitin chains, the covalent ligation of the lysine 63 amino group of one ubiquitin protein with the carboxy terminus of a second ubiquitin. This type of linkage is most associated with activation of signaling by formation of a scaffold recognized by signaling adaptors such as TAB1/2. (Chapter 3)

kallikreins Proteases that can cleave desmosomes in the skin, leading to keratinocyte shedding and disturbed barrier function of the skin. (Chapter 14)

keratinocytes Epithelial cells that produce keratin, which are the major cell type in the skin. (Chapter 12)

killer cell immunoglobulin-like receptors (KIRs) Large family of receptors present on NK cells, through which the cells' cytotoxic activity is controlled. The family contains both activating and inhibitory receptors. (Chapters 3, 6)

killer cell lectin-like receptors (KLRs) Large family of receptors present on NK cells, through which the cells' cytotoxic activity is controlled. The family contains both activating and inhibitory receptors. (Chapter 3)

kinetic proofreading model A mathematical model for T-cell receptor signal initiation. The model posits a temporal lag between receptor–ligand binding and receptor signaling. When the duration of receptor binding is shorter than that needed to initiate signaling, the receptor and ligand disengage, and no downstream signal ensues. (Chapter 7)

kinin system An enzymatic cascade of plasma proteins that is triggered by tissue damage to produce several inflammatory mediators, including the vasoactive peptide bradykinin. (Chapter 3)

Kostmann's disease A form of severe congenital neutropenia, an inherited condition in which the neutrophil count is low. In Kostmann's disease, this is due to a deficiency of the mitochondrial protein HAX1, which leads to apoptosis of developing myeloid cells and persistent neutropenia. (Chapter 13)

Ku A DNA repair protein required for immunoglobulin and T-cell receptor gene rearrangement. (Chapter 5)

Kupffer cells Phagocytes lining the hepatic sinusoids; they remove debris and dying cells from the blood but are not known to elicit immune responses. (Chapter 3)

λ chain One of the two classes or isotypes of immunoglobulin light chains. (Chapters 4, 5)

λ5 *See* **surrogate light chain**. (Chapter 8)

lacteal A blind lymphatic capillary vessel that originates in the lamina propria of villi of the small intestine that ultimately delivers absorbed nutrients (especially lipids in the form of chylomicrons) to the draining lymph nodes. The vessels may also deliver antigens and immune cells to lymph nodes. (Chapter 12)

lamellar bodies Lipid-rich secretory organelles in keratinocytes and lung pneumocytes that release β-defensins into the extracellular space. (Chapter 2)

lamina propria A layer of connective tissue underlying a mucosal epithelium. It contains lymphocytes and other immune-system cells. (Chapter 1)

Langerhans cells A unique immune lineage with features of dendritic cells and monocyte-derived macrophages that resides in the epidermis but can migrate upon activation to lymph nodes and present antigens to T cells. (Chapters 6, 9, 12)

large pre-B cell Stage of B-cell development immediately after the pro-B cell, in which the cell expresses the pre-B-cell receptor and undergoes several rounds of division. (Chapter 8)

laser-capture microdissection A technique for isolating cells from a tissue using a microscope and a laser to capture the cells in a microscopic region of interest. (Appendix I)

LAT *See* **linker for activation of T cells**. (Chapter 7)

late-phase reaction Allergic reaction that occurs several hours after initial encounter with an antigen. Thought to be a manifestation of recruitment of multiple leukocyte subsets to the site of allergen exposure. (Chapter 14)

late pro-B cell Stage in B-cell development in which VH to DJH joining occurs. (Chapter 8)

latency A state in which a virus infects a cell but does not replicate. (Chapter 13)

Lck An Src family tyrosine kinase that associates with the cytoplasmic tails of CD4 and CD8 and phosphorylates the cytoplasmic tails of the T-cell receptor signaling chains, thus helping to activate signaling from the T-cell receptor complex once antigen has bound. (Chapters 4, 7)

lectin A carbohydrate-binding protein. (Chapter 2)

lectin pathway Complement-activation pathway that is triggered by mannose-binding lectin (MBL) or ficolins bound to bacteria. (Chapters 2, 10)

lentiviruses A group of retroviruses that include the human immunodeficiency virus, HIV-1. They cause disease after a long incubation period. (Chapter 13)

lethal factor protease An endopeptidase produced by *Bacillus anthracis* that cleaves NLRP1, inducing cell death within the infected cell, typically a macrophage. (Chapter 3)

leucine-rich repeat (LRR) Protein motif that is repeated in series to form, for example, the extracellular portions of Toll-like receptors. (Chapter 3)

leukocyte A white blood cell. Leukocytes include lymphocytes, polymorphonuclear leukocytes, and monocytes. (Chapter 1)

leukocyte adhesion deficiencies (LADs) A class of immunodeficiency diseases in which the ability of leukocytes to enter sites infected by extracellular pathogens is affected, impairing elimination of infection. There are several different causes, including a deficiency of the common β chain of the leukocyte integrins. (Chapters 3, 13)

leukocyte adhesion deficiency type 1 (LAD-1) Disease caused by defects in the production of integrin common β subunit CD18, a component of LFA-1 and other integrins needed for leukocyte adherence to blood endothelium. (Chapter 13)

leukocyte adhesion deficiency type 2 (LAD-2) Disease caused by defects in the production of sulfated sialyl-Lewis^X that prevent neutrophils from interacting with P-selectin and E-selectin, eliminating their ability to migrate properly to sites of infection. (Chapters 3, 13)

leukocyte adhesion deficiency type 3 (LAD-3) Disease caused by defects in the production of kindlin-3, a protein needed for the conversion of β integrins to their high-affinity binding state. High-affinity binding of integrins to their ligands on blood endothelium is required for leukocyte transmigration from the blood into tissues at sites of infection. (Chapter 13)

leukocyte functional antigens (LFAs) Cell-adhesion molecules on leukocytes that were initially defined using monoclonal antibodies. LFA-1 is a β2 integrin; LFA-2 (now usually called CD2) is a member of the immunoglobulin superfamily, as is LFA-3 (now called CD58). LFA-1 is particularly important in T-cell adhesion to endothelial cells and antigen-presenting cells. (Chapters 3, 9)

leukocyte receptor complex (LRC) A large cluster of immunoglobulin-like receptor genes that includes the killer cell immunoglobulin-like receptor (KIR) genes. (Chapter 3)

leukocytosis The presence of increased numbers of leukocytes in the blood. It is commonly seen in acute infection. (Chapter 3)

leukotrienes Lipid mediators of inflammation that are derived from arachidonic acid. They are produced by macrophages and other cells. (Chapters 3, 11, 16)

LFA-1 (CD11a:CD18, or $\alpha_L\beta_2$) *See* **leukocyte functional antigens**. (Chapters 3, 9, 11)

LGP2 A member of the RLR family, it cooperates with RIG-I and MDA-5 in the recognition of viral RNA. (Chapter 3)

licensing The activation of a dendritic cell so that it is able to present antigen to naive T cells and activate them. (Chapter 9)

light chain, L chain The smaller of the two types of polypeptide chains that make up an immunoglobulin molecule. It consists of one V and one C domain and is disulfide-bonded to the heavy chain. There are two classes, or isotypes, of light chain, known as κ and λ, which are produced from separate genetic loci. (Chapters 1, 4)

light-chain variable region (V_L) Referring to the V region of the light chain of an immunoglobulin. (Chapter 5)

light zone A region of the germinal center enriched in B cells interacting with T follicular helper cells and antigen on follicular dendritic cells. (Chapter 10)

linear model of memory-cell development One of two general models of memory lymphocyte development that posits that memory T (and B) cells arise from fully differentiated effector cells. *See also* **branching** (or **asymmetric division**) **model of memory-cell development**. (Chapter 11)

lineage tracing The process of genetically marking a progenitor cell with the goal of tracing all of its subsequent progeny. (Appendix I)

lingual tonsils Paired masses of organized peripheral lymphoid tissue situated at the base of the tongue, in which adaptive immune responses can be initiated. They are part of the mucosal immune system. *See also* **palatine tonsils**. (Chapter 1)

linked recognition The rule that for a helper T cell to be able to activate a B cell, the epitopes recognized by the B cell and the helper T cell have to be derived from the same antigen (i.e., they must originally have been physically linked). (Chapters 10, 16)

linker for activation of T cells A cytoplasmic adaptor protein with several tyrosines that become phosphorylated by the tyrosine kinase ZAP-70. It helps to coordinate downstream signaling events in T-cell activation. (Chapter 7)

LIP10 A cleaved fragment of invariant chain retaining the transmembrane segments and which remains bound to MHC class II proteins and helps target the complex to the endosome. (Chapter 6)

LIP22 The initial cleaved fragment of invariant chain bound to MHC class II molecules. (Chapter 6)

lipocalin-2 An antimicrobial peptide produced in abundance by neutrophils and mucosal epithelial cells that inhibits bacterial and fungal growth by limiting availability of iron. (Chapter 11)

lipopeptide antigens A diverse set of antigens derived from microbial lipids typically presented by nonclassical MHC class Ib molecules such as CD1 molecules to invariant T-cell populations, including iNKT cells. (Chapter 6)

lipopolysaccharide (LPS) The surface lipopolysaccharide of Gram-negative bacteria, which stimulates TLR-4 on macrophages and dendritic cells. (Chapters 2, 3, 16)

lipoteichoic acids Components of bacterial cell walls that are recognized by Toll-like receptors. (Chapter 3)

listeriolysin O (LLO) A hemolysin secreted by the bacterium *Listeria monocytogenes* to disrupt endosomal membranes and allow bacterial entry into the cytosol of an infected cell. (Chapters 11, 12)

long-term nonprogressors HIV-infected individuals who mount an immune response that controls viral loads such that they do not progress to AIDS despite the absence of antiretroviral therapy. *See also* **elite controllers**. (Chapter 13)

LPS-binding protein Protein in blood and extracellular fluid that binds bacterial lipopolysaccharide (LPS) shed from bacteria. (Chapter 3)

L-selectin (CD62L) Adhesion molecule of the selectin family found on lymphocytes. L-selectin binds to CD34 and GlyCAM-1 on high endothelial venules to initiate the migration of naive lymphocytes into lymphoid tissue. (Chapters 9, 11, 12)

Ly49 receptors A family of C-type lectins expressed by mouse, but not human, NK cells. These can be either activating or inhibitory in function. (Chapter 3)

Ly49H *See* **Ly49 receptors**. (Chapter 3)

Ly108 *See* **SLAM**. (Chapter 10)

lymph The extracellular fluid that accumulates in tissues and is drained by lymphatic vessels that carry it through the lymphatic system to the thoracic duct, which returns it to the blood. (Chapter 1)

lymphatic system The system of lymph-carrying vessels and peripheral lymphoid tissues through which extracellular fluid from tissues passes before it is returned to the blood via the thoracic duct. (Chapter 1)

lymphatic vessels, lymphatics Thin-walled vessels that carry lymph. (Chapter 1)

lymph nodes A type of peripheral lymphoid organ present in many locations throughout the body where lymphatic vessels converge. (Chapter 1)

lymphoblast A lymphocyte that has enlarged after activation and has increased its rate of RNA and protein synthesis but is not yet fully differentiated. (Chapter 1)

lymphocyte A class of white blood cells that bear variable cell-surface receptors for antigen and are responsible for adaptive immune responses. There are two main types—B lymphocytes (B cells) and T lymphocytes (T cells)—which mediate humoral and cell-mediated immunity, respectively. On antigen recognition, a lymphocyte enlarges to form a lymphoblast and then proliferates and differentiates into an antigen-specific effector cell. (Chapter 1)

lymphocyte receptor repertoire All the highly variable antigen receptors carried by B and T lymphocytes. (Chapter 1)

lymphoid Describes tissues composed mainly of lymphocytes. (Chapter 1)

lymphoid–myeloid primed multipotent progenitors (LMPPs) Progenitor cells in the bone marrow that are no longer self-renewing stem cells, but are committed to producing lymphoid and myeloid cell lineages. (Chapter 8)

lymphoid organs Organized tissues characterized by very large numbers of lymphocytes interacting with a nonlymphoid stroma. The central, or primary, lymphoid organs, where lymphocytes are generated, are the thymus and bone marrow. The main peripheral, or secondary, lymphoid organs, in which adaptive immune responses are initiated, are the lymph nodes, spleen, and mucosa-associated lymphoid organs such as tonsils and Peyer's patches. (Chapter 1)

lymphoid tissue Tissue composed of large numbers of lymphocytes. (Chapter 1)

lymphoid tissue inducer (LTi) cells Cells of the blood lineage, which arise in the fetal liver and are carried in the blood to sites where they will form lymph nodes and other peripheral lymphoid organs. (Chapters 9, 12)

lymphoid tissue (LT)-resident cDCs Conventional dendritic cells that reside in the T-cell zones of secondary lymphoid tissues. (Chapter 9)

lymphopenia Abnormally low levels of lymphocytes in the blood. (Chapter 13)

lymphopoiesis The differentiation of lymphoid cells from a common lymphoid progenitor. (Chapter 8)

lymphotoxins (LTs) Cytokines of the tumor necrosis factor (TNF) family that are directly cytotoxic for some cells. They occur as trimers of LT-α chains (LT-α_3) and heterotrimers of LT-α and LT-β chains (LT-$\alpha_1\beta_2$). (Chapter 9)

lysogenic phase The phase of the viral life cycle in which the virus genome integrates into the host-cell genome but remains dormant, employing mechanisms to avoid destroying its cellular host. (Chapter 13)

lysozyme Antimicrobial enzyme that degrades bacterial cell walls. (Chapter 2)

lytic phase, productive phase The phase of the viral life cycle in which there is active viral replication followed by destruction of the infected host cell as the virus escapes to infect new target cells. (Chapter 13)

M1 macrophages The name sometimes given to 'classically' activated macrophages, which develop in the context of type 1 responses and have pro-inflammatory properties. (Chapter 11)

M2 macrophages The name sometimes given to 'alternatively' activated macrophages, which develop in the context of type 2 responses (e.g., parasite infection) and promote tissue remodeling and repair. (Chapter 11)

macrophages Large mononuclear phagocytic cells present in most tissues that have many functions; for example, scavenger cells, pathogen-recognition cells, and production of pro-inflammatory cytokines. Macrophages arise both embryonically and from bone marrow precursors throughout life. (Chapters 1, 3)

macropinocytosis A process in which large amounts of extracellular fluid are taken up into an intracellular vesicle. This is one way in which dendritic cells can take up a wide variety of antigens from their surroundings. (Chapters 1, 3, 9)

MAdCAM-1 Mucosal addressin cell-adhesion molecule-1. A mucosal addressin that is recognized by the lymphocyte surface proteins L-selectin and VLA-4, enabling the specific homing of lymphocytes to mucosal tissues. (Chapters 9, 11, 12)

MAIT cells *See* **mucosal associated invariant T cells**. (Chapter 6)

major basic protein Protein released by activated eosinophils that acts on mast cells and basophils to cause their degranulation. (Chapter 14)

major histocompatibility complex (MHC) A cluster of genes on human chromosome 6 that encodes a set of membrane glycoproteins called the MHC molecules. The MHC also encodes proteins involved in antigen processing and other aspects of host defense. The genes for the MHC molecules are the most polymorphic in the human genome, having large numbers of alleles at the various loci. (Chapters 1, 4)

MAL An adaptor protein that associates with MyD88 in signaling by TLR-2–TLR-1, TLR-2–TLR-6, and TLR-4. (Chapter 3)

mannose-binding lectin (MBL) Mannose-binding protein present in the blood. It can opsonize pathogens bearing mannose on their surfaces and can activate the complement system via the lectin pathway, an important part of innate immunity. (Chapter 2)

mannose receptor A receptor on macrophages that is specific for mannose-containing carbohydrates that occur on the surfaces of pathogens but not on host cells. (Chapter 3)

mantle zone A rim of B lymphocytes that surrounds lymphoid follicles. (Chapter 10)

MAp19 A non-enzymatically active splice variant encoded by the MASP-2 gene that can associate with mannose-binding lectin (MBL) and may regulate lectin pathway complement activation. (Chapter 2)

MAp44 A non-enzymatically active splice variant encoded by the MASP-1 gene that can associate with mannose-binding lectin (MBL) and may regulate lectin pathway complement activation. (Chapter 2)

MAP kinase (MAPK) *See* **mitogen-activated protein kinase**. (Chapter 7)

MARCO (macrophage receptor with a collagenous structure) *See* **scavenger receptor**. (Chapter 3)

marginal sinus A blood-filled vascular network that branches from the central arteriole and demarcates each area of white pulp in the spleen. (Chapters 9, 10)

marginal zone Area of lymphoid tissue lying at the border of the white pulp in the spleen. (Chapter 1)

marginal zone B cells A unique population of B cells found in the spleen marginal zones; they do not circulate and are distinguished from conventional B cells by a distinct set of surface proteins. (Chapters 1, 8, 9)

MASP-1, MASP-2, MASP-3 Serine proteases of the classical and lectin pathways of complement activation that bind to C1q, ficolins, and mannose-binding lectin, and function in their activation to cleave C4. (Chapter 2)

mass spectrometry A technique for measuring the mass-to-charge ratio of ions in a complex mixture. For instance, when a mixture of peptides is analyzed, a spectrum of separated peaks is generated. Each peak represents an ion, or peptide, with a distinct mass-to-charge ratio. The amino acid sequence of the peptide can often be inferred by the precisely measured mass-to-charge ratio of the peak. (Appendix I)

mast cell A large granule-rich cell found in connective tissues throughout the body, most abundantly in the submucosal tissues and the dermis. The granules store bioactive molecules including the vasoactive amine histamine, which are released on mast-cell activation. Mast cells are thought to be involved in defenses against parasites, and they have a crucial role in allergic reactions. (Chapters 1, 3, 10)

mastocytosis The overproduction of mast cells. (Chapter 10)

mature B cell B cell that expresses IgM and IgD on its surface and has gained the ability to respond to antigen. (Chapter 8)

mature cDCs Conventional dendritic cells that have been activated for antigenic priming of naive T cells, typically after recognition of pathogen-associated molecular patterns (PAMPs). Mature cDCs express high levels of co-stimulatory molecules, such as B7.1, and express high levels of MHC:peptide complexes but have down-regulated their antigen-processing capabilities. (Chapter 9)

MAVS (mitochondrial antiviral signaling protein) A CARD-containing adaptor protein attached to the outer mitochondrial membrane that signals downstream of RIG-I and MDA-5 to activate IRF3 and NFκB in response to viral infection. (Chapter 3)

MBL-associated serine proteases *See* **MASP-1, MASP-2, MASP-3**. (Chapter 2)

M cells Specialized epithelial cell type in the intestinal epithelium over Peyer's patches, through which antigens and pathogens enter from the gut. (Chapters 1, 9, 12)

MD-2 Accessory protein for TLR-4 activity. (Chapter 3)

MDA-5 (melanoma differentiation–associated 5, also **helicard)** This protein contains an RNA helicase–like domain similar to RIG-I and senses double-stranded RNA for detection of intracellular viral infections. (Chapter 3)

medulla The central or collecting point of an organ. The thymic medulla is the central area of each thymic lobe, rich in bone marrow–derived antigen-presenting cells and the cells of a distinctive medullary epithelium. The medulla of the lymph node is a site of macrophage and plasma-cell concentration through which the lymph flows on its way to the efferent lymphatics. (Chapter 8)

Mek1 A MAPK kinase in the Raf–Mek1–Erk signaling module, which is a part of a signaling pathway in lymphocytes leading to activation of the transcription factor AP-1. (Chapter 7)

melanoma-associated antigens (MAGEs) Heterogeneous group of proteins of diverse or unknown functions characterized by restricted expression limited to tumors (i.e., melanoma) or testis germ cells. (Chapter 16)

membrane-associated ring finger (C3HC4) 1, MARCH-1 An E3 ligase expressed in B cells, dendritic cells, and macrophages that induces the constitutive degradation of MHC class II molecules, regulating their steady-state expression. (Chapter 6)

membrane attack Effector pathway of complement that is based on formation of the membrane-attack complex (MAC). (Chapter 2)

membrane-attack complex (MAC) Protein complex composed of C5b to C9 that assembles a membrane-spanning hydrophilic pore on pathogen surfaces, causing cell lysis. (Chapter 2)

membrane cofactor of proteolysis (MCP or **CD46)** A complement-regulatory protein; a host-cell membrane protein that acts in conjunction with factor I to cleave C3b to its inactive derivative iC3b and thus prevent convertase formation. (Chapter 2)

membrane immunoglobulin (mIg) Transmembrane immunoglobulin present on B cells; it is the B-cell receptor for antigen. (Chapter 1)

memory B cells *See* **memory cells**. (Chapters 10, 11)

memory cells B and T lymphocytes that mediate immunological memory. They are more sensitive to antigen than are naive lymphocytes and respond rapidly on reexposure to the antigen that originally induced them. (Chapters 1, 10, 11)

memory phase The period of the clonal lymphocyte response (T or B cell) marked by the persistence of long-lived memory lymphocytes that emerge during the course of antigenic challenge. (Chapter 11)

memory T cells *See* **memory cells**. (Chapter 11)

mesenteric lymph nodes Lymph nodes located in the connective tissue (mesentery) that tethers the intestine to the rear wall of the abdomen. They drain the GALT. (Chapter 12)

metastasis Spread of a tumor from its original location to distant organs of the body by traveling through the blood or lymphatics or by direct extension. (Chapter 16)

2′-*O*-methyltransferase (MTase) An enzyme that transfers a methyl group to the 2′ hydroxyl of the first and second ribose groups in mRNA. Viruses that acquire MTase can produce cap-1 and cap-2 on their transcripts and thereby evade restriction by IFIT1. (Chapter 3)

MF-59 A proprietary adjuvant based on squalene and water that is used in Europe, Canada, and the United States in conjunction with influenza vaccine. (Chapter 16)

MHC class I *See* **MHC class I molecules**. (Chapters 1, 4)

MHC class I deficiency An immunodeficiency disease in which MHC class I molecules are not present on the cell surface, usually as a result of an inherited deficiency of either TAP-1 or TAP-2. (Chapters 6, 13)

MHC class I molecules Polymorphic cell-surface proteins encoded in the MHC locus and expressed on most cells. They present antigenic peptides generated in the cytosol to CD8 T cells and also bind the co-receptor CD8. (Chapters 1, 3, 4)

MHC class Ib molecules Cell-surface receptors with structural homology to MHC class I molecules. Generally nonpolymorphic and able to present nonpeptide antigens to specialized subsets of T lymphocytes, such as γδ T cells, iNKT cells, and MAIT cells. (Chapter 4)

MHC class II *See* **MHC class II molecules**. (Chapters 1, 4)

MHC class II compartment (MIIC) The cellular vesicles in which MHC class II molecules accumulate, encounter HLA-DM, and bind antigenic peptides, before migrating to the surface of the cell. (Chapter 6)

MHC class II deficiency A rare immunodeficiency disease in which MHC class II molecules are not present on cells as a result of various inherited defects. Individuals are severely immunodeficient and have few CD4 T cells. (Chapters 6, 13)

MHC class II molecules Polymorphic cell-surface proteins encoded in the MHC locus and expressed primarily on specialized antigen-presenting cells. They present antigenic peptides derived from internalized extracellular pathogens to CD4 T cells and also bind the co-receptor CD4. (Chapters 1, 3, 4)

MHC class II transactivator (CIITA) Protein that activates transcription of MHC class II genes. Defects in the CIITA gene are one cause of MHC class II deficiency. (Chapter 6)

MHC haplotype A set of alleles in the MHC that is inherited unchanged (i.e., without recombination) from one parent. (Chapter 6)

MHC molecules Highly polymorphic cell-surface proteins encoded by MHC class I and MHC class II genes involved in presentation of peptide antigens to T cells. They are also known as histocompatibility antigens. (Chapters 1, 4)

MHC restriction The fact that a peptide antigen can only be recognized by a given T cell if it is bound to a particular self MHC molecule. MHC restriction is a consequence of events that occur during T-cell development. (Chapters 4, 6)

MIC-A, MIC-B MHC class Ib proteins that are induced by stress, infection, or transformation in many cell types and are recognized by NKG2D. (Chapters 3, 6)

microbial glycolipids Diverse class of antigens frequently presented by CD1 molecules to iNKT cells. (Chapter 6)

microbiome The collection of genomes from all the microorganisms in an environment, such as the commensal microorganisms of the gut or skin. The term is to be contrasted with 'microbiota,' which refers to the collection of microorganisms themselves. *See* **commensal microorganisms**. (Chapters 1, 12)

microbiota *See* **commensal microorganisms**. (Chapter 2)

microclusters Assemblies of small numbers of T-cell receptors that may be involved in the initiation of T-cell receptor activation by antigen in naive T cells. (Chapter 7)

microfold cells *See* **M cells**. (Chapters 1, 12)

microglial cell An embryonically derived form of tissue macrophage in the central nervous system that is dependent on IL-34 for local self-renewal throughout life. (Chapter 3)

minor histocompatibility antigens Peptides of polymorphic cellular proteins bound to MHC molecules that can lead to graft rejection when they are recognized by T cells. (Chapters 6, 15)

minor lymphocyte stimulating (Mls) antigens An old term referring to non-MHC antigens responsible for unusually strong T-cell responses to cells from different strains of mice, now known to be superantigens encoded by endogenous retroviruses. (Chapter 6)

mismatch repair A type of DNA repair that causes mutations and is involved in somatic hypermutation and class switching in B cells. (Chapter 10)

missing self Refers to the loss of cell-surface molecules that engage with inhibitory receptors on NK cells, resulting in NK-cell activation. (Chapter 3)

mitogen-activated protein kinases (MAPKs) A series of protein kinases that become phosphorylated and activated on cellular stimulation by a variety of ligands and lead to new gene expression by phosphorylating key transcription factors. The MAPKs are part of many signaling pathways, especially those leading to cell proliferation, and have different names in different organisms. (Chapters 3, 7)

mixed essential cryoglobulinemia Disease due to the production of cryoglobulins (cold-precipitable immunoglobulins), sometimes in response to chronic infections such as hepatitis C, which can lead to the deposition of immune complexes in joints and tissues. (Chapter 15)

mixed lymphocyte reaction (MLR) A test for histocompatibility in which lymphocytes from donor and recipient are cultured together. If the two people are histoincompatible, the recipient's T cells recognize the allogeneic MHC molecules on the cells of the donor as 'foreign' and proliferate. (Chapters 6, 15)

molecular mimicry The similarity between some pathogen antigens and host antigens, such that antibodies and T cells produced against the former also react against host tissues. This similarity may be the cause of some autoimmunity. (Chapter 15)

monoclonal antibodies Antibodies produced by a single clone of B lymphocytes, so that they are all identical. (Chapters 1, 4, Appendix I)

monocyte Type of white blood cell with a bean-shaped nucleus; it is a precursor of tissue macrophages. (Chapters 1, 3)

monocyte-derived DCs (MoDCs) Myeloid cells with dendritic morphology that are derived from circulating monocytes that are recruited into inflamed tissues. These cells can take up antigen and migrate to secondary lymphoid tissues where they deliver antigens to resident DCs for T-cell priming, but they are inefficient at naive T-cell priming themselves. (Chapter 9)

monogenic disorders Disorders that are caused by variations in a single gene. These disorders typically have a clear familial pattern of inheritance and can be dominant or recessive, or autosomal or sex-linked. (Chapter 13)

monoglucosylated glycan A protein modification consisting of a single attached glucosyl moiety indicating an incompletely folded protein within the endoplasmic reticulum. This modification of nascent MHC molecules is recognized by calreticulin to recruit incompletely loaded MHC class I proteins to the peptide-loading complex. (Chapter 6)

monomorphic Describes a gene that occurs in only one form. Cf. **polymorphic**. (Chapter 6)

motheaten A mutation in the SHP-1 protein phosphatase that impairs the function of some inhibitory receptors, such as Ly49, resulting in overactivation of various cells, including NK cells. Mice with this mutation have a 'motheaten' appearance because of chronic inflammation. (Chapter 3)

moxetumomab pasudotox-tdfk (Lumoxiti) An immunotoxin composed of an anti-CD22 variable region fused to a fragment of *Pseudomonas* toxin and used to treat a kind of B-cell leukemia, hairy-cell leukemia, in patients whose disease was resistant to chemotherapy. (Chapter 16)

MR1 (MHC-related protein 1) A 'nonclassical' MHC class Ib molecule that binds certain folic acid metabolites produced by bacteria for recognition by mucosal-associated invariant T (MAIT) cells. (Chapters 4, 6)

MSH2, MSH6 Mismatch repair proteins that detect uridine and recruit nucleases to remove the damaged and several adjacent nucleotides. (Chapter 10)

mTOR (mammalian target of rapamycin) A serine/threonine kinase that functions in regulating numerous aspects of cell metabolism and function in complex with regulatory proteins Raptor or Rictor. The Raptor:mTOR complex (mTORC1) is inhibited by the immunosuppressive drug rapamycin. (Chapters 7, 16)

mTORC1, mTORC2 Active complexes of mTOR formed with the regulatory proteins Raptor and Rictor, respectively. (Chapter 16)

MUC2 An oligomeric, mucus gel-forming protein in the colon, where it is secreted by epithelial goblet cells into the lumen of the large intestine to create a protective, lubricating barrier. (Chapter 12)

mucins Highly glycosylated cell-surface proteins. Mucin-like molecules are bound by L-selectin in lymphocyte homing. (Chapter 2)

Muckle–Wells syndrome An inherited episodic autoinflammatory disease caused by mutations in the gene encoding NLRP3, a component of the inflammasome. (Chapters 3, 13)

mucociliary escalator The system of cilia-transported mucus by which the airways of the respiratory system trap and transport particles toward the pharynx and out of the lungs. (Chapter 12)

mucosa-associated lymphoid tissue (MALT) Generic term for all organized lymphoid tissue found at mucosal surfaces, in which an adaptive immune response can be initiated. It comprises gut-associated lymphoid tissue (GALT), nasal-associated lymphoid tissue (NALT), and bronchus-associated lymphoid tissue (BALT) (when present). (Chapters 1, 9, 12)

mucosal-associated invariant T cells (MAIT cells) Primarily γδ T cells with limited diversity present in the mucosal immune system that respond to bacterially derived folate derivates presented by the nonclassical MHC class Ib molecule MR1. (Chapters 4, 12)

mucosal epithelia Mucus-coated epithelia lining the body's internal cavities that connect with the outside (such as the gut, airways, and vaginal tract). (Chapter 2)

mucosal immune system The immune system that protects internal mucosal surfaces (such as the linings of the gut, respiratory tract, and urogenital tracts), which are the site of entry for virtually all pathogens and other antigens. *See also* **mucosa-associated lymphoid tissue**. (Chapters 1, 12)

mucosal mast cells Specialized mast cells present in mucosa. They produce little histamine but large amounts of prostaglandins and leukotrienes. (Chapter 11)

mucosal tolerance The suppression of specific systemic immune responses to an antigen by the previous administration of the same antigen by a mucosal route. (Chapter 12)

mucus Sticky solution of proteins (mucins) secreted by goblet cells of internal epithelia, forming a protective layer on the epithelial surface. (Chapter 2)

multinucleated giant cells Large phagocytic cells that form at sites of chronic inflammation by the fusion of multiple monocytes or macrophages. These cells are often found as components of granulomas, such as those that develop in response to poorly eradicated infections (e.g., tuberculosis) or foreign bodies. (Chapter 11)

multiple sclerosis A neurological autoimmune disease characterized by focal demyelination in the central nervous system, lymphocytic infiltration in the brain, and a chronic progressive course. (Chapter 15)

multiplex assay An assay in which multiple antigens or antibodies can simultaneously be detected and quantified in a single sample. (Appendix I)

muramyl dipeptide (MDP) A component of the peptidoglycan of most bacteria that is recognized by the intracellular sensor NOD2. (Chapter 3)

muromonab A mouse antibody against human CD3 used to treat transplant rejection; this was the first monoclonal antibody approved as a drug in humans. (Chapter 16)

mutualism A symbiotic relationship between two organisms in which both benefit, such as the relationship between a human and its normal resident (commensal) gut microorganisms. (Chapter 12)

Mx (myxoma resistant) proteins Interferon-inducible proteins required for cellular resistance to influenza virus replication. (Chapter 3)

myasthenia gravis An autoimmune disease in which autoantibodies against the acetylcholine receptor on skeletal muscle cells cause a block in neuromuscular junctions, leading to progressive weakness and eventually death. (Chapter 15)

mycophenolate An inhibitor of the synthesis of guanosine monophosphate that acts as a cytotoxic immunosuppressive drug. It acts by killing rapidly dividing cells, including lymphocytes proliferating in response to antigen. (Chapter 16)

mycophenolate mofetil Pro-drug used in cancer treatment that is metabolized to mycophenolate, an inhibitor of inosine monophosphate dehydrogenase, thereby impairing guanosine monophosphate, and thus DNA, synthesis. (Chapter 16)

MyD88 An adaptor protein that functions in signaling by all TLR proteins except TLR-3. (Chapter 3)

myeloid Refers to the lineage of blood cells that includes all leukocytes except lymphocytes. (Chapter 1)

myeloid-derived suppressor cells (MDSCs) Cells in tumors that can inhibit T-cell activation within the tumor. (Chapter 16)

myeloma protein Individuals who have the disease multiple myeloma have a malignant expansion of plasma cells, all of which arose from a single cell, and therefore all secrete the same antibody protein. This antibody, known as myeloma protein, accumulates in large quantities in an affected individual's serum. (Appendix I)

myelomonocytic cells Innate immune cells derived from myelomonocytic bone marrow precursors, including neutrophils, basophils, eosinophils, monocytes, and dendritic cells. (Chapter 11)

NADPH oxidase Multicomponent enzyme complex that is assembled and activated in the phagolysosome membrane in stimulated phagocytes. It generates superoxide in an oxygen-requiring reaction called the respiratory burst. (Chapter 3)

NAIPs (NLR family, apoptosis inhibitory proteins) A family of NLR-containing proteins that serve as intracellular pattern-recognition receptors (PRRs). (Chapter 3)

NAIP2 An NLR protein that, together with NLRC4, recognizes the PrgJ protein of the *Salmonella enterica* ssp. *typhimurium* type III secretion system to activate an inflammasome pathway in response to infection. (Chapter 3)

NAIP5 An NLR protein that, together with NLRC4, recognizes intracellular flagellin to activate an inflammasome pathway in response to infection. (Chapter 3)

naive lymphocytes T cells or B cells that have undergone normal development in the thymus or the bone marrow but have not yet been activated by foreign (or self) antigens. (Chapter 1)

naive T cells Lymphocytes that have never encountered their specific antigen and thus have never responded to it, as distinct from effector and memory lymphocytes. (Chapter 9)

nasal- (or **nasopharynx-**) **associated lymphoid tissue (NALT)** Organized lymphoid tissues found in the upper respiratory tract. In humans, NALT consists of Waldeyer's ring, which includes the adenoids and palatine and lingual tonsils, plus other similarly organized lymphoid tissue located around the pharynx. It is part of the mucosal immune system. (Chapters 1, 12)

natalizumab Humanized antibody to α_4 integrin used to treat Crohn's disease and multiple sclerosis. It blocks the adhesion of lymphocytes to endothelium, impairing their migration into tissues. (Chapter 16)

natural antibodies Antibodies produced by the immune system in the apparent absence of any infection. They have a broad specificity for self and microbial antigens, can react with many pathogens, and can activate complement. (Chapter 2)

natural cytotoxicity receptors (NCRs) Activating receptors on NK cells that recognize infected cells and stimulate cell killing by the NK cell. (Chapter 3)

natural interferon-producing cells *See* **plasmacytoid dendritic cells**. (Chapter 3)

natural killer (NK) cell A type of ILC that is important in innate immunity to viruses and other intracellular pathogens and in antibody-dependent cell-mediated cytotoxicity (ADCC). NK cells express activating and inhibitory receptors but not the antigen-specific receptors of T or B cells. (Chapters 1, 3)

negative selection The process by which self-reactive thymocytes are deleted from the repertoire during T-cell development in the thymus. Autoreactive B cells undergo a similar process in bone marrow. (Chapter 8)

NEMO *See* **IKK**. (Chapters 3, 7)

NEMO deficiency *See* **X-linked hypohidrotic ectodermal dysplasia and immunodeficiency**. (Chapter 3)

neoantigen, neoepitope Type of tumor-rejection antigen created by mutations in protein that can be presented by self-MHC molecules to T cells. (Chapter 16)

neonatal Fc receptor (FcRn) *See* **FcRn**. (Chapter 12)

nephritic factor An autoantibody that leads to inflammation in the kidney by increasing C3 deposition. Nephritic factors may inhibit the activity of complement-regulatory proteins, such as factor H, or may stabilize the alternative pathway C3 convertase C3bBb. (Chapter 2)

neuraminidase An influenza virus protein that cleaves sialic acid from host cells to allow viral detachment; a common antigenic determinant and a target of antiviral neuraminidase inhibitors. (Chapters 12, 16)

neuroimmune interactions Interactions between components of the immune and nervous systems coordinated by chemical and electrophysiological signals. (Chapter 12)

neutralization Inhibition of the infectivity of a virus or the toxicity of a toxin molecule by the binding of antibodies. (Chapters 1, 10, 16)

neutralizing antibodies Antibodies that inhibit the infectivity of a virus or the toxicity of a toxin. (Chapter 10)

neutropenia Abnormally low levels of neutrophils in the blood. (Chapters 3, 13)

neutrophil The most numerous type of white blood cell in human peripheral blood. Neutrophils are phagocytic cells with a multilobed nucleus and granules that stain with neutral stains. They enter infected tissues and engulf and kill extracellular pathogens. (Chapters 1, 3)

neutrophil elastase Proteolytic enzyme stored in the granules of neutrophils that is involved in the processing of antimicrobial peptides. (Chapter 2)

neutrophil extracellular traps (NETs) A meshwork of nuclear chromatin that is released into the extracellular space by neutrophils undergoing apoptosis at sites of infection, serving as a scaffold that traps extracellular bacteria to enhance their phagocytosis by other phagocytes. (Chapter 3)

NFκB A heterodimeric transcription factor activated by the stimulation of Toll-like receptors and also by antigen receptor signaling composed of p50 and p65 subunits. (Chapter 3)

NFAT *See* **nuclear factor of activated T cells**. (Chapter 7)

Nfil3 A transcription factor important during the development of several types of immune cells including certain types of NK cells. (Chapter 3)

NHEJ *See* **nonhomologous end joining**. (Chapter 5)

nitric oxide (NO) A reactive molecular gas species produced by cells—particularly macrophages—during infection and which is toxic to bacteria and intracellular microbes. (Chapter 3)

nitric oxide radical The uncharged compound NO, having an unpaired electron conferring its high reactivity, formed in activated phagocytes by the action of inducible nitric oxide synthetase. (Chapter 3)

nivolumab Human anti-PD-1 antibody used for checkpoint blockade in treatment of metastatic melanoma. (Chapter 16)

NKG2 Family of C-type lectins that supply one of the subunits of the killer cell lectin-like receptors (KLRs) on NK cells. (Chapter 3)

NKG2D Activating C-type lectin receptor on NK cells, cytotoxic T cells, and γδ T cells that recognizes the stress-response proteins MIC-A and MIC-B. (Chapter 3)

NK receptor complex (NKC) A cluster of genes that encode a family of receptors on NK cells. (Chapter 3)

NKT cell A subclass of αβ T cells expressing surface receptors, such as NK1.1, that are more typical of NK cells. NKT cells recognize various nonpeptide ligands presented by nonclassical MHC class I–like proteins. (Chapter 6)

NLRC4 An NLR family member that cooperates with NAIP2 and NAIP5. (Chapter 3)

NLRP A group of 14 NOD-like receptor (NLR) proteins that contain a pyrin domain and function in the formation of a signaling complex called the inflammasome. (Chapter 3)

NLRP1 An NLR family member that assembles into an inflammasome that recruits and activates caspase 1. (Chapter 3)

NLRP3 A member of the family of intracellular NOD-like receptor proteins that have pyrin domains. It acts as a sensor of cellular damage and is part of the inflammasome. Sometimes called NALP3. (Chapters 3, 16)

N-nucleotides Non-templated nucleotides inserted by the enzyme terminal deoxynucleotidyl transferase into the junctions between gene segments of T-cell receptor and immunoglobulin heavy-chain V regions during gene segment joining. Translation of these N-regions markedly increases the diversity of these receptor chains. (Chapter 5)

nociceptors Various neuropeptide-producing sensory neurons that encode pain and are found in the skin. These cells can become stimulated by cysteine protease present in the feces of house dust mites to secrete substance P, which can activate nearby mast cells. (Chapter 14)

NOD A subgroup of NLR proteins that contain a CARD domain that is used for activation of downstream signaling. (Chapter 3)

NOD1, NOD2 Intracellular proteins of the NOD subfamily that contain a leucine-rich repeat (LRR) domain that binds components of bacterial cell walls to activate the NFκB pathway and initiate inflammatory responses. (Chapter 3)

NOD-like receptors (NLRs) Large family of proteins containing a nucleotide-binding and oligomerization domain (NOD) associated with various other domains, and whose general function is the detection of microbes and of cellular stress. (Chapters 1, 3, 12)

nonamer Conserved nine-nucleotide DNA sequence in the recombination signal sequences (RSSs) flanking gene segments in the immunoglobulin and T-cell receptor loci. (Chapter 5)

non-canonical NFκB pathway This pathway relies on activation of NIK (NFκB-inducing kinase) to induce proteolytic processing of the p100 precursor into p52, which forms an active transcription factor by associating with RelB. NIK is activated downstream of the receptors for various cytokines, such as lymphotoxin β. (Chapters 7, 10)

nonclassical MHC class Ib genes Genes encoded within the MHC whose proteins are related to the MHC class I molecules but are not highly polymorphic and present a restricted set of antigens. (Chapter 5)

nonclassical MHC class I proteins Proteins related to MHC class I molecules but are not highly polymorphic and present a restricted set of antigens. (Chapter 6)

nonclassical MHC genes *See* **nonclassical MHC class Ib genes**. (Chapter 6)

nondepleting antibodies Immunosuppressive antibodies that block the function of target proteins on cells without causing the cells to be destroyed. (Chapter 16)

nonhomologous end joining (NHEJ) DNA repair pathway that directly ligates double-strand DNA breaks without use of a homologous template. (Chapter 5)

nonlymphoid tissue (NLT)-resident (or **migratory**) **cDCs** Conventional dendritic cells that reside in nonlymphoid tissues, particularly at barrier tissue sites, and migrate to T-cell zones of lymphoid organs in response to infection. (Chapter 9)

nonproductive rearrangements Rearrangements of T-cell receptor or immunoglobulin gene segments that cannot encode a protein because the coding sequences are in the wrong translational reading frame. (Chapter 5)

nonreceptor kinase Cytoplasmic protein kinases that associate with the intracellular tails of signaling receptors and help generate the signal but are not an intrinsic part of the receptor itself. (Chapter 7)

nuclear factor of activated T cells (NFAT) A family of transcription factors that are activated in response to increased cytoplasmic calcium after antigen receptor signaling in lymphocytes. (Chapter 7)

nucleotide-binding and oligomerization domain (NOD) A type of conserved domain originally recognized in ATP-binding cassette (ABC) transporters present in a large number of proteins, but which also mediates protein homo-oligomerization. (Chapters 3, 12)

nude A mutation in mice that results in hairlessness and defective formation of the thymic stroma, so that mice homozygous for this mutation have no mature T cells. (Chapters 8, 13)

NY-ESO-1 A particular highly immunogenic cancer-testis antigen expressed by many types of human tumors including melanoma. (Chapter 16)

occupational allergies An allergic reaction induced to an allergen to which someone is habitually exposed in their work. (Chapter 14)

odds ratio Represents the strength of association between the occurrence of a particular SNP and a phenotype, typically a disease. For example, an odds ratio of 10 for some specific SNP and asthma means that having that SNP confers 10 times the risk of having asthma over that of a person who has a common variant. (Chapter 14)

oligoadenylate synthetase Enzyme produced in response to stimulation of cells by interferon. It synthesizes unusual nucleotide polymers, which in turn activate a ribonuclease that degrades viral RNA. (Chapter 3)

Omenn syndrome A severe immunodeficiency disease characterized by defects in either of the *RAG* genes. Affected individuals make small amounts of functional RAG protein, allowing a small amount of V(D)J recombination. (Chapters 5, 13)

opportunistic pathogens Microorganisms that are unable to invade a healthy host, but can cause disease when there is compromise of host defenses, whether due to weakened immunity (e.g., chemotherapy or HIV/AIDS), alteration of the healthy microbiota (e.g., dysbiosis induced by antibiotic therapy), or breach of normal integrity of a barrier tissue (e.g., penetrating trauma). (Chapters 12, 13)

opsonization The coating of the surface of a pathogen by antibody and/or complement that makes it more easily ingested by phagocytes. (Chapters 1, 2, 10)

oral tolerance The suppression of specific systemic immune responses to an antigen by the prior administration of the same antigen by the oral (enteric) route. (Chapters 12, 15)

original antigenic sin The tendency of humans to make antibody responses to those epitopes shared between the first strain of a virus they encounter and subsequent related viruses, while ignoring other highly immunogenic epitopes on the second and subsequent viruses. (Chapter 11)

oxidative phosphorylation (OXPHOS) A highly efficient means of producing ATP in mitochondria from oxidative nutrients, such as pyruvate produced by glycolysis. In oxidative phosphorylation, a series of mitochondrial membrane–bound protein complexes catalyze oxidation–reduction reactions to generate a transmembrane electrical potential difference that ultimately drives ATP synthesis. (Chapter 9)

p50 *See* **NFκB**. (Chapter 3)

p65 *See* **NFκB**. (Chapter 3)

PA28 proteasome-activator complex A multi-subunit protein complex induced by interferon-γ and which takes the place of the 19S regulatory cap of the proteasome and increases the rate of peptides exiting from the proteasome catalytic core. (Chapter 6)

palatine tonsils Paired masses of organized peripheral lymphoid tissues located on each side of the throat, and in which an adaptive immune response can be generated. They are part of the mucosal immune system. (Chapter 1)

Paneth cells Specialized epithelial cells at the base of the crypts in the small intestine that secrete antimicrobial peptides. (Chapters 2, 12)

papain A protease that cleaves the IgG antibody molecule on the amino-terminal side of disulfide linkages, producing two Fab fragments and one Fc fragment. (Chapter 4)

parabiosis A technique in which two mice are surgically joined at the flanks by suturing skin from the two mice together. After 2 weeks, new blood vessels are formed in the skin, and the mice develop a shared circulatory system. Circulating cells in the blood of these mice will be a mixture of cells derived from the two conjoined partners. (Appendix I)

paracortical areas The T-cell areas of lymph nodes. (Chapter 1)

paracrine Describes a cytokine or other biologically active molecule acting on cells near to those that produce it. (Chapter 3)

parasites Organisms that obtain sustenance from a live host. In immunology, it refers to worms and protozoa, the subject matter of parasitology. (Chapter 1)

paroxysmal nocturnal hemoglobinuria A disease in which complement-regulatory proteins are defective, so that activation of complement binding to red blood cells leads to episodes of spontaneous hemolysis. (Chapters 2, 13)

passive immunization The injection of antibody or immune serum into a naive recipient to provide specific immunological protection. Cf. **active immunization**. (Chapter 10, Appendix I)

pathogen Microorganism that typically causes disease when it infects a host. (Chapters 1, 3)

pathogen-associated molecular patterns (PAMPs) Molecules specifically associated with groups of pathogens that are recognized by cells of the innate immune system. (Chapters 1, 3)

pathogenesis The origin or cause of the pathology of a disease. (Chapter 2)

pathogenic microorganism Microorganism that typically causes disease when it infects a host. (Chapter 2)

patrolling monocyte A form of circulating monocyte that adheres to and surveys the vascular endothelium, distinguished from classical monocytes by its low expression of Ly6C. (Chapter 3)

pattern-recognition receptors (PRRs) Receptors of the innate immune system that recognize common molecular patterns on pathogen surfaces. (Chapters 1, 3)

PD-1 (programmed death-1) A receptor on T cells that when bound by its ligands, PD-L1 and PD-L2, inhibits signaling from the antigen receptor. PD-1 contains an ITIM motif in its cytoplasmic tail. It is a target of cancer therapies aimed at stimulating T-cell responses to tumors. (Chapters 7, 16)

PD-L1 (programmed death ligand-1; B7-H1) Transmembrane receptor that binds to the inhibitory receptor PD-1. PD-L1 is expressed on many cell types and is up-regulated by inflammatory cytokines. (Chapters 7, 16)

PD-L2 (programmed death ligand-2; B7-DC) Transmembrane receptor that binds to the inhibitory receptor PD-1; mainly expressed on dendritic cells. (Chapter 7)

PECAM *See* **CD31**. (Chapter 3)

pembrolizumab Human anti-PD-1 antibody used for checkpoint blockade in treatment of metastatic melanoma. (Chapter 16)

pemphigus vulgaris An autoimmune disease characterized by severe blistering of the skin and mucosal membranes. (Chapter 15)

pentameric IgM Major form of the IgM antibodies produced by the action of J chain resulting in higher avidity for antigens. (Chapter 10)

pentraxin A family of acute-phase proteins formed of five identical subunits, to which C-reactive protein and serum amyloid protein belong. (Chapter 3)

pepsin A protease that cleaves several sites on the carboxy-terminal side of the disulfide linkages, producing the $F(ab')_2$ fragment and several fragments of the Fc region. (Chapter 4)

peptide-binding cleft, peptide-binding groove The longitudinal cleft in the top surface of an MHC molecule into which the antigenic peptide is bound. (Chapter 4)

peptide editing In the context of antigen processing and presentation, the removal of unstably bound peptides from MHC class II molecules by HLA-DM. (Chapter 6)

peptide-loading complex (PLC) A protein complex in the endoplasmic reticulum that loads peptides onto MHC class I molecules. (Chapter 6)

peptide:MHC tetramer Four specific peptide:MHC complexes bound to a single molecule of fluorescently labeled streptavidin, which is used to identify populations of antigen-specific T cells. (Appendix I)

peptidoglycan A component of bacterial cell walls that is recognized by certain receptors of the innate immune system. (Chapter 2)

peptidoglycan-recognition proteins (PGRPs) A family of *Drosophila* proteins that bind peptidoglycans from bacterial cell walls and serve to initiate the proteolytic cascade of the Toll pathway. (Chapter 3)

perforin A cytolytic protein produced by cytotoxic T lymphocytes and natural killer cells. Perforin functions by binding to a target cell's plasma membrane and oligomerizing to form pores, which then allow pro-apoptotic granzymes to diffuse into the target cell. (Chapter 9)

periarteriolar lymphoid sheath (PALS) Part of the inner region of the white pulp of the spleen; it contains mainly T cells. (Chapters 1, 9)

peripheral blood mononuclear cells (PBMCs) The components of blood composed of mononucleated cells. This includes lymphocytes and monocytes, but excludes red blood cells and platelets, which have no nucleus, and excludes granulocytes (neutrophils, basophils, and eosinophils), which have multilobed nuclei. (Appendix I)

peripheral lymphoid organs, peripheral lymphoid tissues The lymph nodes, spleen, and mucosa-associated lymphoid tissues, in which adaptive immune responses are induced, as opposed to the central lymphoid organs, in which lymphocytes develop. They are also called secondary lymphoid organs and tissues. (Chapters 1, 8)

peripheral tolerance Tolerance acquired by mature lymphocytes in the peripheral tissues, as opposed to central tolerance, which is acquired by immature lymphocytes during their development. (Chapters 8, 12, 15)

Peyer's patches Organized peripheral lymphoid organs under the epithelium in the small intestine, especially the ileum, and in which an adaptive immune response can be initiated. They contain lymphoid follicles and T-cell areas. They are part of the gut-associated lymphoid tissue (GALT). (Chapters 1, 9, 12)

phage display library A collection of bacteriophages that have been engineered to express proteins of interest. Each bacteriophage expresses a single extra protein as a fusion of its surface-coat protein and therefore displays multiple copies of that extra protein on the bacteriophage surface. The collection of bacteriophages, each expressing a different extra protein on its surface, is known as a library. (Appendix I)

phagocyte oxidase *See* **NADPH oxidase**. (Chapter 3)

phagocytic glycoprotein-1 (Pgp1) *See* **CD44**. (Chapter 11)

phagocytosis The internalization of particulate matter by cells by a process of engulfment, in which the cell membrane surrounds the material, eventually forming an intracellular vesicle (phagosome) containing the ingested material. (Chapters 2, 3)

phagolysosome Intracellular vesicle formed by the fusion of a phagosome (containing ingested material) and a lysosome, and in which the ingested material is broken down. (Chapter 3)

phagophore A crescent-shaped double-membrane cytoplasmic structure. (Chapter 12)

phagosome Intracellular vesicle formed when particulate material is ingested by a phagocyte. (Chapter 3)

phosphatidylinositol 3-kinase (PI 3-kinase) Enzyme involved in intracellular signaling pathways. It phosphorylates the membrane lipid phosphatidylinositol 4,5-bisphosphate (PIP_2) to form phosphatidylinositol 3,4,5-trisphosphate (PIP_3), which can recruit signaling proteins containing pleckstrin homology (PH) domains to the membrane. (Chapters 3, 7)

phosphatidylinositol kinases Enzymes that phosphorylate the inositol headgroup on membrane lipids to produce phosphorylated derivatives that have a variety of functions in intracellular signaling. (Chapter 7)

phospholipase C-γ (PLC-γ) Key enzyme in intracellular signaling pathways leading from many different receptors. It is activated by membrane recruitment and tyrosine phosphorylation after receptor ligation and cleaves membrane inositol phospholipids into inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol. (Chapter 7)

phosphorylation Addition of a phosphate group to a molecule, usually a protein, catalyzed by enzymes called kinases. (Chapter 7)

phycoerythrin (PE) A light-harvesting protein pigment made by algae and used in conjunction with flow cytometry; it can also be recognized as a ligand by some γδ T-cell receptors. (Chapter 6)

pilin An adhesin of *Neisseria gonorrhoeae* allowing attachment to and infection of epithelial cells of the urinary and reproductive tracts. (Chapter 10)

PIP_2 Phosphatidylinositol 4,5-bisphosphate, a membrane-associated phospholipid that is cleaved by phospholipase C-γ to give the signaling molecules diacylglycerol and inositol trisphosphate and is phosphorylated by PI 3-kinase to generate PIP_3. (Chapter 7)

PIP_3 Phosphatidylinositol 3,4,5-trisphosphate, a membrane-associated phospholipid that can recruit intracellular signaling molecules containing pleckstrin homology (PH) domains to the membrane. (Chapter 7)

PKR Serine/threonine kinase activated by IFN-α and IFN-β. It phosphorylates the eukaryotic protein synthesis initiation factor eIF-2, inhibiting translation and thus contributing to the inhibition of viral replication. (Chapter 3)

plasma The liquid component of whole blood. (Appendix I)

plasma cells Terminally differentiated activated B lymphocytes. Plasma cells are the main antibody-secreting cells of the body. They are found in the medulla of the lymph nodes, in splenic red pulp, in bone marrow, and in mucosal tissues. (Chapters 1, 10)

plasmablasts A B cell in a lymph node that already shows some features of a plasma cell. (Chapter 10)

plasmacytoid dendritic cells (pDCs) A distinct lineage of dendritic cells that secrete large amounts of interferon on activation by pathogens and their products via receptors such as Toll-like receptors. Cf. **conventional dendritic cells**. (Chapters 3, 9)

platelet-activating factor (PAF) A lipid mediator that activates the blood clotting cascade and several other components of the innate immune system. (Chapter 3)

pluripotent Typically referring to the capacity of a progenitor cell to generate all possible lineages of an organ system. (Chapter 1)

P-nucleotides Short palindromic nucleotide sequences formed between gene segments of the rearranged V-region gene generated by the asymmetric opening of the hairpin intermediate during RAG-mediated rearrangement. (Chapter 5)

poison ivy This plant is a common cause of allergic contact dermatitis in the United States. The urushiol oil of this plant contains a mixture of pentadecacatechols that can cross cell membranes and attach to intracellular proteins. When modified peptides from these proteins are processed and presented by MHC class I molecules on the cell's surface, they may activate CD8 T cells that recognize the peptides and cause damage through killing and by cytokine secretion. (Chapter 14)

Polη An error-prone 'translesion' DNA polymerase involved in repairing DNA damage caused by UV radiation and in somatic hypermutation. (Chapter 10)

polyclonal mitogens Compounds that stimulate lymphocytes to undergo cell division regardless of the antigen specificity of the cells. (Appendix I)

polygenic Containing several separate loci encoding proteins of identical function; applied to the MHC. Cf. **polymorphic**. (Chapter 6)

polymerase stalling The halting of RNA polymerase during the transcription of a gene at locations within the gene locus, known to be a regulated process, and involved in mechanisms of isotype switching. (Chapter 10)

polymeric immunoglobulin receptor (pIgR) The receptor for polymeric immunoglobulins IgA and IgM on basolateral surfaces of mucosal and glandular epithelial cells that transports IgA (or IgM) into secretions. (Chapters 10, 12)

polymorphic Existing in a variety of different forms; applied to a gene, occurring in a variety of different alleles. (Chapters 1, 4, 6)

polymorphism Applied to genes, variability at a gene locus in which all variants occur at a frequency greater than 1%. (Chapter 6)

polymorphonuclear leukocytes *See* **granulocytes**. (Chapter 1)

polysaccharide capsule A distinct structure in some bacteria—both Gram-negative and Gram-positive—that lies outside the cell membrane and cell wall and which can prevent direct phagocytosis by macrophages without the aid of antibody or complement. (Chapter 10)

polyubiquitin chains Polymers of ubiquitin covalently linked from lysine residues within one ubiquitin monomer to the carboxy terminus of a second ubiquitin. (Chapter 3)

PorA Outer membrane protein of *Neisseria meningitidis* that binds C4BP, thereby inactivating C3b deposited on its surface. (Chapter 2)

positive selection A process occurring in the thymus in which only those developing T cells whose receptors can recognize antigens presented by self MHC molecules can mature. (Chapters 6, 8)

post-transplant lymphoproliferative disorder B-cell expansion driven by Epstein–Barr virus (EBV) in which the B cells can undergo mutations and become malignant. This can occur when patients are immunosuppressed after, for example, solid organ transplantation. (Chapter 16)

pre-B-cell receptor Receptor produced by pre-B cells that includes an immunoglobulin heavy chain, as well as surrogate light-chain proteins, and Igα and Igβ signaling subunits. Signaling through this receptor induces the pre-B cell to enter the cell cycle, to turn off the RAG genes, to degrade the RAG proteins, and to expand by several cell divisions. (Chapter 8)

pre-T cell The first subset of thymocytes that are fully committed to the T-cell lineage and have lost the ability to develop into B cells, NK cells, or myeloid cells. T-cell receptor β-chain gene rearrangements are completed at this stage. (Chapter 8)

pre-T-cell receptor Receptor protein produced by developing T lymphocytes at the pre-T-cell stage. It is composed of TCRβ chains that pair with a surrogate α chain called pTα (pre-T-cell α) and is associated with the CD3 signaling chains. Signaling through this receptor induces pre-T-cell proliferation, expression of CD4 and CD8, and cessation of TCR β-chain rearrangement. (Chapter 8)

prednisone A synthetic steroid with potent anti-inflammatory and immunosuppressive activity used in treating acute graft rejection, autoimmune disease, and lymphoid tumors. (Chapter 16)

PrEP (pre-exposure prophylaxis) The daily administration of a combination of two reverse transcriptase inhibitors to uninfected individuals at high risk of HIV infection to lower their risk of contracting HIV infection. (Chapter 13)

PREX1 A guanine nucleotide exchange factor (GEF) activated downstream of small G proteins in response to activation of GPCRs such as the fMLP or C5a receptor. (Chapter 3)

primary focus Site of early antibody production by plasmablasts in medullary cords of lymph nodes that precedes the germinal center reaction and differentiation of plasma cells. (Chapter 10)

primary granules Granules in neutrophils that correspond to lysosomes and contain antimicrobial peptides such as defensins and other antimicrobial agents. (Chapters 2, 3)

primary immune response The adaptive immune response that follows the first exposure to a particular antigen. (Chapters 9, 11)

primary immunization *See* **priming**. (Chapter 1)

primary immunodeficiency A lack of immune function that is caused by a genetic defect. (Chapter 13)

primary lymphoid follicles Aggregates of resting B lymphocytes in peripheral lymphoid organs. Cf. **secondary lymphoid follicle**. (Chapter 10)

primary lymphoid organs *See* **central lymphoid organs**. (Chapters 1, 8)

primary lymphoid tissues *See* **central lymphoid organs**. (Chapters 1, 8)

priming The first encounter with a given antigen, which generates the primary adaptive immune response. (Chapter 9)

pro-B cells A stage in B-lymphocyte development in which cells have displayed B-cell surface marker proteins but have not yet completed heavy-chain gene rearrangement. (Chapter 8)

pro-inflammatory Tending to induce inflammation. (Chapter 3)

profilin An actin-binding protein that sequesters monomeric actin. Protozoan profilins contain sequences recognized by TLR-11 and TLR-12. (Chapter 3)

programmed cell death *See* **apoptosis**. (Chapter 1)

programmed death ligand-1 *See* **PD-L1**. (Chapter 16)

progressive multifocal leukoencephalopathy (PML) Disease in immunocompromised patients caused by opportunistic infection by JC virus, for example as a consequence of immunotherapy. (Chapter 16)

propeptide Inactive precursor form of a polypeptide or peptide, which requires proteolytic processing to produce the active peptide. (Chapter 2)

properdin *See* **factor P**. (Chapter 2)

prostaglandins Lipid products of the metabolism of arachidonic acid that have a variety of effects on tissues, including activities as inflammatory mediators. (Chapters 3, 16)

prostatic acid phosphatase (PAP) Enzyme expressed by prostate cancer cells and used as a tumor-rejection antigen in the vaccine sipuleucel-T (Provenge). (Chapter 16)

pro-T cells In the thymus, ETPs differentiate into pro-T cells. At this stage, the cells begin to lose Kit expression along with their ability to develop into other lineages, such as B cells, NK cells, and myeloid cells. T-cell receptor gene rearrangements begin at this stage. (Chapter 8)

proteasome A large intracellular multi-subunit protease that degrades proteins, producing peptides. (Chapter 6)

protein inhibitors of activated STAT (PIAS) A small family of proteins that inhibit STAT family transcription factors. (Chapter 3)

protein-interaction domains, protein-interaction modules Protein domains, usually with no enzymatic activity themselves, that have binding specificity for particular sites (such as phosphorylated tyrosines, proline-rich regions, or membrane phospholipids) on other proteins or cellular structures. (Chapter 7)

protein kinase C-Θ (PKC-Θ) A serine/threonine kinase that is activated by diacylglycerol as part of the signaling pathways from the antigen receptor in lymphocytes. (Chapter 7)

protein kinases Enzymes that add phosphate groups to proteins at particular amino acid residues: tyrosine, threonine, or serine. (Chapter 7)

protein phosphatases Enzymes that remove phosphate groups from proteins phosphorylated on tyrosine, threonine, or serine residues by protein kinases. (Chapter 7)

proteolytic subunits β1, β2, β5 Constitutive components of the proteasome's catalytic chamber. (Chapter 6)

protein tyrosine kinases Enzymes that specifically phosphorylate tyrosine residues in proteins. They are critical in the signaling pathways that lead to T- and B-cell activation. (Chapter 7)

provirus The DNA form of a retrovirus when it is integrated into the host-cell genome, where it can remain transcriptionally inactive for long periods. (Chapter 13)

P-selectin *See* **selectins**. (Chapter 3)

P-selectin glycoprotein ligand-1 (PSGL-1) Protein expressed by activated effector T cells that is a ligand for P-selectin on endothelial cells and may enable activated T cells to enter all tissues in small numbers. (Chapters 9, 11)

pseudogenes Gene elements that have lost the ability to encode a functional protein but that are retained in the genome and may continue to be transcribed normally. (Chapter 5)

psoriasis Chronic autoimmune disease thought to be driven by T cells manifested in skin, but which can also involve nails and joints (psoriatic arthropathy). (Chapter 16)

psoriatic arthropathy *See* **psoriasis**. (Chapter 16)

pTα *See* **pre-T-cell receptor**. (Chapter 8)

purine nucleotide phosphorylase (PNP) deficiency An enzyme defect that results in severe combined immune deficiency. The deficiency of PNP causes an intracellular accumulation of purine nucleosides, which are toxic to developing T cells. (Chapter 13)

purinergic receptor P2X7 An ATP-activated ion channel that allows potassium efflux from cells when activated, which can trigger inflammasome activation in response to excessive extracellular ATP. (Chapter 3)

pus Thick yellowish-white liquid typically found at sites of infection with some types of extracellular bacteria, which is composed of the remains of dead neutrophils and other cells. (Chapter 3)

pus-forming bacteria Capsulated bacteria that result in pus formation at the site of infection. Also called pyogenic (pus-forming) bacteria. (Chapters 3, 13)

PYHIN A family of four intracellular sensor proteins containing an HIN (hematopoietic expression, interferon-inducible nature, and nuclear localization) domain in place of the LRR domain found in most other NLR proteins. The HIN domain functions in recognition of cytoplasmic dsDNA. Examples are AIM2 and IFI16. (Chapter 3)

pyogenic arthritis, pyoderma gangrenosum, and acne (PAPA) Auto-inflammatory syndrome that is caused by mutations in a protein that interacts with Pyrin. (Chapter 13)

pyogenic bacteria *See* **pus-forming bacteria**. (Chapters 3, 13)

Pyrin An inflammasome sensor protein that becomes dephosphorylated when Rho GTPase is inactivated by toxins produced by certain bacteria such as *Clostridium difficile*, thereby acquiring an active conformation that recruits ASC and leads to caspase 1 activation. (Chapters 3, 13)

pyrin One of several protein-interaction domains, structurally related to but distinct from CARD, TIR, DD, and DED domains. (Chapter 3)

pyroptosis A form of programmed cell death that is associated with abundant pro-inflammatory cytokines such as IL-1β and IL-18 produced through inflammasome activation. (Chapter 3)

Qa-1 determinant modifiers (Qdm) A class of peptides derived from the leader peptides of various HLA class I molecules that can be bound by the human HLA-E and murine Qa-1 proteins, and then are recognized by the inhibitory NKG2A:CD94 receptor. (Chapter 6)

quasi-species The different genetic forms of certain RNA viruses that are formed by mutation during the course of an infection. (Chapter 13)

Rac *See* **Rho family small GTPase proteins**. (Chapter 3)

radiation bone marrow chimera An individual treated with a high dose of radiation to eliminate his or her hematopoietic cells and then transfused with bone marrow or purified hematopoietic stem cells from a different individual, the donor. The donor bone marrow stem cells reconstitute the hematopoietic system in the recipient, who is referred to as a chimera because of the distinct genetic origin of his or her hematopoietic cells compared to all other cells in that individual's body. (Appendix I)

radiation-sensitive SCID (RS-SCID) Severe combined immune deficiency due to a defect in DNA repair pathways, which renders cells unable to perform V(D)J recombination and unable to repair radiation-induced double-strand breaks. (Chapters 5, 13)

radioimmunoassay (RIA) An assay to measure quantities of a specific compound, such as a hormone, in a complex mixture such as serum. The assay uses radioactively labeled antigen and an antibody against that antigen in a competitive binding assay. (Appendix I)

RAE1 (retinoic acid early inducible 1) protein family Several murine MHC class Ib proteins; these are orthologs of human RAET1 family proteins, including H60 and MULT1, and are ligands for murine NKG2D. (Chapter 3)

RAET1 *See* **UL16-binding proteins**. (Chapters 3, 6)

Raf A protein kinase in the Raf–Mek1–Erk signaling cascade that is the first protein kinase in the pathway and is activated by the small GTPase Ras. (Chapter 7)

RAG-1, RAG-2 Proteins encoded by the recombination-activating genes *RAG1* and *RAG2*, which form a dimer that initiates V(D)J recombination. (Chapter 5)

rapamycin An immunosuppressant drug that blocks intracellular signaling pathways involving the serine/threonine kinase mammalian target of rapamycin (mTOR) required for the inhibition of apoptosis and T-cell expansion. Also called sirolimus. (Chapter 16)

Raptor *See* **mTORC1**. (Chapter 16)

Ras A small GTPase with important roles in intracellular signaling pathways, including those from lymphocyte antigen receptors. (Chapter 7)

reactive oxygen species (ROS) Superoxide anion (O_2^-) and hydrogen peroxide (H_2O_2), produced by phagocytic cells such as neutrophils and macrophages after ingestion of microbes, and which help kill the ingested microbes. (Chapter 3)

rearrangement by inversion In V(D)J recombination, the rearrangement of gene segments having RSS elements in an opposing orientation, leading to retention. (Chapter 5)

receptor editing The replacement of a light or heavy chain of a self-reactive antigen receptor on immature B cells with a newly rearranged chain that does not confer autoreactivity. (Chapter 8)

receptor-mediated endocytosis The internalization into endosomes of molecules bound to cell-surface receptors. (Chapter 3)

recessive lethal gene A gene that when inactivated on both alleles of the chromosome encoding the gene results in impaired survival of the homozygous individuals. (Appendix I)

recombination signal sequences (RSSs) DNA sequences at one or both ends of V, D, and J gene segments that are recognized by the RAG-1:RAG-2 recombinase. They consist of a conserved heptamer and nonamer element separated by 12 or 23 base pairs. (Chapter 5)

red pulp The nonlymphoid area of the spleen in which red blood cells are broken down. (Chapters 1, 9)

RegIIIγ An antimicrobial protein of the C-type lectin family, produced by Paneth cells in the gut in mice. (Chapter 2)

regulatory T cells (T_{reg} cells) Effector CD4 T cells that inhibit T-cell responses and are involved in controlling immune reactions and preventing autoimmunity. Several different subsets have been distinguished, notably the natural regulatory T-cell lineage that is produced in the thymus, and the induced regulatory T cells that differentiate from naive CD4 T cells in the periphery in certain cytokine environments. (Chapters 1, 9)

regulatory tolerance Tolerance due to the actions of regulatory T cells. (Chapter 15)

Relish A distinct member of the *Drosophila* NFκB transcription factor family that induces the expression of several antimicrobial peptides in response to Gram-negative bacteria. (Chapter 3)

resistance A general immune strategy aimed at reducing or eliminating pathogens. Cf. **avoidance** and **tolerance**. (Chapter 1)

respiratory burst An oxygen-requiring metabolic change in neutrophils and macrophages that have taken up opsonized particles, such as complement- or antibody-coated bacteria, by phagocytosis. It leads to the production of toxic metabolites that are involved in killing the engulfed microorganisms. (Chapter 3)

restriction factors Host proteins that act in a cell-autonomous manner to inhibit the replication of retroviruses such as HIV. (Chapter 13)

retinoic acid Signaling molecule derived from vitamin A with many roles in the body. It is thought to be involved in the induction of immunological tolerance in the gut. (Chapter 9)

retrotranslocation complex A multi-subunit membrane protein complex in the endoplasmic reticulum that allows the transport of misfolded proteins across the membrane of the endoplasmic reticulum and into the cytosol where ubiquitin-dependent degradation by the proteasome takes place. (Chapter 6)

retrovirus A single-stranded RNA virus that uses the viral enzyme reverse transcriptase to transcribe its genome into a DNA intermediate that integrates into the host-cell genome to undergo viral replication. (Chapter 13)

reverse transcriptase Viral RNA-dependent DNA polymerase that is found in retroviruses and transcribes the viral genomic RNA into DNA during the life cycle of retroviruses (such as HIV). (Chapter 13)

reverse transcriptase–polymerase chain reaction (RT–PCR) A technique for determining the presence and amount of a transcript for a specific gene. mRNA is isolated from cells and converted into cDNA by the enzyme reverse transcriptase (RT). The cDNA is then subjected to a polymerase chain reaction (PCR) in which primers that bind to a specific cDNA sequence are used to amplify a fragment of that gene's sequence. The amplified DNA product can then be visualized on an agarose gel. (Appendix I)

Rheb A small GTPase that activates mTOR when in its GTP-bound form and which is inactivated by a GTPase-activating protein (GAP) complex TSC1/2. (Chapter 16)

rhesus (or **Rh**) **blood-group antigen** Individuals in the human population vary in expression of a protein called Rh, expressed on the surface of red blood cells. A subset of individuals lacks expression of the Rh-D protein. When pregnant, an Rh-D–negative mother can make antibodies to the Rh-D protein expressed on her fetus after exposure to fetal blood during delivery. (Appendix I)

rheumatic fever Disease caused by antibodies elicited by infection with some *Streptococcus* species. These antibodies cross-react with kidney, joint, and heart antigens. (Chapter 15)

rheumatoid arthritis (RA) A common inflammatory joint disease that is probably due to an autoimmune response. (Chapter 15)

rheumatoid factor An anti-IgG autoantibody of the IgM class first identified in patients with rheumatoid arthritis, but which is also found in healthy individuals. (Chapter 15)

Rho *See* **Rho family small GTPase proteins**. (Chapter 3)

Rho family small GTPase proteins Several distinct small GTPase family members that regulate the actin cytoskeleton in response to signaling through various receptors. Examples: Rac, Rho, and Cdc42. (Chapter 3)

riboflavin (vitamin B_2) A dietary vitamin that is metabolized by intestinal bacteria to generate derivatives that bind to MR1, forming ligands for MAIT cells (Chapter 6)

Rictor *See* **mTORC2**. (Chapter 16)

RIG-I (retinoic acid–inducible gene I) *See* **RIG-I-like receptors (RLRs)**. (Chapter 3)

RIG-I–like receptors (RLRs) A small family of intracellular viral sensors that use a carboxy-terminal RNA helicase–like domain in detection of various forms of viral RNA. These signal through MAVS to activate antiviral immunity. Examples include RIG-I, MDA-5, and LGP2. (Chapter 3)

RIP2 A CARD containing serine/threonine kinase that functions in signaling by NOD proteins to activate the NFκB transcription factor. (Chapter 3)

Riplet An E3 ubiquitin ligase involved in signaling by RIG-I and MDA-5 for the activation of MAVS. (Chapter 3)

rituximab A chimeric antibody to CD20 used to eliminate B cells in treatment of non-Hodgkin's lymphoma. (Chapter 16)

R-loops A structure formed when transcribed RNA displaces the non-template strand of the DNA double helix at switch regions in the immunoglobulin constant-region gene cluster. R-loops are thought to promote class switch recombination. (Chapter 10)

RNA exosome A multi-subunit complex involved in processing and editing of RNA. (Chapter 10)

RORγt RAR-related orphan nuclear receptor γt. One of two isoforms of the liganded transcription factor RORγ, which is a member of the NR1 subfamily of nuclear receptors. RORγt is important for the development of T_H17 cells and ILC3 cells. The ligand bound by RORγt is derived from the cholesterol biosynthesis pathway. (Chapter 9)

ruxolitinib An inhibitor of Jak1 and Jak2 approved for treatment of myelofibrosis. (Chapter 16)

S1P lyase A membrane-bound enzyme that degrades S1P. (Chapter 9)

S1PR1 A G protein–coupled receptor expressed on circulating lymphocytes that binds the chemotactic phospholipid sphingosine 1-phosphate (S1P), which forms a chemotactic gradient that promotes the egress of nonactivated lymphocytes out of peripheral lymphoid tissues into the efferent lymphatics and blood. *See also* **CD69**. (Chapters 8, 9)

SAP (SLAM-associated protein) An intracellular adaptor protein involved in signaling by SLAM (signaling lymphocyte activation molecule). Inactivating mutations in this gene cause X-linked lymphoproliferative (XLP) syndrome. (Chapters 3, 10)

scavenger receptors Receptors on macrophages and other cells that bind to numerous ligands, such as bacterial cell-wall components, and remove them from the blood. The Kupffer cells in the liver are particularly rich in scavenger receptors. Includes SR-A I, SR-A II, and MARCO. (Chapter 3)

scid Mutation in mice that causes severe combined immune deficiency. It was eventually found to be due to mutation of the DNA repair protein DNA-PK. (Chapter 5)

SCID *See* **severe combined immune deficiency**. (Chapter 3)

SDS-PAGE A technique for separating proteins on the basis of their molecular mass. Proteins in a cell lysate are treated with a strong detergent, sodium dodecyl sulfate (SDS), and then subjected to electrophoresis in a polyacrylamide gel (PAGE: polyacrylamide gel electrophoresis). Because the SDS binds relatively uniformly to all proteins, the net charge on the protein reflects the number of SDS molecules bound and, hence, the protein's molecular mass. PAGE then separates the proteins on the basis of this relative charge. (Appendix I)

seasonal allergic rhinoconjunctivitis IgE-mediated allergic rhinitis and conjunctivitis caused by exposure to specific seasonally occurring antigens; for example, grass or weed pollens. Commonly called hay fever. (Chapter 14)

second messengers Small molecules or ions (such as Ca^{2+}) that are produced in response to a signal; they act to amplify the signal and carry it to the next stage within the cell. Second messengers generally act by binding to and modifying the activities of enzymes. (Chapter 7)

secondary granules Type of granule in neutrophils that stores certain antimicrobial peptides. (Chapters 2, 3)

secondary (or **recall**) **immune response** The immune response that occurs in response to a second exposure to an antigen. In comparison with the primary response, it starts sooner after exposure, produces greater levels of antibody, and produces class-switched antibodies. It is generated by the reactivation of memory lymphocytes. (Chapters 9, 11)

secondary immunization A second or booster injection of an antigen, given some time after the initial immunization. It stimulates a secondary immune response. (Chapter 1)

secondary immunodeficiency Deficiency in immune function that is a consequence of infection (e.g., HIV infection), other diseases (e.g., leukemia), malnutrition, and so forth. (Chapter 13)

secondary lymphoid follicle A follicle containing a germinal center of proliferating activated B cells during an ongoing adaptive immune response. (Chapter 10)

secondary lymphoid organs *See* **peripheral lymphoid organs**. (Chapters 1, 8)

secondary lymphoid tissues *See* **peripheral lymphoid organs**. (Chapters 1, 8)

secretory component (SC) Fragment of the polymeric immunoglobulin receptor that remains after cleavage and is attached to secreted IgA after transport across epithelial cells. (Chapters 10, 12)

secretory phospholipase A_2 Antimicrobial enzyme present in tears and saliva and also secreted by the Paneth cells of the gut. (Chapter 2)

selectins Family of cell-adhesion molecules on leukocytes and endothelial cells that bind to sugar moieties on specific glycoproteins with mucin-like features. (Chapter 3)

self antigens The potential antigens on the tissues of an individual, against which an immune response is not usually made except in the case of autoimmunity. (Chapter 1)

self-tolerance The failure to make an immune response against the body's own antigens. (Chapter 15)

sensitization The acute adaptive immune response made by susceptible individuals on first exposure to an allergen. In some of these individuals, subsequent exposure to the allergen will provoke an allergic reaction. (Chapter 14)

sensitized In allergy, describes an individual who has made an IgE response on initial encounter with an environmental antigen and who manifests IgE-producing memory B cells. Subsequent allergen exposure can elicit an allergic response. (Chapter 14)

sensor cells Cells of the innate immune system that detect the presence of pathogens using their innate recognition receptors. In response to triggering of their innate recognition receptors, sensor cells produce inflammatory mediators that promote pathogen clearance and recruit additional cells into the immune response. (Chapter 1)

sentinel goblet cells Goblet cells present at the entrance of colonic crypts and which sense TLR ligands to activate an NLRP inflammasome to alert adjacent goblet cells deeper in the crypt to secrete MUC2, producing a jet of mucus that expels invading microbes from the crypts. (Chapter 12)

sepsis Bacterial infection of the bloodstream. This is a very serious and frequently fatal condition. (Chapter 3)

septic shock Systemic shock reaction that can follow infection of the bloodstream with endotoxin-producing Gram-negative bacteria. It is caused by the systemic release of TNF-α and other cytokines. Also called endotoxic shock. (Chapter 3)

sequence motif A pattern of nucleotides or amino acids shared by different genes or proteins that often have related functions. (Chapter 6)

serglycin A proteoglycan found in the secretory granules of many immune cells that serves to protect and store a variety of secreted proteins, such as perforin and granzymes, until they are released by exocytosis. (Chapter 9)

serine protease inhibitor (serpin) Class of proteins that inhibit various proteases, originally referring to those specific to serine proteases. (Chapter 2)

seroconversion The phase of an infection when antibodies against the infecting agent are first detectable in the blood. (Chapter 13)

serological assays Diagnostic tests performed on blood serum, often to detect antibodies. (Appendix I)

serology The study of components in the serum, often using antibodies to detect specific antigens. (Appendix I)

serotype Name given to a strain of bacteria or other pathogen that can be distinguished from other strains of the same species by specific antibodies. (Chapter 13)

serum The fluid phase of clotted blood. Clotting involves fibrinogen and multiple clotting factors. After centrifugation, the clot and cells in the blood are removed, and the fluid phase, or serum, can be recovered. (Appendix I)

serum sickness A usually self-limiting immunological hypersensitivity reaction originally seen in response to the therapeutic injection of large amounts of foreign serum (now most usually evoked by the injection of drugs such as penicillin). It is caused by the formation of immune complexes of the antigen and the antibodies formed against it, which become deposited in the tissues, especially the kidneys. (Chapters 14, 16)

severe acute respiratory syndrome (SARS) A coronavirus-caused respiratory illness of zoonotic origin that was responsible for a global disease outbreak in 2003. (Chapter 12)

severe combined immune deficiency (SCID) Type of immune deficiency (due to various causes) in which both B-cell (antibody) and T-cell responses are lacking; it is fatal if not treated. (Chapters 3, 5, 13)

severe congenital neutropenia (SCN) An inherited condition in which the neutrophil count is persistently extremely low. This is in contrast to cyclic neutropenia, in which neutrophil numbers fluctuate from near normal to very low or absent, with an approximate cycle time of 21 days. (Chapter 13)

SH2 (Src homology 2) domain *See* **Src family protein tyrosine kinases**. (Chapters 3, 7)

shear-resistant rolling The capacity of neutrophils to remain attached to the vascular endothelium under high rates of flow—or shear—enabled by specialized plasma membrane extensions called slings. (Chapter 3)

shingles Disease caused when varicella-zoster virus (the virus that causes chickenpox) is reactivated later in life in a person who has had chickenpox. (Chapter 13)

SHIP (SH2-containing inositol phosphatase) An SH2-containing inositol phosphatase that removes the phosphate from PIP_3 to produce PIP_2. (Chapter 7)

shock The potentially fatal circulatory collapse caused by the systemic actions of cytokines such as TNF-α. (Chapter 3)

short-chain fatty acids (SCFAs) Fatty acids with fewer than six carbon atoms that are primary metabolic products of bacterial fermentation of dietary fibers and resistant starch in the large intestine. SCFAs can act on intestinal epithelial cells as well as local immune cells to promote intestinal immune homeostasis. (Chapter 12)

SHP (SH2-containing phosphatase) An SH2-containing protein phosphatase. (Chapter 7)

SHP-1, SHP-2 Intracellular tyrosine phosphatases that are recruited to phosphorylated ITIM domains of various inhibitory receptors and which can remove phosphate residues from other signaling molecules, with effect of reducing signaling. (Chapter 3)

signaling scaffold A configuration of proteins and modifications, such as phosphorylation or ubiquitination, that facilitates signaling by binding various enzymes and their substrates. (Chapter 3)

signal joint The noncoding joint formed in DNA by the recombination of RSSs during V(D)J recombination. Cf. **coding joint**. (Chapter 5)

signal peptide The short N-terminal peptide sequence responsible for directing newly synthesized proteins into the secretory pathway. (Chapter 3)

signal transducers and activators of transcription (STATs) A family of seven transcription factors activated by many cytokine and growth factor receptors. *See also* **Janus kinase (JAK) family**. (Chapter 3)

single-chain antibody Referring to the heavy-chain-only IgGs produced by camelids or shark species that lack the light chain present in conventional antibodies. (Chapter 4)

single-nucleotide polymorphisms (SNPs) Positions in the genome that differ by a single base between individuals. (Chapters 14, 15)

single-positive thymocyte A mature T cell that expresses either the CD4 or the CD8 co-receptor, but not both. (Chapter 8)

single-stranded RNA (ssRNA) Usually confined to the nucleus and cytoplasm, this normal molecular form serves as a ligand for TLR-7 and TLR-8 when it is present in endosomes, as during parts of a viral life cycle. (Chapter 3)

sipuleucel-T (Provenge) Cell-based immunotherapy used to treat prostate cancer that combined prostatic acid phosphatase as a tumor-rejection antigen presented by dendritic cells derived from a patient's monocytes. (Chapter 16)

sirolimus *See* **rapamycin**. (Chapter 16)

Sjögren's syndrome An autoimmune disease in which exocrine glands, particularly the lacrimal glands of the eyes and salivary glands of the mouth, are damaged by the immune system. This results in dry eyes and mouth. (Chapter 15)

Skint-1 A transmembrane immunoglobulin superfamily member expressed by thymic stromal cells and keratinocytes that is required for the development of dendritic epidermal T cells, which are a type of γδ T cell. (Chapter 6)

SLAM (signaling lymphocyte activation molecule) A family of related cell-surface receptors that mediate adhesion between lymphocytes and which includes SLAM, 2B4, CD84, Ly108, Ly9, and CRACC. (Chapters 3, 10)

slings *See* **shear-resistant rolling**. (Chapter 3)

SLP-65 A scaffold protein in B cells that recruits proteins involved in the intracellular signaling pathway from the antigen receptor. Also called BLNK. (Chapter 7)

SLP-76 A scaffold protein involved in the antigen receptor signaling pathway in lymphocytes. (Chapter 7)

small G proteins, small GTPases Single-subunit G proteins, such as Ras, that act as intracellular signaling molecules downstream of many transmembrane signaling events. (Chapter 7)

small pre-B cell Stage in B-cell development immediately after the large pre-B cell in which cell proliferation ceases and light-chain gene rearrangement commences. (Chapter 8)

somatic diversification theories General hypotheses proposing that the immunoglobulin repertoire was formed from a small number of V genes that diversified in somatic cells. Cf. **germline theory**. (Chapter 5)

somatic DNA recombination DNA recombination that takes place in somatic cells (to distinguish it from the recombination that takes place during meiosis and gamete formation). (Chapter 5)

somatic gene therapy The introduction of functional genes into somatic cells to treat disease. (Chapter 13)

somatic hypermutation Mutations in V-region DNA of rearranged immunoglobulin genes that produce variant immunoglobulins, some of which bind antigen with a higher affinity. These mutations affect only somatic cells and are not inherited through germline transmission. (Chapters 5, 10)

spacer *See* **12/23 rule**. (Chapter 5)

specificity The strength of binding between an antibody and an antigen. When an antibody binds more strongly to some antigens and more weakly to others, it is considered to have greater specificity for the strongly bound antigens. (Appendix I)

sphingolipids A class of membrane lipids containing sphingosine (2-amino-4-octadecene-1,3-diole), an amino alcohol with an unsaturated 18-hydrocarbon chain. (Chapter 6)

sphingosine 1-phosphate (S1P) A phospholipid with chemotactic activity that controls the egress of T cells from lymph nodes. (Chapter 9)

sphingosine 1-phosphate receptor 1 (S1PR1) A G protein–coupled receptor activated by sphingosine 1-phosphate, a lipid mediator in the blood that regulates several physiological processes, including the trafficking of naive lymphocytes from tissues into the blood. (Chapters 10, 12)

spleen An organ in the upper left side of the peritoneal cavity containing a red pulp, involved in removing senescent blood cells, and a white pulp of lymphoid cells that respond to antigens delivered to the spleen by the blood. (Chapter 1)

S-protein (vitronectin) Plasma protein that binds incompletely formed MAC complexes, such as C5b67, preventing bystander complement damage to host membranes. (Chapter 2)

Spt5 A transcription elongation factor required for isotype switching in B cells that functions in association with RNA polymerase to enable recruitment of AID to its targets in the genome. (Chapter 10)

SR-A I, SR-A II *See* **scavenger receptors**. (Chapter 3)

Src family protein tyrosine kinases Receptor-associated protein tyrosine kinases characterized by Src homology protein domains (SH1, SH2, and SH3). The SH1 domain contains the kinase, the SH2 domain can bind phosphotyrosine residues, and the SH3 domain can interact with proline-rich regions in other proteins. In T cells and B cells they are involved in relaying signals from the antigen receptor. (Chapter 3)

staphylococcal complement inhibitor (SCIN) Staphylococcal protein that inhibits the activity of the classical and alternative C3 convertases, promoting the evasion of destruction by complement. (Chapter 2)

staphylococcal enterotoxins (SEs) Secreted toxins produced by some staphylococci, which cause food poisoning and also stimulate many T cells by binding to MHC class II molecules and the V_b domain of certain T-cell receptors, acting as superantigens. (Chapter 6)

staphylococcal protein A (Spa) Staphylococcal protein that blocks the binding of the antibody Fc region with C1, thereby preventing complement activation. (Chapter 2)

staphylokinase (SAK) Staphylococcal protease that cleaves immunoglobulins bound to its surface, thereby preventing complement activation. (Chapter 2)

STAT1 A member of the signal transducer and activator of transcription (STAT) family of transcription factors activated by type I and type II interferon signaling. (Chapters 3, 9)

STAT2 A member of the signal transducer and activator of transcription (STAT) family of transcription factors activated by type II interferon signaling and which heterodimerizes with STAT1 and associates with IRF9 to form a complex called ISGF3. (Chapter 3)

STAT3 *See* **signal transducers and activators of transcription**. (Chapters 9, 10)

STAT3 deficiency A primary immune deficiency with an autosomal pattern of inheritance caused by mutations in the gene *STAT3* that lead to defective STAT3 signaling. *See* also **hyper IgE syndrome**; **Job syndrome**. (Chapter 13)

STAT4 *See* **signal transducers and activators of transcription**. (Chapter 9).

STAT6 *See* **signal transducers and activators of transcription**. (Chapters 9, 10)

statins Drug inhibitors of HMG-CoA reductase used to lower cholesterol. (Chapter 16)

sterile injury Damage to tissues due to trauma, ischemia, metabolic stress, or autoimmunity, bearing many immune features similar to infection. (Chapter 3)

sterilizing immunity An immune response that completely eliminates a pathogen. (Chapter 11)

STIM1 A transmembrane protein that acts as a Ca^{2+} sensor in the endoplasmic reticulum. When Ca^{2+} is depleted from the endoplasmic reticulum, STIM1 is activated and induces opening of plasma membrane CRAC channels. (Chapter 7)

STING (stimulator of interferon genes) A dimeric protein complex in the cytoplasm anchored to the endoplasmic reticulum membrane that functions in intracellular sensing for infection. It is activated by specific cyclic dinucleotides to activate TBK1, which phosphorylates IRF3 to induce transcription of type I interferon genes. (Chapter 3)

stress-induced self *See* **dysregulated self**. (Chapter 3)

stromal cells The nonlymphoid cells in central and peripheral lymphoid organs that provide soluble and cell-bound signals required for lymphocyte development, survival, and migration. (Chapter 8)

stromal organizer cells Precursors of fibroblast reticular cells (FRCs) and follicular dendritic cells (FDCs) that develop from mesenchymal cells in response to lymphotoxins produced by lymphoid tissue inducer (LTi) cells. (Chapter 9)

subcapsular sinus (SCS) The site of lymphatic entry in lymph nodes lined by phagocytes, including subcapsular macrophages, which capture particulate and opsonized antigens draining in from tissues. (Chapters 9, 10)

subcutaneous Under the epidermal and dermal layers of the skin. (Appendix I)

succinate A metabolite produced by intestinal parasites that stimulates IL-25 production by tuft cells. (Chapter 11)

sulfated sialyl-Lewis^X A sulfated tetrasaccharide carbohydrate structure attached to many cell surface proteins, it binds the P-selectin and E-selectin molecules on the surface of cells, such as neutrophils, that mediate interactions with the endothelium. (Chapter 3)

superoxide dismutase (SOD) An enzyme that converts the superoxide ion produced in the phagolysosome into hydrogen peroxide, a substrate for further reactive antimicrobial metabolites. (Chapter 3)

superoxide radical A highly reactive form of oxygen having an unpaired electron (making it a radical) and being negatively charged, making it an ion, formed in the phagolysosome by the action of the NADPH oxidase. (Chapter 3)

suppressor of cytokine signaling (SOCS) Regulatory protein that interacts with Janus kinases (JAKs) to inhibit signaling by activated receptors. (Chapter 3)

supramolecular activation complex (SMAC) Organized structure that forms at the point of contact between a T cell and its target cell, in which the ligand-bound antigen receptors are co-localized with other cell-surface signaling and adhesion molecules. (Chapter 7)

surface immunoglobulin (sIg) The membrane-bound immunoglobulin that acts as the antigen receptor on B cells. (Chapter 1)

surface plasmon resonance (SPR) A technique for measuring the binding kinetics of interaction between two molecules. One molecule is immobilized on the surface of a glass slide, and a solution of the binding partner is streamed over the surface. The instrument measures the binding and then dissociation of the fluid-phase component. (Appendix I)

surfactant proteins A and **D (SP-A** and **SP-D)** Acute-phase proteins that help protect the epithelial surfaces of the lung against infection. (Chapters 2, 3)

surrogate light chain A protein in pre-B cells, made up of two subunits, VpreB and λ5, that can pair with a full-length immunoglobulin heavy chain and the Igα and Igβ signaling subunits and signals for pre-B-cell differentiation. (Chapter 8)

switch regions Genomic regions, several kilobases in length each, located between the J_H region and the heavy-chain Cμ genes, or in equivalent positions upstream of other C-region genes (except C_δ), containing hundreds of G-rich repeated sequences that function in class switch recombination. (Chapter 10)

Syk A cytoplasmic tyrosine kinase found in B cells that acts in the signaling pathway from the B-cell antigen receptor. (Chapter 7)

symbiotic Relationship between two agents, typically diverse species, that confers benefits to both. (Chapter 1)

sympathetic ophthalmia Autoimmune response that occurs in the other eye after one eye is damaged. (Chapter 15)

syngeneic graft A graft between two genetically identical individuals. It is accepted as self. (Chapter 15)

systemic immune system Name sometimes given to the lymph nodes and spleen to distinguish them from the mucosal immune system. (Chapter 12)

systemic lupus erythematosus (SLE) An autoimmune disease in which autoantibodies against DNA, RNA, and proteins associated with nucleic acids form immune complexes that damage small blood vessels, especially in the kidney. (Chapters 10, 15)

T10, T22 MHC class Ib molecules expressed by activated lymphocytes and recognized by a subset of γδ T cells. (Chapters 4, 6)

TAB1, TAB2 An adaptor complex that binds K63-linked polyubiquitin chains. TAB1 and TAB2 complex with TAK1, targeting TAK1 to signaling scaffolds where it phosphorylates substrates such as IKKα. (Chapter 3)

TACE (TNF-α–converting enzyme) A protease responsible for cleavage of the membrane-associated form of the cytokine TNF-α into its soluble form, which can enter the systemic circulation. (Chapter 3)

TACI A receptor for BAFF expressed on B cells that activates the canonical NFκB pathway. (Chapter 10)

tacrolimus An immunosuppressant polypeptide drug that binds FK-binding proteins (FKBPs) and inactivates T cells by inhibiting calcineurin, thus blocking activation of the transcription factor NFAT. Also called FK506. (Chapters 7, 16)

TAK1 A serine/threonine kinase that is activated by phosphorylation by the IRAK complex and which activates downstream targets such as IKKβ and MAPKs. (Chapter 3)

talin An intracellular protein involved in the linkage of activated integrins, such as LFA-1, to the cytoskeleton to allow changes in cellular motility and migration, such as in the diapedesis of neutrophils across the vascular endothelium. (Chapter 3)

TAP-1, TAP-2 Transporters associated with antigen processing-1 and -2. ATP-binding cassette proteins that form a heterodimeric TAP-1:TAP-2 complex in the endoplasmic reticulum membrane, through which short peptides are transported from the cytosol into the lumen of the endoplasmic reticulum, where they associate with MHC class I molecules. (Chapter 6)

tapasin TAP-associated protein. A key molecule in the assembly of MHC class I molecules; a cell deficient in this protein has only unstable MHC class I molecules on the cell surface. (Chapter 6)

TAPBPR A quality-control protein in the Golgi apparatus that can recognize improperly folded proteins and cause their re-glucosylation by UDP-glucose:glycoprotein glucosyltransferase 1 (UGT1). It can function to redirect improperly loaded MHC class I back to the endoplasmic reticulum for additional peptide editing by the peptide-loading complex. (Chapter 6)

Tbet A transcription factor active in many immune cell types but most typically associated with ILC1 and T_H1 function. (Chapters 3, 9, 12)

TBK1 (TANK-binding kinase 1) A serine/threonine kinase activated during signaling by TLR-3 and MAVS and serving to phosphorylate and activate IRF3 for induction of type I interferon gene expression. (Chapter 3)

T cell, T lymphocyte One of the two types of antigen-specific lymphocytes responsible for adaptive immune responses, the other being the B cells. T cells are responsible for the cell-mediated adaptive immune reactions. They originate in the bone marrow but undergo most of their development in the thymus. The highly variable antigen receptor on T cells is called the T-cell receptor and recognizes a complex of peptide antigen bound to MHC molecules on cell surfaces. There are two main lineages of T cells: those carrying αβ receptors and those carrying γδ receptors. Effector T cells perform a variety of functions in an immune response, acting always by interacting with another cell in an antigen-specific manner. Some T cells

activate macrophages, some help B cells produce antibody, and some kill cells infected with viruses and other intracellular pathogens. (Chapter 1)

T-cell antigen receptor *See* **T-cell receptor**. (Chapter 1)

T-cell areas Regions of peripheral lymphoid organs that are enriched in naive T cells and are distinct from the follicles. They are the sites at which adaptive immune responses are initiated. (Chapters 1, 10)

T-cell clones Expanded populations of cultured T cells in which all cells in a given population derive from a single initial T cell. Each T cell in such a clonal population expresses the same TCR. (Appendix I)

T-cell hybrids Hybridomas of a T cell that was isolated from a T-cell lymphoma cell of an animal fused to a primary antigen-specific T cell to generate an immortalized cell line with a single T-cell receptor specificity. *See also* **hybridoma**. (Appendix I)

T-cell lines Expanded populations of cultured T cells in which all cells in a given population share the same antigen specificity. Each population of T cells in a T-cell line is not necessarily derived from a single initial T cell, and instead is generally composed of a mixture of cells with different TCRs. (Appendix I)

T-cell plasticity Flexibility in the developmental programming of CD4 T cells such that effector T-cell subsets are not irreversibly fixed in their function or the transcriptional networks that underpin those functions. (Chapter 11)

T-cell receptor (TCR) The cell-surface receptor for antigen on T lymphocytes. It consists of a disulfide-linked heterodimer of the highly variable α and β chains in a complex with the invariant CD3 and ζ proteins, which have a signaling function. T cells carrying this type of receptor are often called $\alpha\beta$ T cells. An alternative receptor made up of variable γ and δ chains is expressed with CD3 and ζ on a subset of T cells. (Chapters 1, 4)

T-cell receptor α (TCRα) and **β (TCRβ)** The two chains of the $\alpha\beta$ T-cell receptor. (Chapter 4)

T-cell receptor excision circles (TRECs) Circular DNA fragments excised from the chromosome during V(D)J recombination in developing thymocytes that are transiently retained in T cells that have recently left the thymus. (Chapter 5)

T-cell zones *See* **T-cell areas**. (Chapter 1)

T-DM1 An antibody–drug conjugate combining trastuzumab (Herceptin) with mertansine used to treat recurrent metastatic breast cancer previously treated with a different trastuzumab drug conjugate. (Chapter 16)

TdT *See* **terminal deoxynucleotidyl transferase**. (Chapter 5)

TEPs *See* **thioester-containing proteins**. (Chapter 2)

terminal deoxynucleotidyl transferase (TdT) Enzyme that inserts non-templated N-nucleotides into the junctions between gene segments in T-cell receptor and immunoglobulin V-region genes during their assembly. (Chapter 5)

tertiary immune response Adaptive immune response provoked by a third injection of the same antigen. It is more rapid in onset and stronger than the primary response. (Chapter 11)

T follicular helper (T_{FH}) An effector T cell found in lymphoid follicles that provides help to B cells for antibody production and class switching. (Chapters 1, 9, 12)

TGF-β (transforming growth factor-β) Multifunctional cytokine that is produced in latent form, particularly in the intestinal mucosa. Its activated form is required for the development of T_{reg} and T_H17 cells, as well as IgA-producing B cells and plasma cells. (Chapter 9)

T_H1 A subset of effector CD4 T cells characterized by the cytokines they produce, notably IFN-γ and TNF-α. They are mainly involved in activating macrophages and promoting inflammation. (Chapters 1, 9, 11)

T_H2 A subset of effector CD4 T cells that are characterized by the cytokines they produce, notably IL-4, IL-5, and IL-13. They are involved in recruiting eosinophils and activating mast cells and basophils, and in promoting enhanced barrier protection. (Chapters 1, 9, 11)

T_H17 A subset of CD4 T cells that are characterized by production of the cytokine IL-17. They help recruit neutrophils to sites of infection. (Chapters 1, 9, 11)

therapeutic vaccination The use of a vaccine to treat an existing disease, typically in the context of treating a tumor, rather than to prevent the occurrence of a disease. (Chapter 16)

thioester-containing proteins (TEPs) Homologs of complement component 3 (C3) that are found in insects and are thought to have some function in insect innate immunity. (Chapter 2)

thymectomy Surgical removal of the thymus. (Chapter 8)

thymic anlage The tissue from which the thymic stroma develops during embryogenesis. (Chapter 8)

thymic cortex The outer region of each thymic lobule in which thymic progenitor cells (thymocytes) proliferate, rearrange their T-cell receptor genes, and undergo thymic selection, especially positive selection on thymic cortical epithelial cells. (Chapter 8)

thymic stroma The epithelial cells and connective tissue of the thymus that form the essential microenvironment for T-cell development. (Chapter 8)

thymic stromal lymphopoietin (TSLP) Thymic stroma–derived lymphopoietin. A cytokine thought to be involved in promoting B-cell development in the embryonic liver. It is also produced by mucosal epithelial cells in response to helminthic infections and promotes type 2 immune responses through its actions on macrophages, ILC2s, and T_H2 cells. (Chapter 3)

thymocytes Developing T cells when they are in the thymus. The majority are not functionally mature and are unable to mount protective T-cell responses. (Chapter 8)

thymoproteasome Specialized form of the proteasome composed of a unique subunit, β5t, that replaces β5i (LMP7) and associates with β1i and β2i in the catalytic chamber. (Chapter 6)

thymus A central lymphoid organ, in which T cells develop, situated in the upper part of the middle of the chest, just behind the breastbone. (Chapters 1, 12)

thymus-dependent (TD) antigens Antigens that elicit responses only in individuals that have T cells. (Chapter 10)

thymus-independent (TI) antigens Antigens that can elicit antibody production without the involvement of T cells. There are two types of TI antigens: the TI-1 antigens, which have intrinsic B-cell activating activity, and the TI-2 antigens, which activate B cells by having multiple identical epitopes that cross-link the B-cell receptor. (Chapter 10)

thymus leukemia antigen (TL) Nonclassical MHC class Ib molecule expressed by intestinal epithelial cells and a ligand for CD8$\alpha\alpha$. (Chapter 12)

TI-1 antigens *See* **thymus-independent antigens**. (Chapter 10)

TI-2 antigens *See* **thymus-independent antigens**. (Chapter 10)

tickover The low-level generation of C3b continually occurring in the blood in the absence of infection. (Chapter 2)

time-lapse video imaging A technique used to capture the movements of cells or molecules over time. A digital camera is combined with two-photon or confocal fluorescent imaging to generate movies of the images. These movies can be sped up for viewing. (Appendix I)

tingible body macrophages Phagocytic cells engulfing apoptotic B cells, which are produced in large numbers in germinal centers at the height of an adaptive immune response. (Chapter 10)

TIR (for Toll–IL-1 receptor) domain Domain in the cytoplasmic tails of the TLRs and in the IL-1 receptor, which interacts with similar domains in intracellular signaling proteins. (Chapter 3)

tissue-resident memory T (T_{RM}) cells Memory lymphocytes that do not migrate after taking up residence in barrier tissues, where they are retained long-term. They appear to be specialized for rapid effector function after restimulation with antigen or cytokines at sites of pathogen entry. (Chapter 11)

TLR-1 Cell-surface Toll-like receptor that acts in a heterodimer with TLR-2 to recognize lipoteichoic acid and bacterial lipoproteins. (Chapter 3)

TLR-2 Cell-surface Toll-like receptor that acts in a heterodimer with either TLR-1 or TLR-6 to recognize lipoteichoic acid and bacterial lipoproteins. (Chapter 3)

TLR-3 Endosomal Toll-like receptor that recognizes double-strand viral RNA. (Chapters 3, 9)

TLR-4 Cell-surface Toll-like receptor that, in conjunction with the accessory proteins MD-2 and CD14, recognizes bacterial lipopolysaccharide. (Chapter 3)

TLR-5 Cell-surface Toll-like receptor that recognizes the flagellin protein of bacterial flagella. (Chapters 3, 12)

TLR-6 Cell-surface Toll-like receptor that acts in a heterodimer with TLR-2 to recognize lipoteichoic acid and bacterial lipoproteins. (Chapter 3)

TLR-7 Endosomal Toll-like receptor that recognizes single-stranded viral RNA. (Chapter 3)

TLR-8 Endosomal Toll-like receptor that recognizes single-stranded viral RNA. (Chapter 3)

TLR-9 Endosomal Toll-like receptor that recognizes DNA containing unmethylated CpG. (Chapter 3)

TLR-11, TLR-12 Mouse Toll-like receptor that recognizes profilin and profilin-like proteins. (Chapter 3)

TLR-13 A member of the Toll-like receptor (TLR) family expressed in mouse and other rodents, but not in human, that has a specificity for certain bacterial ribosomal RNAs. (Chapter 3)

T lymphocytes (T cells) *See* **T cell**. (Chapter 1)

TNF family Cytokine family, the prototype of which is tumor necrosis factor-α (TNF-α, or TNF). It contains both secreted (e.g., TNF-α and lymphotoxin) and membrane-bound (e.g., CD40 ligand) members. (Chapter 3)

TNF receptor–associated periodic syndrome (TRAPS) An autoinflammatory disease characterized by recurrent, periodic episodes of inflammation and fever caused by mutations in the gene that encodes TNF receptor I. The defective TNFR-I proteins fold abnormally and accumulate in cells in such a way that they spontaneously activate production of TNF-α. *See also* **familial Mediterranean fever**. (Chapter 13)

TNF receptors Family of cytokine receptors that includes some that lead to apoptosis of the cell on which they are expressed (e.g., Fas and TNFR-I), whereas others lead to activation. (Chapter 3)

tocilizumab Humanized anti-IL-6 receptor antibody used in treating rheumatoid arthritis. (Chapter 16)

tofacitinib An inhibitor of Jak3 and Jak1 used to treat rheumatoid arthritis and under investigation in other inflammatory disorders. (Chapter 16)

tolerance The failure to respond to an antigen. Tolerance to self antigens is an essential feature of the immune system; when tolerance is lost, the immune system can destroy self tissues, as happens in autoimmune disease. (Chapters 1, 8)

tolerant Describes the state of immunological tolerance, in which the individual does not respond to a particular antigen. (Chapter 1)

tolerogenic Describes an antigen or type of antigen exposure that induces tolerance. (Chapter 8)

Toll Receptor protein in *Drosophila* that activates the transcription factor NFκB, leading to the production of antimicrobial peptides. (Chapter 3)

Toll-like receptors (TLRs) Innate receptors on macrophages, dendritic cells, and some other cells that recognize pathogens and their products, such as bacterial lipopolysaccharide. Recognition stimulates the receptor-bearing cells to produce cytokines that help initiate immune responses. (Chapters 1, 3)

tonsils *See* **lingual tonsils, palatine tonsils**. (Chapter 1)

toxic shock syndrome A systemic toxic reaction caused by the massive production of cytokines by CD4 T cells activated by the bacterial superantigen toxic shock syndrome toxin-1 (TSST-1), which is secreted by *Staphylococcus aureus*. (Chapter 6)

toxic shock syndrome toxin-1 (TSST-1) *See* **toxic shock syndrome**. (Chapter 6)

toxoids Inactivated toxins that are no longer toxic but retain their immunogenicity so that they can be used for immunization. (Chapters 10, 16)

TRAF3 An E3 ligase that produces a K63 polyubiquitin signaling scaffold in TLR-3 signaling to induce type I interferon gene expression. (Chapters 3, 10)

TRAF6 (tumor necrosis factor receptor–associated factor 6) An E3 ligase that produces a K63 polyubiquitin signaling scaffold in TLR-4 signaling to activate the NFκB pathway. (Chapter 3)

TRAIL (tumor necrosis factor–related apoptosis-inducing ligand) A member of the TNF cytokine family expressed on the cell surface of some cells, such as NK cells, that induces cell death in target cells by ligation of the 'death' receptors DR4 and DR5. (Chapter 3)

TRAM An adaptor protein that pairs with TRIF in signaling by TLR-4. (Chapter 3)

transcytosis The active transport of molecules, such as secreted IgA, through epithelial cells from one face to the other. (Chapter 12)

transdifferentiation The transition of one non-stem cell into another cell type. For T cells, this term is often used in the context of the transition of committed T-cell phenotype into another phenotype, such as the transition of T_H17 cells into T_H1 cells or T_{reg} cells into T_H17 cells. (Chapter 11)

transepithelial dendrites (TEDs) Cellular processes of intestinal macrophages and dendritic cells that extend across the epithelial barrier to sample antigens in the intestinal lumen. (Chapter 12)

transgenic mice The process of generating transgenic mice. *See also* **transgenic mice**. (Appendix I)

transgenesis Mice that are experimentally engineered to carry an extra gene in all of their cells, including germ cells. (Appendix I)

Transib A superfamily of transposable elements identified computationally and proposed to date back more than 500 million years and to have given rise to transposons in diverse species. (Chapter 5)

transitional B cells B cells that are newly emerged from the bone marrow into the periphery and are not yet functionally mature. (Chapter 8)

transitional stages Defined stages in the development of immature B cells into mature B cells in the spleen, after which the B cell expresses B-cell co-receptor component CD21. (Chapter 8)

transporters associated with antigen processing-1 and -2 (*TAP1* and *TAP2*) *See* **TAP-1, TAP-2**. (Chapter 6)

transposase An enzyme capable of cutting DNA and allowing integration and excision of transposable genetic elements into or from the genome of a host. (Chapter 5)

trastuzumab Humanized antibody to HER-2/neu used in treatment of breast cancer. (Chapter 16)

TRECs *See* **T-cell receptor excision circles**. (Chapter 5)

Trex1 Three-prime repair exonuclease 1 (Trex1) is a DNA exonuclease with 3′-to-5′ activity, which, while playing a proofreading role for DNA polymerase, also has immune activity in degrading cytosolic DNA. The absence of Trex1 can lead to activation of cGAS, causing autoinflammatory disorders resembling lupus erythematosus. (Chapter 3)

TRIF An adaptor protein that alone is involved in signaling by TLR-3 and which when paired with TRAM functions in signaling by TLR-4. (Chapter 3)

TRIKA1 A complex of the E2 ubiquitin ligase UBC13 and cofactor Uve1A that interacts with TRAF6 in forming the K63 polyubiquitin signaling scaffold in TLR signaling downstream of MyD88. (Chapter 3)

TRIM21 (tripartite motif-containing 21) A cytosolic Fc receptor and E3 ligase that is activated by IgG and can ubiquitinate viral proteins after an antibody-coated virus enters the cytoplasm. (Chapter 10)

TRIM25 An E3 ubiquitin ligase involved in signaling by RIG-I and MDA-5 for the activation of MAVS. (Chapter 3)

tropism The characteristic of a pathogen that describes the cell types it will infect. (Chapters 6, 10, 13)

TSC Tuberous sclerosis complex. Protein complex that acts as a GTPase-activating protein (GAP) for Rheb in its non-phosphorylated state. TSC is inactivated when phosphorylated by AKT. (Chapter 16)

TSLP Thymic stromal lymphopoietin. A cytokine thought to be involved in promoting B-cell development in the embryonic liver. (Chapter 11)

tuft cells Chemosensory sentinel cells present in mucosal tissues, such as the intestinal and respiratory tracts, which detect products of helminths and protozoans to activate type 2 immune responses. The ligands recognized by tuft cells share features with tastants/odorants recognized by taste-bud cells and lead to the secretion of IL-25, eicosanoids, and acetylcholine. (Chapters 11, 12)

tumor necrosis factor-α (TNF-α, or TNF) *See* **TNF family**. (Chapter 3)

tumor-rejection antigens Antigens on the surface of tumor cells that can be recognized by T cells, leading to attack on the tumor cells. Tumor-rejection antigens are peptides of mutant or overexpressed cellular proteins bound to MHC class I molecules on the tumor-cell surface. (Chapter 16)

tumor-specific antigens These are newly immunogenic forms of normal proteins that may induce a T-cell response against a tumor. They are expressed by a tumor cell and may arise from mutations in normal genes that alter the expressed amino acid sequence to produce a peptide epitope that can bind to MHC class I molecules and be recognized by T cells. Such peptides may have already been able to bind MHC molecules but become immunogenic by altering a residue recognized by T cells or may become immunogenic by acquiring *de novo* the ability to bind MHC molecules. (Chapter 16)

TUNEL (TdT-dependent dUTP–biotin nick-end labeling) staining A technique to identify cells undergoing apoptosis on the basis of the DNA fragmentation that occurs in apoptotic cells. The technique labels the 3′ ends of fragmented DNA with biotin. The biotin is detected with enzyme-coupled streptavidin followed by the addition of a substrate that forms a colored precipitate when acted on by the enzyme. (Appendix I)

two-dimensional gel electrophoresis A solution of proteins is subjected to isoelectric focusing in a narrow tube of polyacrylamide, separating the proteins on the basis of the isoelectric point. This tube is then placed across the top of an SDS-PAGE apparatus and electrophoresed in this second dimension, thereby separating the proteins on the basis of molecular mass. When completed, the proteins are distributed in two dimensions in the rectangular SDS-PAGE gel on the basis of a combination of the protein's isoelectric point and its molecular mass. *See also* **isoelectric focusing**; **SDS-PAGE**. (Appendix I)

two-photon scanning fluorescence microscopy A fluorescence imaging technique that allows visualization of signals at greater depths in tissues than does standard fluorescent microscopy. Images are captured in thin optical sections from which a three-dimensional image can be built. (Appendix I)

type 1 diabetes mellitus Disease in which the β cells of the pancreatic islets of Langerhans are destroyed so that no insulin is produced. The disease is believed to result from an autoimmune attack on the β cells. It is also known as insulin-dependent diabetes mellitus (IDDM), because the symptoms can be ameliorated by injections of insulin. (Chapter 15)

type 1 immunity Class of effector activities aimed at elimination of intracellular pathogens. (Chapters 1, 11)

type 2 immunity Class of effector activities aimed at elimination of parasites and promoting barrier and mucosal immunity. (Chapters 1, 11)

type 3 immunity Class of effector activities aimed at elimination of extracellular pathogens such as bacteria and fungi. (Chapters 1, 11)

type 1 LAD (LAD-1) *See* **leukocyte adhesion deficiency type 1**. (Chapter 13)

type 2 LAD (LAD-2) *See* **leukocyte adhesion deficiency type 2**. (Chapter 13)

type 3 LAD (LAD-3) *See* **leukocyte adhesion deficiency type 3**. (Chapter 13)

type 1 NKT cells A subset of NKT cells restricted by CD1d and having a restricted TCRα chain repertoire. (Chapter 6)

type 2 NKT cells A subset of NKT cells restricted by CD1d and having a more diverse TCRα chain repertoire. (Chapter 6)

type 1 regulatory (T_R1) cells A poorly characterized population of CD4 T cells that produce immunosuppressive cytokines, such as IL-10, but lack expression of FoxP3. They are thought to regulate inflammatory responses. At steady state, they are most abundant in the small intestine. (Chapter 9)

type I interferons The antiviral interferons IFN-α and IFN-β. (Chapter 3)

type II interferon The antiviral interferon IFN-γ. (Chapter 3)

type III secretion system (T3SS) Specialized appendage of Gram-negative bacteria used to aid infection of eukaryotic cells by direct secretion of effector proteins into their cytoplasm. (Chapter 3)

tyrosinase Enzyme in melanin synthesis pathway and frequently a tumor-rejection antigen in melanoma. (Chapter 16)

tyrosine phosphatases Enzymes that remove phosphate groups from phosphorylated tyrosine residues on proteins. *See also* **CD45**. (Chapters 3, 7)

UBC13 *See* **TRIKA1**. (Chapter 3)

ubiquitin A small protein that can be attached to other proteins and functions as a protein interaction module or to target them for degradation by the proteasome. (Chapter 7)

ubiquitination The process of attachment of one or many subunits of ubiquitin to a target protein, which can mediate either degradation by the proteasome or formation of scaffolds used for signaling, depending on the nature of the linkages. (Chapter 6)

ubiquitin ligase Enzyme that attaches ubiquitin covalently to exposed lysine residues on the surfaces of other proteins. (Chapters 3, 7)

ubiquitin–proteasome system (UPS) A quality-control system in the cell that involves K48-linked ubiquitination of target proteins that are then recognized by the proteasome for degradation. (Chapter 6)

UDP-glucose:glycoprotein glucosyltransferase 1 (UGT1) An enzyme in the Golgi apparatus that can re-glycosylate proteins detected by TAPBPR as being improperly folded to cause their redirection to the endoplasmic reticulum for additional editing. (Chapter 6)

UL16-binding proteins (ULBPs) A family of 10 MHC class Ib proteins that are ligands for NKG2D. Also called **RAET1** proteins. (Chapters 3, 6)

ULBP4 *See* **RAET1**. (Chapter 6)

ulcerative colitis (UC) One of the two major types of inflammatory bowel disease thought to result from an abnormal overresponsiveness to the commensal gut microbiota. *See also* **Crohn's disease**. (Chapters 12, 15)

UNC93B1 A multipass transmembrane protein that is necessary for the normal transport of TLR-3, TLR-7, TLR-8, TLR-9, TLR-11, TLR-12, and TLR-13 from the endoplasmic reticulum, where they are assembled, to the endosome, where they function. (Chapter 3)

unmethylated CpG dinucleotides While mammalian genomes have heavily methylated the cytosine within CpG sequences, unmethylated CpG is more typically characteristic of bacterial genomes and is recognized by TLR-9 when encountered in the endosomal compartment. (Chapter 3)

uracil-DNA glycosylase (UNG) Enzyme that removes uracil bases from DNA in a DNA repair pathway that can lead to somatic hypermutation, class switch recombination, or gene conversion. (Chapter 10)

urticaria The technical term for hives, which are red, itchy skin wheals usually brought on by an allergic reaction. (Chapter 14)

Uve1A *See* **TRIKA1**. (Chapter 3)

Vα Variable region from the TCRα chain. (Chapter 5)

V_β Variable region from the TCRβ chain. (Chapter 5)

vaccination The deliberate induction of adaptive immunity to a pathogen by injecting a dead or attenuated (nonpathogenic) live form of the pathogen or its antigens (a vaccine). (Chapters 1, 16)

vacuolar pathway Relating to the intracellular transport of extracellular materials taken up into endosomes and processed within these and other related membrane compartments such as lysosomes, but excluding entry into the cytosol. (Chapter 6)

variability plot A measure of the difference between the amino acid sequences of different variants of a given protein. The most variable proteins known are antibodies and T-cell receptors. (Chapter 4)

variable gene segments, V gene segments Gene segments in immunoglobulin and T-cell receptor loci that encode the first 95 amino acids or so of the protein chain. There are multiple different V gene segments in the germline genome. To produce a complete exon encoding a V domain, one V gene segment must be rearranged to join up with a J or a rearranged DJ gene segment. (Chapter 5)

variable Ig domains (V domains) The amino-terminal protein domain of the polypeptide chains of immunoglobulins and T-cell receptor, which is the most variable part of the chain. (Chapter 4)

variable lymphocyte receptors (VLRs) Non-immunoglobulin LRR-containing variable receptors and secreted proteins expressed by the lymphocyte-like cells of the lamprey. They are generated by a process of somatic gene rearrangement. (Chapter 5)

variable region (V region) The region of an immunoglobulin or T-cell receptor that is formed of the amino-terminal domains of its component polypeptide chains. These are the most variable parts of the molecule and contain the antigen-binding sites. Cf. **constant region**. (Chapters 1, 4, 5)

variolation The intentional inhalation of or skin infection with material taken from smallpox pustules of an infected person for the purpose of deriving protective immunity. (Chapters 1, 16)

VCAM-1 Vascular cell adhesion molecule-1. An adhesion molecule expressed by vascular endothelium at sites of inflammation; it binds the integrin VLA-4, which allows effector T cells to enter sites of infection. (Chapters 9, 11)

V(D)J recombinase A multiprotein complex containing RAG-1 and RAG-2, as well as other proteins involved in cellular DNA repair. (Chapter 5)

V(D)J recombination The process exclusive to developing lymphocytes in vertebrates that recombines different gene segments into sequences encoding complete protein chains of immunoglobulins and T-cell receptors. (Chapter 5)

vesicular compartments One of several major compartments within cells, composed of the endoplasmic reticulum, Golgi apparatus, endosomes, and lysosomes. (Chapter 6)

viral entry inhibitors Drugs that inhibit the entry of HIV into its host cells. (Chapter 13)

viral integrase inhibitors Drugs that inhibit the action of the HIV integrase, so that the virus cannot integrate into the host-cell genome. (Chapter 13)

viral protease Enzyme encoded by the human immunodeficiency virus that cleaves the long polyprotein products of the viral genes into individual proteins. (Chapter 13)

viral set point In human immunodeficiency virus infection, the level of HIV virions persisting in the blood after the acute phase of infection has passed. (Chapter 13)

virus Pathogen composed of a nucleic acid genome enclosed in a protein coat. Viruses can replicate only in a living cell, because they do not possess the metabolic machinery for independent life. (Chapter 1)

virus-neutralizing antibodies Antibodies that block the ability of a virus to establish infection of cells. (Chapter 10)

vitronectin *See* **S-protein**. (Chapter 2)

VLA-4 Very late antigen-4. *See* **integrin $\alpha_4\beta_1$**. (Chapter 11)

VLRs *See* **variable lymphocyte receptors**. (Chapter 5)

VpreB *See* **surrogate light chain**. (Chapter 8)

V-region gene The exon encoding the complete variable region sequence of a fully rearranged antigen receptor gene. (Chapter 5)

V-type ATPase A class of enzymes that use ATP typically to transport H^+ ions across the membrane of organelles to acidify various vacuolar compartments. (Chapter 6)

WAS *See* **Wiskott–Aldrich syndrome**. (Chapters 10, 13)

WASp (Wiskott–Aldrich syndrome protein) The protein defective in patients with Wiskott–Aldrich syndrome. When activated, WASp promotes actin polymerization. (Chapter 7)

Weibel–Palade bodies Granules within endothelial cells that contain P-selectin. (Chapter 3)

western blotting *See* **immunoblotting**. (Appendix I)

wheal-and-flare reaction A skin reaction observed in an allergic individual when an allergen to which the individual has been sensitized is injected into the dermis. It consists of a raised area of skin containing edema fluid and a spreading, red, itchy inflammatory reaction around it. (Chapter 14)

white pulp The discrete areas of lymphoid tissue in the spleen. (Chapters 1, 9)

Wiskott–Aldrich syndrome (WAS) An immunodeficiency disease characterized by defects in the cytoskeleton of cells due to a mutation in the protein WASp, which is involved in interactions with the actin cytoskeleton. Individuals with this disease are highly susceptible to infections with pyogenic bacteria because of defects in T-follicular helper cell interactions with B cells. (Chapters 10, 13)

XBP1 (X-box binding protein 1) A transcription factor that induces genes required for optimal protein secretion by plasma cells and is part of the

unfolded protein response. XBP1 mRNA is spliced from an inactive to an active form by signals produced by ER stress. (Chapter 10)

XCL1 Chemokine produced by CD8 T cells and NK cells that binds XCR1. (Chapter 9)

XCR1 Chemokine receptor expressed by type 1 conventional dendritic cells (cDC1 cells) that binds XCL1 (lymphotactin). (Chapter 9)

xenografts Grafted organs taken from a different species than the recipient. (Chapter 15)

xenoimmunity In the context of immune-mediated disease, refers to immunity directed against foreign antigens of nonhuman species, such as bacteria-derived antigens of the commensal microbiota that are targets in inflammatory bowel disease (IBD). (Chapter 15)

xeroderma pigmentosum Several autosomal recessive diseases caused by defects in repair of ultraviolet light–induced DNA damage. Defects in Polη cause type V xeroderma pigmentosum. (Chapter 10)

xid *See* **X-linked immunodeficiency**. (Chapter 8)

X-linked agammaglobulinemia (XLA) A genetic disorder in which B-cell development is arrested at the pre-B-cell stage and no mature B cells or antibodies are formed. The disease is due to a defect in the gene encoding the protein tyrosine kinase Btk, which is encoded on the X chromosome. (Chapters 7, 8, 13)

X-linked hyper IgM syndrome *See* **CD40 ligand deficiency**. (Chapter 11)

X-linked hypohidrotic ectodermal dysplasia and immunodeficiency A syndrome with some features resembling hyper IgM syndrome. It is caused by mutations in the protein NEMO, a component of the NFκB signaling pathway. Also called NEMO deficiency. (Chapters 3, 7)

X-linked immunodeficiency (xid) An immunodeficiency disease in mice due to defects in the protein tyrosine kinase Btk. Shares the gene defect with X-linked agammaglobulinemia in humans, but leads to a milder B cell defect than that seen in the human disease. (Chapter 8)

X-linked lymphoproliferative (XLP) syndrome Rare immunodeficiency diseases that result from mutations in the gene *SH2D1A* (XLP1) or *XIAP* (XLP2). Boys with this deficiency typically develop overwhelming Epstein–Barr virus infection during childhood, and sometimes lymphomas. (Chapters 10, 13)

X-linked severe combined immune deficiency (X-linked SCID, or XSCID) An immune deficiency disease in which T-cell development fails at an early intrathymic stage, and no production of mature T cells or T cell–dependent antibody occurs. It is due to a defect in a gene that encodes the γ_c chain shared by the receptors for several different cytokines. (Chapters 3, 13)

XLP *See* **X-linked lymphoproliferative syndrome**. (Chapter 13)

XRCC4 A protein that functions in NHEJ DNA repair by interacting with DNA ligase IV and Ku70:Ku80 at double-strand breaks. (Chapter 5)

ζ chain A subunit of the T-cell receptor:CD3 complex that forms a disulfide-linked dimer. Each monomer of ζ has multiple ITAM signaling motifs in the cytoplasmic tail. (Chapter 7)

ZAP-70 (ζ chain–associated protein) A cytoplasmic tyrosine kinase found in T cells that binds to the phosphorylated ζ chain of the T-cell receptor and is a key enzyme in signaling T-cell activation. (Chapter 7)

ZFP318 A spliceosome protein expressed in mature and activated B cells, but not immature B cells, that favors splicing from the rearranged VDJ exon of immunoglobulin heavy chain to the C_δ exon, thereby promoting expression of surface IgD. (Chapter 5)

zoonotic Describes a disease of animals that can be transmitted to humans. (Chapters 2, 12)

zymogen An inactive form of an enzyme, usually a protease, that must be modified in some way, for example by selective cleavage of the protein chain, before it can become active. (Chapter 2)

  overview 663–664
  types 663
Allergic rhinitis *664*, 665, 681–682, *681–683*
Allergic seasonal rhinoconjunctivitis *664*, 665, 668, 681–682, *681–683*
Allergy(ies) 32
  occupational 667
Allison, James P. 773
Alloantibodies 737
Alloantigens 732–742
Allogeneic graft 732, *733*
Allogenicity 243
Allograft 732
  chronic vasculopathy 738, *738*
  fetus as *741*, 741–742
Alloimmune response 699
Alloreaction 243–245, *244*
Alloreactive response 733
Alloreactive T cells 243–245, *244*
  transplant rejection 735–737, *736*
Alloreactivity 243–245, *244*
Allorecognition
  direct 735–737, *736*
  indirect 736, *736*
All-*trans*-retinoic acid (at-RA) 385, *385*
αβ heterodimer 159, *159*
αβ T-cell(s) 217
  development 322–327, *324*, 329–332, *330*, *332*
αβ T-cell receptor(s) 159
  cartilaginous fishes 210
  development *319*
  structure *160*, 160–161
αβ T-cell receptor ligands 218–235
Alphacoronavirus 571–572
$\alpha_4\beta_1$ 376, *377*, 427, 789, *793*
$\alpha_4\beta_7$ 356, *465*, 789
α chain *12*, 13
  rearrangements 331–332, *332*
$\alpha_E\beta_7$ 490
$\alpha_L\beta_2$ 464
ALPS (autoimmune lymphoproliferative syndrome) 397, 483, 724–725
Altered peptide ligands (APLs) 792
Alternative pathway for complement activation 50, 51, *52*, 59–60, *59–61*
Alum (aluminum hydroxide) 758, *759*, *A4*
  plus *Bordetella pertussis* A4, *A4*
Alveolar capillaries 566
Alveolar cells *565*, 566
Alveolar epithelial cells 566
Alveolar macrophages *565*, 566, 567, 568
Alveolus(i) *565*, 565–566
Ambrosia 666
AMD (age-related macular degeneration) 72
Amevive (alefacept) 791
7-Amino-actinomycin D (7-ADD) A32–A33
Amino-bisphosphonates *254*
Amoeboid coelomocytes 62
Amorphic loss-of-function 589
AMP(s) *see* Antimicrobial peptides (AMPs)
Amphipathic structure 47
Anakinra (Kineret) 789
Anaphylactic shock 680
Anaphylaxis
  bloodstream allergens 679–680
  defined *664*, 665
  food allergy 683
  treatment 685, 784
Anatomic barriers 5, *5*, 26, *26*, 38–45
Anchor residues 166, *166*, *167*
Anemia, autoimmune hemolytic 707, *712*, 713, *713*, 731
Anergy 16
  peripheral *700*
Angioedema, hereditary 69–71, 608
Angiotensin-converting enzyme 2 (ACE2), SARS-CoV-2 *572*, 573–574
Animal venom 435–436
Ankylosing spondylitis *727*, 788
Annexin A32–A33, *A33*
Anopheles gambiae 202–203
Anthrax *435*
Anthrax toxic complex *435*
Antibody(ies)
  alternative structures 157–158, *158*
  antigen recognition 13–14, *14*, 141–158
  bound 27, *28*
  bound to conformational shapes on surface of antigens *155*, 155–156, *156*
  broadly neutralizing 645–646
  against cell-surface molecules 783–784
  chimeric 784, *785*
  classes (isotypes) 27, 405, 480–482, *481*
  defects in production 596–598, *597*, *598*
  defined 141
  depleting *vs.* nondepleting 784
  discovery 2
  engineered to reduce immunogenicity 784–785, *785*, *786*
  functions 141, 405
  interaction with specific antigen 152–158, *152–158*
  monoclonal *see* Monoclonal antibody(ies) (MAbs)
  natural 58
  neutralizing 434–436, *435–437*
  nonspecific A2
  protection against extracellular pathogens 27, *28*
  single-chain 158
  structural variation in constant regions 148–152, *149*, *150*
  structure *12*, 13, 27, 142–148, *143*, *145–147*
  tissue damage in autoimmune disease 711–713, *712*
  virus-neutralizing 436, *436*
  in vivo administration *A38*, A38–A39
Antibody-coated magnetic beads, lymphocyte isolation *A23*, A23–A24
Antibody-coated pathogens, destruction via Fc receptors 440–446, *441–445*
Antibody-combining site 153
Antibody deficiencies *590*
  isotype-specific 601
Antibody-dependent cell-mediated cytotoxicity (ADCC)
  course of infection 457
  Fc receptors 438, 443–444, *444*
  helminth infections 474
  HIV 645–646
  ITAMs 274, *274*
  NK cell activation 128
  stages of infection 457
  in vivo antibody administration A39
Antibody-directed enzyme/pro-drug therapy (ADEPT) 176
Antibody repertoire 180
  diversity 190
Antibody response 23–24, *24*, A4–A5
  defects 600–601
  primary 23–24, *24*, *494*, 494–495
  secondary 23–24, *24*, *494*, 494–495
  tertiary *495*
Anticholinergic drugs 685
Anti-citrullinated protein antibodies (ACPAs) 720
Antigen(s)
  antibody binding to conformational shapes on surface *155*, 155–156, *156*
  B-cell activation 406–408, *407*
  defined 2, 141

discovery 2
dose A3, *A3*
'environmental' 663
vs. immunogens A2
initiation of adaptive immune responses 17–18, *18*
interaction of antibody with specific 152–158, *152–158*
interaction with antigen receptors 12–13, *13*
lymphocyte activation 15, *15*
self *15*, 16, *220*
thymus-dependent 406, *407*
thymus-independent 406, *407*, *427*, 427–429, *428*
tumor-rejection 765, *765*, *769*, 769–771
Antigen:antibody complexes
complement activation 436–438, *437*, *438*
removal from circulation *438*, 438–439
Antigen-antibody interactions, steric constraints 156–157, *157*
Antigen-binding region 141–142
Antigen-binding site *12*, 13, *143*, 153, *153*
Antigen capture 220
Antigen-capture assay A6
Antigenic determinant 14, *14*, 155
Antigenic drift 568, *569*, 627
Antigenic shift 568, *569*, 627
Antigenic variation *618*, 620, *620*, 625–628
Antigen presentation 217–260
activation and inhibition of NK cells and unconventional T-cell subsets 249–251
autophagy 220, *220*
blocking *628*
cessation of MHC class II antigen processing *233*, 233–234
cross-presentation by dendritic cells 226–227
defined 218
direct 218–219, *219*
direction of newly synthesized MHC class II molecules by invariant chain *229*, 229–230, *230*
extension of range of antigen response by MHC polymorphism 246
generation of peptide:MHC class II complexes 227–229, *228*
generation of αβ T-cell receptor ligands 218–235
of lipid-based antigens to NKT cells *251*, 251–253, *252*
major histocompatibility complex and its functions 235–247
of microbial riboflavin metabolites to MAIT cells 253
peptide binding and contacts between T-cell receptor and MHC molecule influenced by MHC polymorphism *240*, 240–243, *241*, *243*
peptide generation from ubiquitinated proteins 220–222, *221*, *222*
peptide transport into endoplasmic reticulum by TAP and further processing 222–224, *223*
polymorphic protein products of MHC class I and class II genes *238*, 238–240, *239*
proteins encoded by MHC genes 235–237, *236*, *237*
purposes 218–220, *219*, *220*
recognition of diverse ligands by γδ T cells *254*, 254–255
recognition of nonpeptide ligands by unconventional T-cell subsets 247–255
recognition of nonself MHC molecules by alloreactive T cells 243–245, *244*
regulation of exchange of CLIP for other peptides by HLA-DM and HLA-DO 230–232, *231*
retention of newly synthesized MHC class I molecules in endoplasmic reticulum 224–226, *225*, *226*
T cell response to superantigens 245, *245*
variety of genes with specialized functions encoded in MHC 247–249, *248*
Antigen-presenting cells (APCs)
delivery in intestines of antigen to 540–543, *541*
effector T cells *389*
initiation of adaptive immune responses 17–18, *18*
integrin adhesion 283, *283*
intraepithelial lymphocytes 533
properties *359*, 359–360
regulatory T cells 387
T-cell activation *368*, 369, *369*
Antigen processing 218–219, *219*
blocking *628*
cessation of MHC class II *233*, 233–234
MHC class II molecules *228*, 228–229
proteins encoded by genes in MHC 235–237, *236*, *237*
Antigen receptor(s) 7
chimeric 295–296, *296*
defects in gene rearrangement 593–594
gene assembly 14–15
generation 179–215
interaction with antigens 12–13, *13*
rates of association and dissociation from ligands A28–A30, *A30*
signaling *see* Lymphocyte receptor signaling
specificity A28, *A29*
structure 12, *12*
Antigen recognition 13–14, *14*
B cells 141–158
cytokine release independent of *478*, 478–479
dual specificity 169
γδ T-cell(s) *254*, 254–255
linked T cell and B cell 408–409, *409*
MHC polymorphism *240*, 240–243, *241*, *243*
nonpeptide ligands by unconventional T-cell subsets 247–255
signal transduction 270–272, *271*
T cells 142, 159–174
Antigen response, peripheral lymphoid organs 18–20, *19–21*
Antigen segregation *700*
Antigen-specific effector cells 15, *15*
Antigen specificity 15, *15*
Antigen-specific receptors 14–15
Antigen-specific response, manipulation 791–792
Antihistamines 685
Anti-host antibody *41*
Anti-HPV vaccine (Gardisil) 762–763, *776–777*, *777*
Antileukotriene drugs 685
Anti-lymphocyte globulin 784
Antimicrobial enzymes 37, 45, *45*
Antimicrobial molecules, epithelial cells and phagocytes 45–49, *46–48*
Antimicrobial peptides (AMPs)
defined 37
early response to infection 461
epithelial surfaces 44, *47*, 47–49, *48*
intestinal epithelium *515*, 523, 527, *527*, *528*
produced or released by phagocytes 85, *85*
resistance *618*
respiratory tract *565*, 566
Antimicrobial proteins 5, *5*
Antiserum(a) 2, A1–A2
Anti-TNF therapy
autoimmune diseases 781, 788–789, *789*
secondary immunodeficiency 616
Antivenins 436, 688
Aorta-gonad-mesonephros (AGM) 81
AP1 *see* Activator protein 1 (AP-1)
Apaf-1 (apoptotic protease activating factor-1) *396*, 397
APARs (agnathan paired receptors resembling Ag receptors) 207
APCs *see* Antigen-presenting cells (APCs)
APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy) 338–339, *590*, 596, *602*, 603, 701, 724
APLs (altered peptide ligands) 792
Apo-2L A72
Apo-3L A72
Apolipoprotein B mRNA editing catalytic polypeptide (APOBEC) 650
Apolipoprotein B mRNA editing catalytic polypeptide 1 (APOBEC1) 421
Apoptosis 16
cytotoxic granules that trigger *398*, 398–399, *399*
extrinsic pathway 394–398, *395–397*
intrinsic (mitochondrial) pathway 394–398, *395–397*
measurements *A32*, A32–A33, *A33*
T-cell precursors 321, *321*
Apoptosome *396*, 397, 398–399, *399*
Apoptotic protease activating factor-1 (Apaf-1) *396*, 397
Appendix *17*, 20, 511, *512*
APRIL 411, *411*, 550, A72
defects 601
APS-1 (autoimmune polyglandular syndrome type 1) 338–339, *590*, 596, *602*, 603, 701
Apurinic/apyrimidinic endonuclease-1 (APE1) 208, 421, *422*, *424*
Arachidonic acid 675

Archaea *5*, 518
Arginase-1 474
Artemis *187*, 188, 189
Arthritis
  Lyme 731
  rheumatoid *701*, *712*, 719–721, *720*, *727*, 788, *789*
Arthus reaction *687*, 687–688
Aryl hydrocarbon receptor (AHR) 534
ASC 105
Ascending colon *512*
Asparagine endopeptidase (AEP) 228
Asplenia, congenital 615
Asthma
  allergic *664*, 665, 681–682, *681–683*
  and atopic eczema 668, 670
  chronic inflammation 682
  'endotypes' 682
  peak expiratory flow rate 677
  responsiveness to therapies 681–682
  susceptibility loci 668, *668*
Asymmetric division model of memory-cell development 487, *487*
Asymptomatic phase of HIV 643, *643*
Ataxia telangiectasia 190, 425
Ataxia telangiectasia mutation (ATM) 190, 425
Atezolizumab 773
ATG16L1 *726*, 729
Atopic dermatitis 577
Atopic eczema 668, 670
Atopic individuals 663, 665
Atopic march 665
Atopy 663
ATPase (adenosine triphosphatase), V-type 228, *228*
ATP (adenosine triphosphate)-binding cassette (ABC) 223, *223*
at-RA (all-*trans*-retinoic acid) 385, *385*
Attenuated organisms, vaccines based on 750–751, *751*, 753–754, *754*
Atypical hemolytic uremic syndrome (aHUS) 71, 608
Autoantibodies 701
  against blood cells 713, *713*
  against extracellular antigens 715–717, *716–718*
  against receptors *714*, 714–715, *715*
Autoantibody-mediated inflammation 709–711, *710*
Autoantigens 701
Autocrine manner 110
Autograft 732
Autoimmune diseases 32, 706–721
  autoantibodies against blood cells 713, *713*
  autoantibodies against extracellular antigens 715–717, *716–718*
  autoantibodies against receptors *714*, 714–715, *715*
  biologics that block TNF-α, IL-1, or IL-6 for 788–789, *789*
  blockade of co-stimulatory pathways that activate lymphocytes 790–791
  chronic 709–711, *710–712*
  classification *706*, 706–707
  common *701*
  complement 713–714
  cross-reactivity between foreign molecules and self molecules *730*, 730–731, *731*
  defined 699
  depletion of autoreactive lymphocytes for 787–788
  drug-induced 731
  environmental toxins 731
  genetic and environmental basis 721–732, *723–725*
  genetic variants that impair innate immune responses 727–730, *729*
  inflammation 709–711
  JAK inhibitors 783, *783*, *784*
  MHC genes 726–727, *727*, *728*
  monogenic defects of immune tolerance *722–725*, *726*
  multiple components of immune system 707–709, *707–709*
  organ-specific *vs.* systemic *706*, 706–707
  pathogenic mechanisms 706–721
  pregnancy 708, *708*, *709*
  T cells specific for self antigens *717–720*, 717–721
  therapeutic agents 792, *793*
  tissue damage 711–713, *712*
Autoimmune encephalomyelitis, experimental 703, 708, *708*
Autoimmune hemolytic anemia 707, *712*, 713, *713*, 731
Autoimmune lymphoproliferative syndrome (ALPS) 397, 483, 724–725
Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED) 338–339, *590*, 596, *602*, 603, 701, 724
Autoimmune polyglandular syndrome type 1 (APS-1) 338–339, *590*, 596, *602*, 603, 701
Autoimmune regulator *(AIRE)* 338, *338*
  defects 596, 603, *726*
Autoimmune responses
  broadening 709–711
  control by regulatory T cells *704*, 704–705
Autoimmune thrombocytopenic purpura *708*, *712*, 713, *713*
Autoimmunity
  activated lymphocytes *702*, 702–703
  defined 699
  immunologically privileged sites 703–704, *704*
  mechanisms preventing 699–701, *700*, *701*
  Toll-like receptors 94
Autoinflammatory diseases 106, *590*, *612*, 612–613
Autophagosome *219*, *220*, 556
Autophagy 220, *220*
  intestinal epithelium 556
  peptide:MHC class II complex generation 227–229, *228*
Autoreactive lymphocytes, depletion 787–788
Autoreactivity, immature B cells 312–314, *312–314*
Avidity 54, 143, A5
Avoidance 5
Avonex *see* Interferon-β (IFN-β, Avonex)
Azathioprine 778, *778*, 780
Azidothymidine (AZT) 649

  antimicrobial molecules 45–49, *46–48*
  cell types, functions, and mechanisms of 26, *26*, 520–528, *521–528*
  commensal microbiota 505, 508–509, *510*, 516–519, *517*, *519*, 563–564
  conventional and unconventional T cells 528–534, *529–533*

cutaneous 574–579, *575*, *578*
effector T-cell responses 557
epithelial surfaces in 42–44, *42–44*
as first level of defense 5, *5*, 38–49
inflammatory adaptive immune responses 556–557
innate immune defenses 44–45, *45*, 520–535, 553–564
intestinal 516–564
location of immune cells 510–516, *511–515*
lymphocyte priming *546*, 546–547, *547*, 552–553
organization 505–519
pattern-recognition receptors 554–556, *555*
protection of internal surfaces of body 506–510, *506–510*
rapid 534–535
respiratory 564–574, *565*, *565–570*, *572*
role of adaptive immunity in regulating 536–553
routes and strategies of infection 38–42, *39–41*, 557–563, *558*, *560–562*
routes for uptake and delivery of antigen to antigen-presenting cells 540–543, *541*
secretory IgA 547–551, *549*, *550*
specialized immune structures 20–22, *22*
tissue-specific adhesion molecules and chemokine receptors *546*, 546–547, *547*
tolerance to harmless foreign antigens *536–538*, 536–540
unique and unusual features *508*, 508–510
Base-excision repair, somatic hypermutation 421–423, *422*
Basic leucine zipper ATF-like transcription factor 3 (BATF3) 227
Basiliximab 785, *786*, 787
Basophils
allergic reactions 676–677
antibody isotypes *481*
IgE antibody binding 444–445, *445*
immune response *7*
infection 458, 459
innate immune system 8, 81
lineage *4*
BATF3 (basic leucine zipper ATF-like transcription factor 3) 227
Bax *396*, 397, *397*, *399*
BCAP 96
BCAP (B-cell activator protein) 305
B cell(s) *see* B lymphocyte(s) (B cells)
B-cell activating factor (BAFF) A72
B-cell development 314–315, *315*
humoral immune response 410, *411*, *428*, 429
IgA production 550
B-cell activating factor receptor (BAFF-R) 314, 315, 410, *411*
defects 601
B-cell activation *303*
activation-induced cytidine deaminase 420–425, *421*, *422*, *423*, *424*
B-cell receptor 406–408, *407*
canonical and non-canonical NFκB pathways *407*, 407–408
class switching 423–426, *424–426*
cytokines 425–426, *426*
defects 598–600, *599*
helper T cells 406–408, *407*
linked recognition of antigen by T cells and B cells 408–409, *409*
memory cells 426–427
microbial antigens 406–408, *407*
migration into follicles and germinal center formation 414–417, *415*, *416*
migration toward boundaries between B-cell and T-cell areas in secondary lymphoid tissues 409–412, *410*, *411*
mismatch and base-excision repair 421–423, *422*
plasmablasts and plasma cells 405, *407*, 413–414, *414*, 426–427
positive selection of germinal center B cells *419*, 419–420
T-cell expression of surface molecules and cytokines *412*, 412–413
TI-1 and TI-2 antigens *427*, 427–429, *428*
TNF receptor superfamily 291–292, *292*
V-region somatic hypermutation of germinal center B cells 416, *417*, 417–419, *418*
B-cell activator protein (BCAP) 305
B-cell areas, B-cell activation 409–411, *410*, *411*
B-cell class switching 383–384
B-cell co-receptor *286*, 286–287
B-cell co-receptor complex 408–409, *409*
B-cell corona, spleen *20*
B-cell follicle *350*
B-cell linker protein (BLNK) *286*, 287, 305, 309, 597
B-cell maturation antigen (BCMA) 314, 410–411, *411*
B-cell mitogens 427–428
B-cell precursor *303*

defects 471–472
defined 348
determination of effector functions 391–392, *392*, *393*
differentiation into 375–376
enhanced clearance of extracellular bacteria and fungi *475*, 475–476
enrichment and further maturation at infection sites 467
expulsion of intestinal helminths and repair of tissue injury 472–474, *473*, *474*
general properties 389–394
granuloma formation 471, *471*
guided to specific tissues and infection sites *463*, 463–467, *465–467*
immunological synapse with targets *389*, 389–391, *390*
intestinal epithelium 557
macrophage activation 467–471, *468–471*
plasticity and cooperativity *479*, 479–480
protection against many types of pathogens 480–482, *481*
release *389*, 389–391, *390*
resolution of infection 482–483
tissue damage in autoimmune disease 711–713, *712*
TNF family cytokine expression 392–394
type 1 responses 467–472, *468–471*
type 2 responses 472–474, *473*, *474*
type 3 responses *475*, 475–476
Efferent lymphatic vessel *20*, *512*
Efferocytosis 539
EGF (epidermal growth factor) 531
Ehrlich, Paul 2, 673, 701, 765
Eicosanoids 461, 675
eIF3 (eukaryotic initiation factor 3) 125, *125*
EILPs (early innate lymphoid progenitors) *302*, 304
ELANE (neutrophil elastase) 609
Elastase deficiency *590*, *609*, 609–610
Electrostatic interactions 155, *156*
Elimination phase 765, *766*
ELISA (enzyme-linked immunosorbent assay) A5–A6, *A6*
capture (sandwich) A6, A35
ELISPOT assay A24–A25, *A25*, A35
Elite controllers 647
Elk-1 *280*
ELL2 195
Embryonic stem (ES) cells A40–A42, *A40–A42*
Encephalomyelitis, experimental autoimmune 703, 708, *708*, 788–789
Endocrine manner 110
Endocytic vesicles, peptide:MHC class II complex generation 227–229, *228*
Endocytosis
peptide:MHC class II complex generation 227–229, *228*
receptor-mediated 82
Endogenous pyrogens 122
Endoplasmic reticulum (ER) *219*, *220*
peptide transport by TAP 222–224, *223*
retention of newly synthesized MHC class I molecules 224–226, *225*, *226*
Endoplasmic reticulum aminopeptidase associated with antigen processing (ERAAP, ERAP1, ERAP2) 224
Endoplasmic reticulum–associated protein degradation (ERAD) 226, 630
Endosome *219*
Endosteum 305
Endothelial activation 89
Endothelial cells
cell-adhesion molecules 116–118, *117*
inflammatory response 10
Endothelial protein C receptor (EPCR) *248*, 254, *254*
Endothelium, inflammatory response 10
Endotoxins 41, *41*
Endotypes, asthma 682
Entamoeba histolytica 554
Enterocytes 506, 521–523, *522*, *523*, *526*
Enteroendocrine cells (EECs) *515*, *522*, 523, *523*, 527–528
Enteropathogenic bacteria, noninvasive *vs.* invasive 557–563, *558*, *560–562*
Enteropathogenic *E. coli* (EPEC) 554, 559, *560*, 620
env *640*
'Environmental' antigens 663
Environmental factors, allergic diseases 669–671, *670*
Environmental toxins, autoimmunity 731
Enzyme(s), antimicrobial 37, 45, *45*
Enzyme-linked immunosorbent assay (ELISA) A5–A6, *A6*
capture (sandwich) A6, A35
Eosinophil(s)
allergic reactions 675–676, *676*
antibody isotypes *481*
attack on parasitic worms 443, *443*
immune response *7*
infection 458, 459
innate immune system 8, 81
lineage *4*
Eosinophilia 676
Eotaxins 676
EPCR (endothelial protein C receptor) *248*, 254, *254*
EPEC (enteropathogenic *E. coli*) 554, 559, *560*, 620
Epidermal growth factor (EGF) 531
Epidermis *43*, 574–576, *575*
Epinephrine 685
Epithelial cells
antimicrobial molecules 45–49, *46–48*
intestinal 517, 520–528, *521–528*
Epithelial cells of the thymic cortex (cTECs) 221
Epithelial surfaces 42–44, *42–44*
Epithelium(a) 42
bronchial ciliated *43*
intestinal 520
keratinized stratified squamous *507*
mucosal *see* Mucosal epithelium
nonkeratinized stratified squamous *507*
pseudostratified columnar *507*
simple columnar *507*
Epitope(s) 14, *14*, 155
Epitope spreading 710–711, *711*, *712*
EPSs (extracellular polymeric substances) 619
Epstein-Barr virus (EBV)
hemophagocytic lymphohistiocytic syndrome 603–604
immune evasion *631*
ITAM-containing receptors 274
latency and reactivation 629, 632–633
MHC polymorphism 246
post-transplant lymphoproliferative disorder 766–767
X-linked lymphoproliferative syndrome *605*, 605–606
X-linked lymphoproliferative system *605*, 605–606
Epstein-Barr virus nuclear antigen 1 (EBNA-1) 229
Equilibrium phase 765, *766*
ER (endoplasmic reticulum) *219*, *220*
peptide transport by TAP 222–224, *223*
retention of newly synthesized MHC class I molecules 224–226, *225*, *226*
ERAAP (endoplasmic reticulum aminopeptidase associated with antigen processing) 224
ERAD (endoplasmic reticulum–associated protein degradation) 226, 630
ERAP1 224
ERAP2 224
Erk (extracellular signal-related kinase) *279*, 279–280, *280*
ERp57 224, *225*, *226*
Error-prone 'translesion' DNA polymerase 423
Erythroblast *4*
Erythroblastosis fetalis 497, A9
Erythrocytes, lineage *4*
Erythrogenic toxin *435*
Escape mutants 643
Escape phase 765, *766*
ES (embryonic stem) cells A40–A42, *A40–A42*
Escherichia coli 93, 202
enteropathogenic 554, 559, *560*
E-selectin *117*, 118, *119*
Esophagus *512*
Etanercept 788
ETPs (early thymic progenitors) *302*, 304, 323, *324*
eT_{reg} (effector regulatory T) cells 387, 544–546, *545*
Eukaryotic initiation factor 3 (eIF3) 125, *125*
'Executioners' 397
Exogenous pyrogens 122
Exotoxins 40–41, *41*
Expansion phase of immune response to infection 485–486, *486*
Experimental autoimmune encephalomyelitis (EAE) 703, 708, *708*, 788–789
Extracellular antigens, autoantibodies against 715–717, *716–718*
Extracellular bacteria 38–40
enhanced clearance *475*, 475–476
immune evasion 617–622, *618–621*
inability to clear 596–598, *597*, *598*
Extracellular immunity 26, *26*
Extracellular pathogens 25, *25*, 27, *28*, 38–40
Extracellular polymeric substances (EPSs) 619
Extracellular signal-related kinase (Erk) *279*, 279–280, *280*

Extrachromosomal DNA 185, *186*
Extravasation, inflammatory response 88, *88*, 118
Extrinsic pathway of apoptosis 395–397, *396*, 482
Eyes, mucosal epithelia *42*

F
$F(ab')_2$ fragment 146, *146*
Fab fragment 159, *159*
Fab segments 146, *146*
FACS (fluorescence-activated cell sorter) A21–A23, *A22*
Factor B 59, *60–62*, 62
Factor D 60, *60*, *61*, 62
  defects *608*
Factor H 61, *62*, 68–69, *69*, 71
  defects 71–72, *608*
Factor H binding protein (fHbp) 73, *73*
Factor I 61, *65*, 68–69, *69*, 71
  deficiency 71–72, 608, *608*
Factor P defects *608*
Factor-replacement therapies 613
Facultative intracellular pathogens 40
FADD (Fas-associated via death domain) *396*, 397
FAE (follicle-associated epithelium) 512–514, *513*, 524
  intestines 540–542, *541*
  respiratory tract 567
Familial cold autoinflammatory syndrome (FCAS) 106, *612*, 613
Familial cold urticaria 106, *612*, 613
Familial hemophagocytic lymphohistiocytosis (FHL) 604, *604*
Familial Hibernian fever *612*, 613
Familial Mediterranean fever (FMF) *612*, 612–613
Farmer's lung 688
Fas 392, 395–397, *396*
  autoimmune diseases *726*
Fas-associated via death domain (FADD) *396*, 397
Fas ligand (FasL) 392, 395–397, *396*, 531, A72
FCAS (familial cold autoinflammatory syndrome) 106, *612*, 613
Fc-binding proteins 620
Fc fragment 146, *146*
Fc receptors (FcRs)
  accessory cells 440–441, *441*
  class switching 480–481
  defined 27, 440
  destruction of antibody-coated pathogens via 440–446, *441–445*
  humoral immune response 405, *405*, *419*, 440–446, *441–445*
  IgE antibody binding 444–445, *445*
  IgG transport across placenta 433–434, *434*
  neonatal 433–434, *434*, 541, *541*
  NK cell activation 443–444, *444*
  phagocytes 441–443, *442*, *443*
  removal of immune complexes from circulation *438*, 438–439
Fc region 150–151
  polymeric immunoglobulin receptor 432–433, *433*
FcRN *248*
FcRn (neonatal Fc receptor) 433–434, *434*, 541, *541*
Fcα receptor 474
FcγRI 538
FcγRIIB 294, *295*
FcγRIII 274, *274*
FcεRI 664, 672, *672*
FcεRII 673
FDCs (follicular dendritic cells)
  adaptive immune response *350*, 350–351, *352*, 353, *356*
  B-cell activation 410, 411, *411*, 412, *418–420*, 419–420
  B-cell development 314, *315*
Fecal microbiota transplantation (FMT) 518–519, *519*
Fedratinib *784*
Fetus as allograft *741*, 741–742
Fever 122
fHbp (factor H binding protein) 73, *73*
FHL (familial hemophagocytic lymphohistiocytosis) 604, *604*
Fibrin clot 89–90
Fibrinogen *123*
Fibrinogen-related proteins (FREPs) 203
Fibroblast reticular cells (FRCs) 350, 351–352, 354, *354*, 356.*356*
Ficolins *52*, 55, *55*, 56, 63, 436
Ficoll-Hypaque solution A20, *A20*
Filaggrin 669
Filgotinib *784*
Fimbriae 620
Fingolimod (FTY720) *358*, 359, *778*, 779, 783
Firmicutes 517, *517*, 518
First-set rejection 733, *733*
FK506 278
FK506 (tacrolimus) 278, *778*, 779, *781*, 781–783, *782*
FK-binding proteins (FKBPs) 781
Flagellins 475, 523, 563
Flatworms 472
Flow cytometry A21–A23, *A22*
FLT3 *304*
FLT3 ligand (FLT3L) 538
Flukes 472
Fluorescein A14, *A14*
Fluorescence-activated cell sorter (FACS) A21–A23, *A22*
Fluorescence microscopy
  confocal A14–A15
  two-photon scanning A15
Fluorescent dyes, imaging using A13–A15, *A14*
Fluorescent proteins A27, *A27*
Fluorochromes A13–A14, *A14*
Fluorophores A13–A14, *A14*
fMet-Leu-Phe (fMLF) receptor 83, *84*
FMF (familial Mediterranean fever) *612*, 612–613
FMT (fecal microbiota transplantation) 518–519, *519*
Follicle(s)
  isolated lymphoid 511, *513*, 514, *514*, 517
  primary lymphoid 19, *20*, 410
  secondary lymphoid 414
Follicle-associated epithelium (FAE) 512–514, *513*, 524
  intestines 540–542, *541*
  respiratory tract 567
Follicular B cells *315*, 315–316, *317*, *318*
Follicular dendritic cells (FDCs)
  adaptive immune response *350*, 350–351, *352*, 353, *356*
  B-cell activation 410, 411, *411*, 412, *418–420*, 419–420
  B-cell development 314, *315*
Food allergy *664*, 665, 682–684, *683*
Food intolerances 682
Food poisoning *435*
Foreign molecules, cross-reactivity between self molecules and *730*, 730–731
6-Formylpterin (6-FP) 253
FOXN1 321
  defects *590*, 594
FOXO1 305
FoxP3
  adaptive immune response *382*, 385, 386–388
  autoimmune diseases 705, *726*
  barrier immune system 543
  IPEX 724
  T-cell development *340*
6-FP (6-formylpterin) 253
Fractalkine *115*
Fragment crystallizable region *see* Fc region
Framework regions 153
FRCs (fibroblast reticular cells) 350, 351–352, 354, *354*, 356.*356*
FREPs (fibrinogen-related proteins) 203
Freund's adjuvant with MDP *A4*
Freund's complete adjuvant 758–759, *A4*
Freund's incomplete adjuvant *A4*
FTY720 (fingolimod) *358*, 359, *778*, 779, 783
α-(1,3)-Fucosyltransferase VII (FucT-VII) 464
Fujimycin (tacrolimus) 278, *778*, 779, *781*, 781–783, *782*
Fungi 3, *5*
  enhanced clearance *475*, 475–476
Fyn 272, 605, *605*

G
G6PC3 (glucose-6-phosphatase catalytic subunit 3) deficiency *609*, 610
G6PD (glucose-6-phosphate dehydrogenase) deficiencies 612
gag *640*
Gain-of-function (GOF) 589
Galactose-α1,3-galactose (α-Gal) 409
α-Galactosylceramide (α-GalCer) 252
Galectin-10 681, *682*
GALT *see* Gut-associated lymphoid tissue (GALT)
γδ T-cell(s) 217
  antigen recognition *254*, 254–255
  development 326–329, *328*
γδ T-cell receptor(s) 173–174, *174*
  antigen recognition 159
  cartilaginous fishes 210
  generation by gene rearrangement *200*, 200–201, *201*
λ5 *309*
λ_c deficiency *590*

λ chain (λ_C), common 111
λ-glutamyl diaminopimelic acid (iE-DAP) 102, *103*, 619
GAPs (goblet cell–associated passages) *541*, 542
GAPs (GTPase-activating proteins) *264*, 265
Gardisil (anti-HPV vaccine) 762–763, *776–777*, *777*
Gasdermin D 103, *104*
Gas gangrene *435*
Gastrointestinal tract
  anatomy and physiology 511–516, *512–515*
  antigen administration via A3
  see also Intestinal immune system
GATA2 deficiency *590*, 606–607
GATA3 323, *324*, *382*, 383
G-CSF *see* Granulocyte colony-stimulating factor (G-CSF)
G domain *263*
GDP-fucose transporter deficiency *609*, 610
GEFs *see* Guanine nucleotide exchange factors (GEFs)
Gel electrophoresis
  polyacrylamide *A16*, A17
  two-dimensional A17, *A17*
Gel-forming mucins *525*
Gell, P. G. H. 663
GEM (germline-encoded mycolyl lipid-reactive) T cells 252
Gene conversion 207–208, *208*, *239*, 239–240
Gene expression
  knockdown A43–A44, *A44*
  primary immunoglobulin 180–196
Gene knockout, targeted disruption A40–A43, *A40–A43*
Gene rearrangement(s) 14–15, 179
  γδ T-cell receptors *200*, 200–201, *201*
  by inversion 185
  primary immunoglobulin 180–196
  T-cell receptor 196–201, *197–201*
  V, D, and J segments 184–185, *184–187*
  V(D)J 185–190, *187–189*
Gene segments 14–15, 179
  different combinations of multiple inherited 191
  multiple contiguous V *182*, 182–184, *183*
  reaction that recombines 186–190, *188*, *189*
  somatic recombination 179, *180*, 180–182, *181*
  T-cell receptor *vs.* immunoglobulin 196–199, *197–199*
  variable (V) *181*, 181–182
  variable addition and subtraction of nucleotides at junctions between 191–193, *192*
Gene targeting A40–A42, *A40–A42*
Gene therapy 614–615
Genetic loci 182–183, *183*
Genome-wide association studies (GWASs)
  allergic disease 667–668, *668*
  autoimmune diseases *722*, *724*
  HIV 647, *648*
  intestinal disease 563–564
Germ-free mice 516
Germinal center(s)
  lymph node 19, *20*
  memory B cell reentry 496
  spleen *20*, 350
  structure 414–415, *415*
Germinal center B cells
  formation 414–417, *415*, *416*
  positive selection *419*, 419–420, *420*
  somatic hypermutation 405, 416, *417*, 417–419, *418*
Germline-encoded mycolyl lipid-reactive (GEM) T cells 252
'Germline-joined' organization 209
Germline theory 180
GFI-1 deficiency *609*, 609–610
GFP (green fluorescent protein) A14
  cell-lineage tracing A44, *A45*
Giant cells, multinucleated 471, *471*
GILT (interferon-γ-induced lysosomal thiol reductase) 229
GITRL *375*
Glandular fever 632
GlcNAc (*N*-acetylglucosamine) 46, *46*
Glomerulopathy, C3 72
GlsII (glucosidase II) 225
Glucose-6-phosphatase catalytic subunit 3 (G6PC3) deficiency *609*, 610
Glucose-6-phosphate dehydrogenase (G6PD) deficiencies 612
Glucose monomycolate 251
Glucose triphosphatase (GTPase)-activating proteins (GAPs) *264*, 265
Glucose triphosphatase (GTPase) proteins
  as molecular switches *264*, 264–265
  Rho family small 84–85
Glucosidase II (GlsII) 225
Gluten 509
Gluten-sensitive enteropathy *689*, 692–694, *692–694*

Immunodeficiency (Imd) signaling pathway 108
Immunodominant epitopes 646
Immunoediting, cancer 765–769, *766–768*
Immunoelectron microscopy A15
Immunoevasins 629, *629*, *630*
Immunofluorescence, indirect A14
Immunofluorescence microscopy A13–A15, *A14*

Immunogen(s), dose A3, *A3*
Immunogenetics A2
  reverse 751
Immunogenicity 8–9
  antibodies engineered to reduce 784–785, *785, 786*
Immunogenic substance A2
Immunoglobulin(s) (Igs) 12, 141
  diversity in different species 207–209, *208, 209*
  expression of cell-surface 310–312, *311*
  intravenous 613, 783–784
  newborns 433–434, *434,* 596–597, *597*
  physical and functional properties 148, *149*
  transmembrane and secreted forms 194–196, *195*
Immunoglobulin A (IgA) 143, 148–150, *149, 150*
  deficiency 551, *590,* 601
  distribution and functions *431,* 432, *434*
  neutralization of toxins and blocking infectivity 434–436, *435–437*
  newborns 597
  polymers 151
  secretory 524, *528,* 547–551, *549, 550,* 567
  transport across epithelial barriers 432–433, *433*
Immunoglobulin (Ig) classes 143, 148–150, *149*
  distributions and functions 430–439, *431, 433–438*
  Fc receptor signaling 440–441, *441*
Immunoglobulin D (IgD) 143
  derivation and expressions 193–194, *194*
  distribution and functions 431, *431*
  hyper IgD syndrome *612*
Immunoglobulin (Ig) domains 144–146, *145*
Immunoglobulin E (IgE) 143, 148–150, 663
  antibody binding 444–445, *445*
  class switching 480
  distribution and functions *431,* 432, *434*
  helminth infections 473, *473*
  hyper IgE syndrome *590,* 599–600, *602*
  parasite infections 445–446
Immunoglobulin E (IgE)-mediated allergic diseases 664–686
  anaphylaxis and urticaria *664,* 665, 679–680
  clinical symptoms 678, *679*
  effector mechanisms 671–686
  environmental factors 669–671, *670*
  eosinophils and basophils 675–677, *676*
  Fc receptors 671–673, *672*
  food *664,* 665, 682–684, *683*
  genetic factors 667–669, *668*
  immediate hypersensitivity reactions 664–665, *665*
  immediate *vs.* late-phase response *677,* 677–678, *679*
  mast cells *665, 672–674,* 673–675, *679*
  overview 663–664, *664*
  rhinitis and asthma *664,* 665, 681–682, *681–683*
  sensitization 663, 664, 665–667, *665–667*
  treatment *684,* 684–686
Immunoglobulin (Ig) fold 145, 180, *180*
Immunoglobulin G (IgG) *143,* 143–144, 148, *149,* 150
  class switching 480
  distribution and functions *431,* 432, *434*
  neutralization of toxins and blocking infectivity 434–436, *435–437*
  newborns 596, *597*
  respiratory immune system 567
  transport across placenta 433–434, *434*
  type 1 response 468
Immunoglobulin (Ig) genes
  diversity of third hypervariable region 191–193, *192*
  lymphocyte-specific and ubiquitous DNA-modifying enzymes 185–190, *188, 189*
  multiple contiguous V segments at each locus *182,* 182–184, *183*
  multiple inherited segments in different combinations 191
  rearrangement of V, D, and J segments *184,* 184–185, *186, 187*
  rearrangements and expression 180–196, 305–308, *306, 307*
  somatic hypermutation 405, 416, *417,* 417–419, *418*
  somatic recombination of segments *180,* 180–182, *181*
Immunoglobulin (Ig)-like domains 145–146
Immunoglobulin (Ig)-like genes
  cartilaginous fishes 205–207, *206*
  diversity in some invertebrates *202,* 202–203
Immunoglobulin (Ig)-like proteins 117, *117, 131*
Immunoglobulin (Ig)-like transcript (ILT) class *131*
Immunoglobulin M (IgM) 58, 143, 148, *150*
  conformations 438, *438*
  derivation and expressions 193–194, *194*
  distribution and functions *431,* 431–432, *434*
  hyper IgM syndrome 426, 598–599, *599,* 600
  IgA deficiency 551
  origins of adaptive immunity 209
  pentameric molecule 437–438, *438*
  polymers 151
  selective deficiency 601
  transmembrane *vs.* secreted 194–196, *195*
  transport across epithelial barriers 432–433, *433*
Immunoglobulin (Ig) new antigen receptor (IgNAR) 158, 209
Immunoglobulin (Ig) receptor, polymeric 432–433, *433*
Immunoglobulin (Ig) repertoire 180
  diversity 190
Immunoglobulin (Ig) superfamily 117, *117,* 146
Immunohistochemistry A15–A16
Immunological ignorance 700, *700, 702, 702*
Immunologically privileged sites 700, *700,* 703, 703–704, *704*
Immunological memory 484–498
  CD4 T-cell help 492–494, *493, 494*
  course of acute infection 453, *454*
  course of antibody response *6, 23,* 23–24
  defined 484
  developmental origins of memory T cells 486–488, *487*
  heterogeneity of memory T cells *488–490,* 488–491
  long-lived 484–485, *485*
  metabolic programming of circulating memory T cells 491–492, *491–493*
  rapid response and higher affinity for antigen of memory B cells 494–496, *495*
  reentry into germinal centers and additional somatic hypermutation of memory B cells 496
  secondary and subsequent responses 486–498, *497*
  study and measurement 485–486, *486*
Immunological synapse between effector T cells and targets *389,* 389–391, *390,* 391
Immunological tolerance 5
  see also Tolerance
Immunology
  basic concepts 1–36
  defined 1
  history 1–2, *2, 3*
Immunomodulatory therapy 781, 788–789, *789*
Immunoprecipitation *A16,* A16–A17
Immunoproteasome 221
Immunoreceptor tyrosine-based activation motifs (ITAMs)
  antimicrobial mechanism 85
  B-cell receptor signaling *285,* 285–286
  class switching 481
  NK cell receptors *131,* 132
  in other receptors that signal for cell activation 274, *274*
  phosphorylation 272–273, *273*
  signal transduction *271,* 271–272
  TCR complex *269,* 269–270, *270*
  ZAP-70 activation 273–274, *274*
Immunoreceptor tyrosine-based inhibition motif (ITIM) 131, *293,* 293–295, *295*
  clonal expansion and contraction 374
  immunoglobulin signaling 440
Immunoreceptor tyrosine-based switch motif (ITSM) 293
Immunosuppression, by DNA viruses *628*
Immunosuppressive drugs 32–33
  antibodies against cell-surface molecules 783–784
  antibodies engineered to reduce immunogenicity 784–785, *785, 786*
  autoimmune diseases 788–791, *789, 790, 793*
  biologics 779, 783–790
  conventional *778,* 778–779
  corticosteroid (prednisone) *777, 778, 779,* 779–780
  cyclosporin A, tacrolimus (FK506, fujimycin) *778,* 779, *781,* 781–783, *782*
  cytotoxic drugs (azathioprine, cyclophosphamide, mycophenolate) 778, *778,* 780

depletion of autoreactive lymphocytes 787–788
drugs with immunomodulatory properties 791
fingolimod (FTY720) *778*, 779, 783
JAK inhibitors (jakinibs) *778*, 779, 783, *783*, *784*
manipulation of nature of antigen-specific responses 791–792
monoclonal antibodies to prevent allograft rejection 785–787
rapamycin (sirolimus) *778*, 779, 781–783, *783*
transplant rejection 739, *739*
Immunotoxin 176
IMQ (imiquimod) 578
vaccines 759
i.m. (intramuscular) route A2
Inactivated pathogens, vaccines based on 751, *751*, 753
Inactivated toxoid, vaccines based on 751, *751*
Inborn errors of immunity, phenocopies *590*
Indirect allorecognition 736, *736*
Indirect Coombs test A10, *A11*
Indirect immunofluorescence A14
Indoleamine 2,3-dioxygenase (IDO) 742
tumors 768
Inducible nitric oxide synthase 2 (iNOS2) 85
Inductive sites, mucosal immune system 510–511
Infection(s)
acute phase 642–643, *643*
adaptive immunity 453, *454*, *455*, 457
course of 453, *454*, 454–458, *455*, *457*, *458*
effector mechanisms recruited to clear 458–460, *459*
exposure stage 455
focus 44–45, *45*, *455*, 455–456
immunological memory after 484–485, *485*

INS *726*
Insect venom 435–436
Insulin, porcine 666
Insulin-dependent diabetes mellitus (IDDM) *see* Diabetes mellitus, type I (insulin-dependent)
Integrin(s) 117, *117*, 118, *119*
T-cell entry into lymphoid tissues *355*

α_E-Integrin 532
$\alpha_E\beta_7$-Integrin 533
β_2-Integrin deficiency *609*, 610
Integrin-mediated cell adhesion 283, *283*
Integrin $\alpha_4\beta_7$ 531
Intercellular adhesion molecule(s) (ICAMs) 117, *117*, *119*
  effector cells *377*, 389, *389*
  T-cell entry into lymphoid tissues *354*, *355*, 356
Intercellular adhesion molecule 1 (ICAM-1) 117, *117*, 119, *119*
  effector cells *377*
  effector T cells guided to specific sites *463*, 464
  T-cell activation 368, *368*
  T-cell entry into lymphoid tissues 354, *354*, 356
  T-cell receptor signaling 283, *283*
Intercellular adhesion molecule 2 (ICAM-2) 117, *117*, 119, *119*
  effector cells *377*
  T-cell activation 368, *368*
  T-cell entry into lymphoid tissues 354, *354*, 356
Interferon(s) (IFNs) *124*, 124–126, *125*, A69
  activation of conventional dendritic cells 363
  host defense *124*, 124–126, *125*
  immune evasion 625, *626*
  MHC class I gene transcription 236–237
  type I 81–82, 95–98, *96*, *98*, 100–102, *101*, 124, 128, *793*
  type II 124
  type III 124
Interferon(s) (IFN)-induced protein with tetratricoid repeats (IFIT) *125*, 125–126
Interferon(s) (IFN)-induced transmembrane protein (IFITM) 126
Interferon-producing cells (IPCs) 124
Interferon (IFN) receptors 111
Interferon regulatory factor (IRF) 96–97, 98, *98*, *100*, *124*
Interferon regulatory factor 4 (IRF4) 426
Interferon regulatory factor 8 (IRF8) defects 607
Interferon (IFN)-stimulated genes (ISGs) 124–125
Interferon-α (IFN-α) 96, 124, *124*, 128, *128*, A69
  cytotoxic T cell activation 378
  MHC class I gene transcription 236–237
Interferon-α (IFN-α) receptor (IFNAR) 124
Interferon-β (IFN-β, Avonex) 96, 124, *124*, 128, *128*, A69
  cytotoxic T cell activation 378
  MHC class I gene transcription 236–237
  multiple sclerosis 789
Interferon-γ (IFN-γ) 26, 30, 124, 128–129, A69
  B-cell activation 408, 412
  class switching 426, *426*, 480
  cytokine release independent of antigen recognition 478
  cytotoxic T cells 400
  effector T cells 391, *393*, 394
  HIV *648*
  infections 460
  influenza virus *570*, 571
  intestinal lamina propria 552
  intraepithelial lymphocytes 531
  memory T-cells 489
  MHC class I gene transcription 236–237
  recombinant 613
  T_H1 cell activation of macrophages 468, *468*, *470*, 470–472
  T helper cell differentiation *379*, 380, 382, *382*, 383, 385, *386*, *387*
Interferon-γ (IFN-γ)-induced lysosomal thiol reductase (GILT) 229
Interferon-γ (IFN-γ) receptor 124
Interferon-γ (IFN-γ) receptor 1 deficiency *590*, 603
Interleukin(s) (ILs) 110, A69–A71
Interleukin-1 (IL-1) 110, *111*
  activation of conventional dendritic cells 363
  biologics that block 788–789, *789*
  cytokine release independent of antigen recognition 479
  T-cell plasticity *479*
  T_H17 development 475
  T helper cell maturation and maintenance 477
Interleukin-1 (IL-1) receptor antagonist (IL-1RA) *474*, *793*
Interleukin-1 (IL-1) receptor–associated kinase 1 (IRAK1) *96*, 97, 98, *98*
Interleukin-1 (IL-1) receptor–associated kinase 4 (IRAK4) *96*, 97, 98
Interleukin-1 (IL-1) receptor–associated kinase 4 (IRAK4) deficiency 97–98
Interleukin-1 receptor (IL-1R) signaling defects *609*
Interleukin-1α (IL-1α) 92, A69
Interleukin-1β (IL-1β) 92, 114, *114*, *122*, 122–123, A69
  infections 456, 461, 462
  intestinal dendritic cells 540
  phagocyte recruitment 469
Interleukin-2 (IL-2) A69
  B-cell activation 429
  CD8 T-cell memory 492–494, *493*, *494*
  defects 590–592
  effector molecules 391, *393*
  helper T cell differentiation 384, *384*
  regulatory T cells 387
  T-cell activation 290–291, *291*, 371, *372*, 372–373, *373*
Interleukin-2 (IL-2) receptor *324*
Interleukin-2 (IL-2) receptor antagonist (IL-2RA) A69
Interleukin-2 (IL-2) receptor α (IL-2Rα)
  autoimmune disease 724
  helper T cell differentiation 384, *384*
  regulatory T cells 386, 387
  T-cell activation 290–291, *291*, *371–373*, 372–373
Interleukin-2 (IL-2) receptor β (IL-2Rβ) *372*, 372–373, *373*, *382*
Interleukin-3 (IL-3) *393*, A69
  helminth infections *473*, 474
  recruitment of phagocytic cells 469, *470*
Interleukin-4 (IL-4) A70
  B-cell activation 408, 412
  class switching 426, *426*, 480, 481
  effector molecules 391, *393*
  helminth infections 472, 473, *473*, *474*
  memory T-cells 489
  T-cell differentiation 380, *382*, 383, 385, *386*, *387*
Interleukin-4 receptor α (IL-4Rα) *474*
Interleukin-5 (IL-5) A70
  class switching 426, *426*, 481
  cytokine release independent of antigen recognition 478
  early response to infection 461
  helminth infections *473*, 474
  T-cell differentiation *379*, 380, *393*
Interleukin-6 (IL-6) 97, 114, *114*, A70
  acute-phase response *122*, 122–123
  B-cell activation 408
  biologics that block 788–789, *789*
  early response to infections 461, 462
  IgA production 550

Zymogens 50

Forty-three animations and videos are available for *Janeway's Immunobiology*, Tenth Edition, and can be accessed at digital.wwnorton.com/janeway10. These animations dynamically illustrate many important concepts from the book, and make many of the more difficult topics accessible.

Movies and Animations

1.1 Innate Recognition of Pathogens
2.1 Complement System
3.1 Phagocytosis
3.2 Patrolling Monocytes
3.3 Chemokine Signaling
3.4 Neutrophil Extracellular Traps
3.5 Pattern-Recognition Receptors
3.6 The Inflammasome
3.7 Cytokine Signaling
3.8 Neutrophil Chase
3.9 Immune-Cell Homing
3.10 Leukocyte Rolling
3.11 Rolling Adhesion
3.12 Neutrophil Rolling Using Slings
3.13 Extravasation
5.1 V(D)J Recombination
6.1 MHC Class I Processing
6.2 MHC Class II Processing
7.1 TCR Signaling
7.2 MAP Kinase Signaling Pathway
7.3 CD28 and Costimulation
8.1 T-Cell Development
9.1 Lymph-Node Development
9.2 Lymphocyte Trafficking
9.3 Dendritic Cell Migration
9.4 Visualizing T-Cell Activation
9.5 TCR-APC Interactions
9.6 Immunological Synapse
9.7 T-Cell Granule Release
9.8 Apoptosis
9.9 Induction of Apoptosis
9.10 T-Cell Killing
10.1 Germinal Center Reaction
10.2 Isotype Switching
11.1 The Immune Response
11.2 *Listeria* Parasites
12.1 Antigenic Drift
12.2 Antigenic Shift
13.1 Viral Evasins
13.2 HIV Infection
14.1 DTH Response
15.1 Crohn's Disease
16.1 NFAT Activation and Cyclosporin

Janeway's
immuno biology

10TH EDITION

Kenneth Murphy
Casey Weaver
Leslie Berg

The gold standard, with the most up-to-date research and resources

digital.wwnorton.com/janeway10

Each new copy of *Janeway's Immunobiology* includes access to the following resources:

InQuizitive Adaptive Assessment
InQuizitive adaptive assessment includes numerous vocabulary-based questions and pop-up definitions for key terms, helping you learn the language of immunology and apply those terms in context.

Animations
A robust suite of animations unravels complex immunology concepts, making these topics easier for you to understand.

Ebook
The *Janeway's Immunobiology* ebook gives you the ability to highlight, bookmark, and take notes that can be viewed on, and synched between, any computer or mobile device. The ebook includes embedded animations and links to relevant cases in *Case Studies in Immunology*.

Case Studies in Immunology ebook
Case Studies in Immunology by Raif Geha and Luigi Notarangelo presents major topics of immunology through a selection of clinical cases that reinforce and extend the basic science of immunology.
